Historically, presence of tracheotomy tubes has been believed to impair swallow functioning, including reduced laryngeal elevation, reduced tracheal sensitivity, reduced glottic sensation and closure function, and, in cuffed tracheotomy tubes, esophageal obstruction (78–81). Further, reduced ability to generate positive subglottic air pressure has been implicated as a cause of aspiration in tracheotomized patients (59,82). Presence of speaking valves, such as the Passy-Muir valve have been found to improve swallow function, with improved expiratory airflow, reduction in oropharyngeal secretions, and reduced aspiration (15,83–86). Digital occlusion and capping of tracheostomy tubes have also been found to be effective in improving swallow function (72,81,87). However, others have found no impact on swallow functioning with the presence of tracheotomy tubes, speaking valves, or tracheal occlusion, including digital and capping (88–91). In addition, others have found no impact of tracheotomy cuff inflation on swallowing (86). However, tracheotomy tubes are typically left in place during instrumental evaluations and swallow therapy. Cuffs are typically deflated during the swallow evaluation and, if medically able, during swallow therapy, as aspiration is likely to be detected via expectorated material through the tracheotomy tube.

Preventative Exercise Programs

Active exercise programs are often prescribed for patients who will undergo organ preservation protocols of chemoradiotherapy (92). These programs are designed to maintain swallow functioning during and following the chemoradiotherapy treatment. They are also used for those patients who will undergo primary radiotherapy and radiotherapy following surgery for head and neck cancer. Programs include range of motion exercises for the jaw, oral tongue, tongue base, pharyngeal constrictors, and hyolaryngeal muscles and strengthening exercises for the oral tongue, tongue base, and hyolaryngeal muscles. Patients are instructed to practice these exercises as able during the course of treatment, as swallowing problem can develop during and after radiotherapy as primary treatment, postsurgical treatment, and as concurrent treatment with chemotherapy (93–98). Patients are also instructed to continue practicing these exercises once daily following completion of treatment, as tissue fibrosis can occur long after completion of radiotherapy treatment (99,100), with resultant swallowing problems (4,21,101).

Swallow therapy, including compensatory and direct therapy procedures can improve swallow functioning in patients with oropharyngeal dysphagia, reducing the risk of aspiration pneumonia associated with dysphagia, and improving nutritional status (69,102–105). The speech–language pathologist plays a key role in performing the instrumental examination; including the VFSS and fiberoptic endoscopic evaluation of swallowing (3,69). In addition, the speech–language pathologist plays a major role in developing and implementing the swallowing rehabilitation program, in collaboration with the patient's attending physician, other health care professionals, and the patient and his/her family.

Subspecialists in laryngology can take charge in the management of patients with swallowing disorders. They must create working relationships with patients while stressing the value of multidisciplinary approaches to dysphagia. Being trained to recognize pathology and implement the armamentarium of medical and surgical tools, laryngologists must help make key decisions regarding escalation of care from conservative to aggressive while counseling the patient regarding the differing merits of each treatment option. Furthermore, tracheotomy placement, management, and possible decannulation should be spearheaded by trained physicians.

MEDICAL MANAGEMENT

Medical management of dysphagia is often ignored in favor of what are often perceived as more "interventional" approaches to improving swallow function. However, there is most certainly value in treating specific issues related to swallow dysfunction with medical treatment. Below we discuss several categories of medications and other treatments that should be considered in patients with dysphagia. Some of these treatments directly target patients' symptoms, while others are designed to prevent adverse consequences and complications associated with swallowing dysfunction.

MOTILITY DRUGS

The management of impaired esophageal motility poses a substantial challenge to the otolaryngologist. A handful of medications have garnered interest for their apparent

TABLE 58.3 ESOPHAGEAL MOTILITY DRUGS

Medication	Receptor Targeting	Adverse Reactions
Macrolides (i.e., erythromycin and clarithromycin)	Motilin, preganglionic Ach receptor targeting	Intravenous dosing, bacterial resistance
Cisapride	Increase acetylcholine release	Cardiac arrhythmias, drug interactions
Domperidone	Blocks dopamine receptors	Inconsistent results, stimulates prolactin secretion
Metoclopramide	Blocks dopamine receptors	Inconsistent results, extrapyramidal symptoms, increased prolactin secretion
Bethanechol	Acetylcholine agonist	Contraindicated in asthma, coronary artery disease, and Parkinsonism, epilepsy
Pyridostigmine	Acetylcholinesterase inhibitor	

clinical benefit in promoting esophageal contraction and lower esophageal sphincter (LES) tone, but few have shown physiologic or practical efficacy in research trials. Recently, new classes of drugs have shown promise in alleviating symptoms of esophageal dysphagia.

Previously employed drugs that have fallen out of favor include medications such as cisapride, macrolide antibiotics, metoclopramide, and domeperidone. Macrolide antibiotics, specifically erythromycin and clarithromycin, have shown efficacy in increasing duration, velocity, and strength of peristalsis in the esophagus, but primarily by intravenous delivery of the drug (106,107). These drugs are theorized to stimulate esophageal contractility by activating motilin receptors in smooth muscle and preganglionic cholinergic neurons (108,109). This subclass clinically has its long-term impracticalities owing to its inability to produce similar effects with oral dosing (110) and likely promoting bacterial resistance. Similarly, cisapride has been unpopular due to its safety profile and drug interactions. The oral form of cisapride showed efficacy in enhancing pressure at the LES and increasing esophageal peristalsis (111,112), but evidence showing an increased potential for cardiac arrhythmias led to its loss of Food and Drug Administration approval. Lastly, metoclopramide and domeperidone showed early success as prokinetic medications (52,113), but more recent studies have not been able to reproduce these results (114).

Recently, some medications have been found to be effective in increasing esophageal motility in their oral form. Comparison of three such drugs (bethanechol, pyridostigmine, and buspirone) found that all three agents cause increased motility and peristaltic amplitude after oral administration (115). Though previous works have described each medication alone as being effective in improving esophageal motility (116–118), they all work by increasing cholinergic activity on the esophageal smooth muscle (119); bethanechol as a direct cholinergic agonist, pyridostigmine as an Ach inhibitor, and buspirone acting on 5-HT1A and 5-HT2A receptors. Buspirone, by being an agonist at serotonergic receptors, can theoretically facilitate Ach release as shown in animal models (120). As efficacy of these drugs is being established, they could soon represent an option for medical management of dysphagia (Table 58.3).

REFLUX CONTROL

It has been shown that gastroesophageal reflux disease (GERD) can commonly lead to changes in esophageal motility (121). Mucosal injury and edema can lead to changes in peristalsis amplitude, bolus transit times, and LES tone and competence (122) In recent studies, duration and frequency of reflux episodes significantly correlated with esophageal dysmotility (122,123), but this has not been universally accepted due to confounding results from other authors (124). Sensation of the larynx can also be affected as seen by differences in Functional Endoscopic Evaluation of Swallowing with Sensory Testing in those with and without laryngopharyngeal reflux (LPR). This can lead to globus sensation, incoordinated swallow, and possible increased aspiration risk.

Treatment for reflux disease-related dysphagia is usually initiated with a trial of proton pump inhibitors (PPIs). Though some authors advocate for definitive diagnosis with pH probe monitoring, empiric treatment of LPR/GERD can be initiated with PPIs. Further investigation is warranted when there are nontraditional clinical presentations or refractory symptoms after therapy. Several authors have noted significant improvement in symptoms of dysphagia and globus sensation after trials of therapy with PPIs (125,126). While on maintenance therapy, these patients' symptoms were often alleviated

regardless of degree of severity of GERD. Others have also endorsed surgical control of reflux (i.e., Nissen Fundoplication, etc.) as an alternative to failed medical management or, in some centers, as a primary modality (127–130).

DRYING AGENTS

Often, dysphagia can stem from the inability to handle one's own secretions. Unmitigated pooling of saliva in the oral cavity, pharynx, or piriforms can lead to aspiration into the trachea. Commonly affected persons include those with neurologic limitations (Down Syndrome, ALS, cerebral palsy [CP]), PD, mental retardation) or anatomic abnormalities that do not allow proper management of oral secretions. Surgical therapy has focused on resection of major salivary glands or ligation of their ducts (131), but conservative options still are the mainstay of treatment. Team approaches with speech and language pathologists, neurologists, otolaryngologists, and occupational therapists can provide numerous options to a patient and family. Positioning techniques along with oral appliances can show benefit from directing saliva toward the pharynx safely (132–134). Furthermore, they can create proper closure of the oral commissure allowing for improved bolus formation and manipulation. In conjunction with these modalities, biofeedback therapy has shown some efficacy (135,136).

In more severe cases, medical management can be used in concert with other nonsurgical measures. These drying agents encompass medications whose mechanism of action affects the cholinergic stimulation of saliva in the upper digestive tract. Glycopyrrolate bromide, classified as an anticholinergic drug, has a quaternary ammonium structure that prevents it from crossing the blood–brain barrier. Recently, randomized prospective trials have shown glycopyrrolate to be a clinically effective method of sialorrhea management in adults and children (137–139). Within these trials, varying degrees of clinical failure due to side effects were demonstrated, though, in the adult PD patients, the adverse outcomes were minimal. Scopolamine and benztropine are anticholinergic drugs known to cross the blood–brain barrier avidly, which can limit their effective use due to dose-related effects. Some common complaints after the use of anticholinergic medications include pupil dilation, urinary retention, constipation, dizziness, blurred vision, and worsening of glaucoma. Proper patient selection and dose adjustments are key to effectively using this class of drugs.

Lastly, numerous authors have used botulinum toxin injections into the salivary glands as an adjunct therapy to medical management (140–144). Commonly, injections of Botox are targeted at the parotid and submaxillary glands with the aim of significantly reducing salivary flow into the oral cavity. Ultrasound guidance can be used to visualize infiltration of the drug into the salivary tissue and to prevent complications of toxin delivery to surrounding tissue (145–147). A recent review demonstrated a wide variability in duration of efficacy ranging from over 1 to 6 months before the need for repeat medication injections (148).

NUTRITION

An oftentimes ignored part of the care of the dysphagic patient is management of nutrition. Patients with dysphagia are often prescribed altered diets based on results of swallow studies. In addition, they often eat slowly and eating becomes a chore; as a consequence, they are unable to complete meals. These factors combine to lead to poor nutrition. Unfortunately, this often compounds the problem as patients become weak and dehydrated. The care provider must work with the nutritionist and speech pathologist to formulate a plan for adequate caloric intake in order to prevent the downward spiral that can lead to a permanent loss of swallow function.

PULMONARY STATUS

Often overlooked is the neurologic and functional codependency of the upper respiratory system and the digestive tract. Swallowing is not only composed of coordinated movement of the oral cavity and pharynx, but also of orchestrated laryngeal movement (149). It is known that laryngeal elevation and vocal fold adduction are key to swallowing action, but carefully timed apnea is also crucial (150,151). Studies aimed at understanding the natural physiology of aerodigestive tract coordination have found that during swallowing there is a reproducible apneic episode in the expiratory phase of respiration (103,152). Small bolus changes would produce similar periods of apnea, but large-volume swallowing necessitated extended apnea. This clearly poses a problem for those with pulmonary disease where shortness of breath or cough could restrict apnea times. This could lead to uncoordinated swallowing and possibly aspiration of food contents. An example of this occurs in chronic obstructive pulmonary disease (COPD) patients who can be prone to tachypnea and often unable to tolerate cessation of respiration while swallowing. In one author's experience, penetration/aspiration scores were significantly higher in stable COPD patients compared to controls (153). Pulmonary pathology often also coincides with GERD, which can lead to worsening of pulmonary status, globus sensation, and dysphagia (153–155). In some cases such as idiopathic pulmonary fibrosis, standard medications such as PPIs can be less effective at acid suppression when compared to normal adults (154). Rehabilitation of chest muscle strength with physical therapy and incentive spirometry use can often be implemented in concert to improve cough effectiveness and tidal volumes (50,156–158).

IMMUNOCOMPROMISE

Those with a nonfunctioning immune system may fall victim to opportunistic infections of the upper aerodigestive tract leading to dysphagia and pulmonary compromise. Oral candidiasis and herpes infection along with bacterial and fungal pharyngitis can lead to odynophagia (159). Tuberculous involvement can be seen often in the larynx, but can also been found in the esophagus and oral cavity (160–163). Similarly Cytomegalovirus, candida, and herpes simplex virus infection are a relatively common pathology in the upper aerodigestive tract and must be ruled out in cases of persistent odynophagia in immunocompromised patients. Some less common but reported causes of infection include aspergillus and actinomyces. HIV infection, transplant-recipients, and those suffering from blood-borne cancers can make patients prone to opportunistic infection. Care must be taken to address underlying causes of immune dysfunction while treating pain, encouraging nutritional supplementation, and treating infections appropriately.

ORAL CARE

Especially in the elderly and debilitated, dental hygiene is crucial to the prevention of aspiration pneumonia. These patients often can become immunocompromised due to chronic disease, develop oral biofilms, and have reduced salivary flow swaying the balance toward overgrowth of pathogenic microflora (164,165). Respiratory pathogens isolated from the oral cavity have been cultured from the pulmonary secretions of chronic aspiration patients (164,166). With proper mechanical cleaning and oral decontamination by patients or caregivers, potential pathogens for pneumonia can be decreased greatly (167–170). Though more research is needed, significant reductions of aspiration pneumonia and death with attention to proper oral care have been revealed in recent studies (171,172).

SUMMARY

The role of nonsurgical management of swallowing disorders can include various modalities from medications to rehabilitation. Without a strong knowledge of anatomy and neurophysiology, targeted treatment cannot be delivered. Careful history taking combined with thorough head and neck examination and the diagnostic radiographic findings can elucidate the etiology of improper swallow function. Once identified, pathologic insults to the upper aero–digestive tract can be first handled conservatively with the techniques outlined in this chapter reserving more aggressive management for refractory cases. Evolving imaging technology and new potent medications will soon expand the clinician's armamentarium.

HIGHLIGHTS

- Identification of the site(s) of swallowing pathology can be accomplished with careful history taking, indirect laryngoscopy, and radiologic imaging such as MBS.
- Compensatory postures are an important measure to redirect food boluses safely into the esophageal inlet. Commonly used postures include chin tuck, head back, head tilt, head rotation, and side-lying positions.
- Improving preswallow sensory stimulus through diet changes can improve lingual activity and trigger appropriate pharyngeal swallow.
- Unlike postures, maneuvers alter the physiology of swallowing by placing certain aspects under voluntary control.
- There are a myriad of esophageal promotility agents available that can be used with careful attention to mechanism of action and side effect profile.
- Those with neurologic disorders (i.e., PD, CP, and ALS) can sometimes pose a challenge to physicians due to poor mental status, uncoordinated swallow, sialorrhea, and aspiration risk.
- In the treatment of sialorrhea, a multidisciplinary approach can provide numerous options to a patient and their family including medications, oral appliances, and salivary gland botulinum toxin injection.
- Compromised pulmonary status can disrupt the necessary balance of respiration, namely coordinated apneic episodes, with swallowing leading to aspiration.
- Immunocompromised patients are at increased risk for infection with opportunistic pathogens leading to odynophagia, dysphagia, and pneumonia.

59 Esophageal Disorders

Catherine Rees Lintzenich

Esophageal disorders are commonly encountered in the evaluation of throat pain, dysphagia, reflux, and globus pharyngeus. Knowledge of the motility, inflammatory, and neoplastic disorders is an essential component in the diagnosis and management of these common otolaryngologic complaints.

ESOPHAGITIS

Infectious Esophagitis

Infectious causes of esophageal inflammation include fungal pathogens, viral pathogens and, much less commonly, bacterial pathogens. The most common cause is *Candida albicans* fungal infection (Fig. 59.1). Risk factors include human immunodeficiency virus (HIV), systemic and inhaled steroids, and antibiotic use. However, esophageal candidiasis is frequently encountered in healthy immunocompetent individuals without risk factors. Pain and dysphagia are the most common presenting symptoms. The appearance of white to yellow plaques on an erythematous base is quite characteristic but may be confirmed with biopsy. It is important to recognize that esophageal candidiasis can be present without findings of candidiasis in the oral cavity or pharynx. Treatment options include topical antifungal solutions or oral antifungals, such as fluconazole.

Viral esophagitis may be caused by herpes simplex virus, cytomegalovirus, or HIV. Typically, multiple shallow ulcerations are seen in the esophageal mucosa. Biopsy is necessary to confirm the diagnosis.

Noninfectious Esophagitis

Pill-Induced Esophagitis

Medications can cause esophageal inflammation and injury via a systemic or local reaction. Systemic medications that relax smooth muscle may increase the incidence of reflux and its sequelae, including esophagitis, dysmotility, and stricture. Examples of drugs causing esophageal effects include alcohol, nicotine, and smooth muscle relaxants.

Alternatively, pills that become lodged in the esophagus can cause direct injury to the mucosa, resulting in stricture, pain, and dysphagia. Large pills, pills taken in the supine position, xerostomia, dehydration, and motility disorders are risk factors for esophageal pill injury (1). Doxycycline, tetracycline, alendronate, and potassium chloride frequently cause such direct esophageal injury. Symptoms include dysphagia, odynophagia, and heartburn. It is important to consider pill-induced esophagitis even when there is no known history of pill becoming lodged in the throat or esophagus. Endoscopic removal of the pill impaction and conversion of medications to liquid forms may be necessary. In severe cases, medications may need to be administered via a nasogastric tube until the esophagus heals. Sequelae of pill-induced esophagitis may include ulceration, stricture, and even perforation of the esophagus.

Eosinophilic Esophagitis

Eosinophilic esophagitis is increasingly diagnosed in both children and adults. This disorder is characterized by eosinophilic infiltration of the esophageal mucosa. Adults typically present with solid food dysphagia, reflux symptoms, and recurrent food impactions (2). Fluoroscopy and endoscopy may reveal a small caliber esophagus with a ringed appearance (trachealization) or esophageal strictures. Small white submucosal lesions may be noted on endoscopy (Fig. 59.2). The mucosa is typically friable and prone to tearing with instrumentation. Alternatively, the esophagus may appear normal. Food and/or inhalant allergies typically coexist with eosinophilic esophagitis. Biopsy confirms the diagnosis, requiring greater than 15 to 20 eosinophils per high power field. Treatments include topical esophageal steroids, allergy treatments, and elimination diets.

Figure 59.1 Candida esophagitis with white and yellowish plaques.

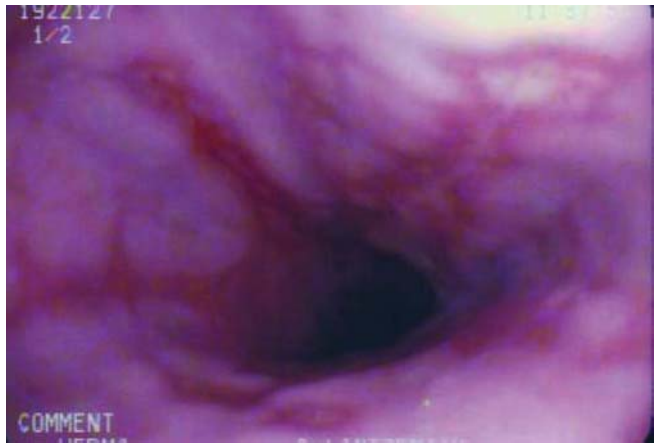

Figure 59.3 Circumferential erosive esophagitis from reflux.

GASTROESOPHAGEAL REFLUX DISEASE

Reflux refers to the backflow of gastric contents in a retrograde fashion into the esophagus and sometimes into the pharynx (laryngopharyngeal reflux is discussed in detail in Chapter 66) (3). Gastroesophageal reflux disease (GERD) occurs when reflux is excessive or symptomatic. Refluxate from the duodenum, containing bile acids, may also contribute to esophageal injury. Typical symptoms of GERD include heartburn and regurgitation, with less typical symptoms being cough, globus, and belching.

GERD is probably associated with inappropriate relaxations of the lower esophageal sphincter (LES) and poor esophageal clearance. The endoscopic appearance of the esophagus in GERD may be normal, or esophagitis with erosion and mucosal breaks may be present (Fig. 59.3). The most commonly used classification system for the endoscopic appearance of reflux esophagitis is the L.A. Classification, which takes into account the length, width, and number of mucosal breaks. Strictures can occur with chronic or prolonged esophageal acid exposure.

Figure 59.2 Small white lesions sometimes seen in eosinophilic esophagitis (guidewire for dilation is seen in the picture).

Ambulatory pH monitoring can aid in the diagnosis of pathologic reflux. When reflux esophagitis is present, proton pump inhibitor therapy is initiated to allow healing of the esophageal injury. Endoscopy may be repeated 3 to 6 months after initiation of therapy to confirm healing.

Reflux is a risk factor for Barrett metaplasia, the presence of which increases the risk of esophageal adenocarcinoma (4). To identify Barrett metaplasia, it is necessary to understand the normal gastroesophageal junction anatomy. The squamous epithelium of the esophagus interfaces with the columnar gastric epithelium at the gastroesophageal junction in the normal setting. This is visualized with a change from a lighter pink to a darker salon-pink in the stomach. Normally, this squamocolumnar junction (SCJ) coincides with the gastroesophageal junction, best identified by the termination of the gastric rugae. When the gastroesophageal junction extends more than 2 cm above the diaphragmatic compression, a hiatal hernia is present. When the SCJ extends proximal to the perceived gastroesophageal junction, Barrett metaplasia is suspected. Suspected areas of Barrett metaplasia must be biopsied to confirm the diagnosis and evaluate for dysplasia. Biopsy-confirmed Barrett metaplasia will include intestinal metaplasia and goblet cells on histopathology. The presence of no dysplasia or low-grade dysplasia indicates low risk for neoplastic transformation. However, high-grade dysplasia represents a significant risk of neoplasm and is usually treated as esophageal adenocarcinoma.

ESOPHAGEAL MOTILITY DISORDERS

Disorders of esophageal motility may be classified as hyperkinetic and hypokinetic. Both classes of motility disorders can lead to dysphagia, globus pharyngeus (feeling of lump in throat), regurgitation, and/or noncardiac chest pain. The mainstay of esophageal function testing is esophageal manometry. The recent advances of high-resolution manometry have allowed for assessment of esophageal pressure along the entire pharynx, upper esophageal

sphincter, esophageal body, and LES (5). High-resolution manometry catheters have pressure sensors at approximately 1-cm intervals. Impedance technology has also added to assessment of esophageal motility. Impedance determines the comparative resistance of air, the bolus, and the esophageal mucosa and therefore indicates bolus transit along the esophagus (6).

Hyperkinetic Esophageal Motility Disorders

Nutcracker Esophagus

Nutcracker esophagus is a disorder typically associated with noncardiac chest pain. This condition typically coexists with reflux disease, and there may be a causal relationship between nutcracker esophagus and reflux. Manometric assessment reveals normal peristalsis and high amplitude esophageal contractions during swallowing, with the average distal esophageal amplitude being greater than 180 mm Hg. Bolus transit is typically normal (7), as is fluoroscopy of the esophagus. Treatment for nutcracker esophagus usually involves antireflux treatment and/or pH testing. Surgical esophageal myotomy is generally not effective for this disorder (8). Nitrates and calcium channel blockers may be beneficial in decreasing the intensity of the esophageal contractions.

The etiology of nutcracker esophagus is still unclear, but it may be related to coordination between the longitudinal and circular muscle layers of the esophagus (9). Jung et al. performed high-frequency intraluminal ultrasound in 5 healthy volunteers and 10 subjects with nutcracker esophagus. In the healthy volunteers, the peak contraction of the circular and longitudinal muscles was nearly synchronous. In nutcracker esophagus, there was asynchrony in contraction between these muscle layers in the distal esophagus.

Distal Esophageal Spasm

Distal esophageal spasm (DES) is a nonperistaltic motility disorder, which may or may not be associated with high amplitude esophageal contractions. In manometric terms, greater than 20% but fewer than 100% of wet swallows produce simultaneous contractions, with onset velocity of the peristaltic wave being greater than 8 cm/s. This disorder is also highly associated with reflux disease and is more likely to produce dysphagia and impaired bolus transit. Chest pain is typically associated with higher distal esophageal amplitudes (10). Esophagram may be normal or may show a "corkscrew" pattern during a swallow (Fig. 59.4). The etiology of DES is likely related to alterations in nitric oxide metabolism.

Treatment of DES usually begins with pH testing and/or antireflux therapy. Other treatment modalities are not well supported by controlled studies, but they have shown some possible efficacy in case series. These therapies include phosphodiesterase inhibitors (11), calcium channel blockers (12), peppermint oil (13), visceral analgesics, and botulinum toxin injections (14). Esophageal dilation may be helpful (15), and surgical myotomy is considered in severe cases (16,17).

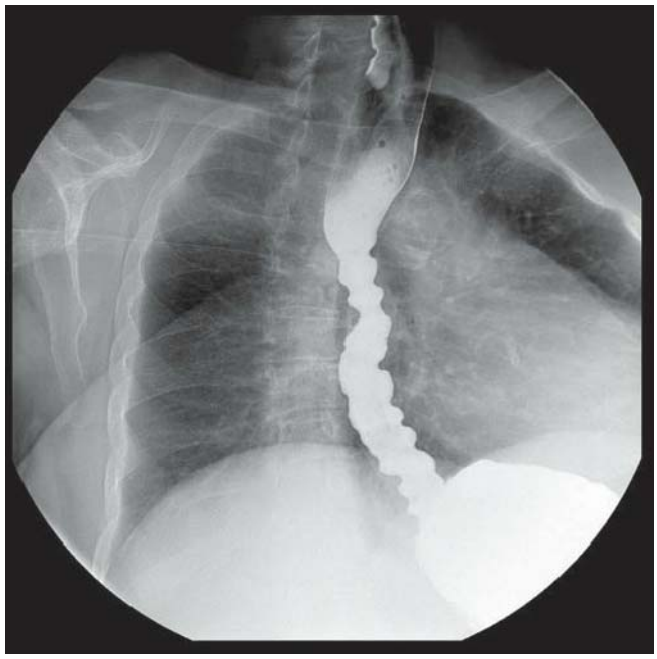

Figure 59.4 Fluoroscopic esophagram showing corkscrew appearance occasionally seen in diffuse esophageal spasm.

Hyperkinetic Disorders of the Lower Esophageal Sphincter

The LES normally relaxes at the initiation of a swallow to allow passage of the bolus into the stomach. When the LES resting pressure is found to be greater than 45 mm Hg on manometry, the sphincter is hypertonic. This disorder does not typically cause dysphagia as long as esophageal peristalsis is normal (7). However, when the LES does not relax completely (resting pressure greater than 8 mm Hg), regardless of the LES resting pressure, dysphagia may result, particularly for solid foods. This disorder can be treated with botulinum toxin injections or surgical myotomy.

Hypokinetic Esophageal Motility Disorders

Ineffective Esophageal Motility

Ineffective esophageal motility (IEM) disorder is a common hypokinetic disorder that may cause dysphagia or globus pharyngeus symptoms. On manometry, 50% or more swallows have amplitudes less than 30 mm Hg in distal esophagus (18). About half of patients with IEM have impaired bolus transit on impedance testing. This disorder often coexists with reflux disease and is difficult to treat effectively. Aside from antireflux treatment, bethanechol, a muscarinic receptor agonist, may improve distal esophageal contractility (19).

Achalasia

Esophageal achalasia is a rare disorder defined by complete absence of peristalsis, usually accompanied by poorly relaxing LES (7). Classic achalasia demonstrates

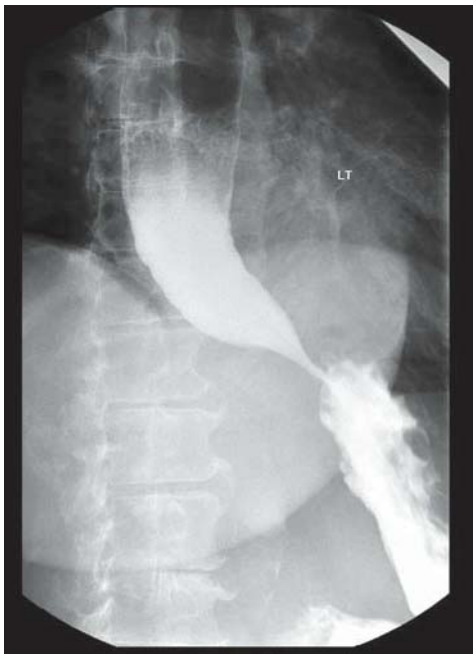

Figure 59.5 Fluoroscopic esophagram showing the "bird's beak" appearance of achalasia, caused by a dilated esophageal body and poorly relaxing LES.

manometric contractions less than 30 mm Hg, and the more uncommon vigorous achalasia may have higher esophageal pressures. Bolus transit is severely impaired in achalasia, and patients are generally present with dysphagia for all consistencies, regurgitation, cough, chest pain, and/or weight loss. Achalasia is thought to be related to ganglion cell degeneration in the myenteric plexus of the distal esophagus. Nitric oxide metabolism is significantly altered at the LES.

Esophagoscopy is essential to rule out pseudoachalasia from an obstructing lesion at the LES, such as a malignancy. Additionally, achalasia is a risk factor for development of esophageal squamous cell carcinoma. Fluoroscopy may show a dilated aperistaltic esophagus with a "bird's beak" pointed appearance at the LES (Fig. 59.5). Treatment options include botulinum toxin, pneumatic dilation with the intent of disrupting the muscularis propria layer, and surgical myotomy (20).

PROGRESSIVE SYSTEMIC SCLEROSIS

Progressive systemic sclerosis (PSS) is historically known as scleroderma. PSS is a multisystem collagen vascular disease with vascular damage contributing to fibrosis and atrophy of smooth muscle. Gastrointestinal involvement is present in 90% of PSS, with the distal esophagus being the most common site of involvement. Since the upper esophageal sphincter and proximal esophagus comprise skeletal muscle rather than smooth muscle, only the distal two-third of the esophagus and the LES are affected in PSS. Manometry reveals poor peristalsis and weak contractions in the distal esophagus, or aperistalsis. The LES is incompetent, putting PSS patients at high risk for reflux and its potential sequelae, including Barrett metaplasia, strictures, candida esophagitis, and neoplasm (21). Treatment of PSS includes antireflux therapy and possibly immunosuppressive agents.

ESOPHAGEAL WEBS, STRICTURES, AND RINGS

The normal esophageal lumen is 20 mm in diameter. When the diameter of the lumen is narrowed to 13 mm or less, symptomatic dysphagia may occur, particularly for solids. However, in the presence of esophagitis, larger diameter strictures may be symptomatic. Narrowing of the esophagus is best assessed with esophagram, although these abnormalities may also be seen on esophagoscopy.

Strictures most commonly result from reflux disease (peptic strictures). Impaired peristalsis, prolonged refluxate exposure, and transient LES relaxations contribute to the development of peptic strictures. These are typically treated with antireflux therapy and dilation of the affected esophageal area. Strictures may also develop in the setting of weakly acidic or alkaline reflux, despite appropriate antisecretory reflux therapy (22). In refractory cases, antireflux surgery or esophageal stents are considered (23).

Esophageal dilation may be undertaken with general anesthesia, conscious sedation, or topical anesthesia only. Bougie-type tapered dilators can be used with or without wire-guidance and/or fluoroscopy. Controlled radial expansion balloons allow for precise dilation at a specific site, rather than diffuse esophageal dilation. For tight strictures or complicated strictures, wire-guidance is safest. Endoscopic evaluation of the esophageal mucosa is always advisable before or during dilation to identify infections, esophagitis, and neoplasms.

Esophageal webs are thin membranous narrowings of the esophageal body that respond well to dilation. Cervical esophageal webs may be incidental or may contribute to solid food and/or pill dysphagia. These are quite thin and may not be well visualized with fluoroscopy.

Plummer-Vinson syndrome is the clinical triad of dysphagia, upper cervical esophageal web, and iron deficiency. This syndrome is also known as the Patterson-Kelly syndrome and may include glossitis, cheilitis, and koilonychia (24). The syndrome typically causes intermittent dysphagia for solids with possible esophageal food impaction. Treatment of Plummer-Vinson syndrome is correction of the iron deficiency with dilation of the web if symptoms persist.

Esophageal rings are limited to the lower esophagus, and clinically significant rings are classified as A or B (25). The A ring represents muscular hypertrophy at the most proximal limit of the LES. This is rarely symptomatic. In the event that a hypertrophic A ring is symptomatic,

chemical or surgical myotomy are the most effective treatments. Esophageal dilation is not helpful for symptomatic A rings.

The B ring is also known as Schatzki ring. This occurs at the SCJ, usually with squamous mucosa covering the superior surface and gastric mucosa on the inferior surface. A hiatal hernia is very frequently found with a B ring. B rings are considered to be reflux-related and are more likely to occur without reflux treatment. Indeed, reflux treatment is a critical aspect of treating a B ring. Fluoroscopy is the best way to visualize a B ring. Schatzki rings generally present with solid food dysphagia and possibly food impaction. Symptomatic B rings are treated with dilation.

ESOPHAGEAL DIVERTICULA

Outpouchings, or diverticula, may occur anywhere along the esophagus but are most commonly seen in the pharyngoesophageal segment. Diverticula are best evaluated with fluoroscopy. If a modified barium pharyngeal function study is performed rather than an esophagram, the shoulder may block visualization of a pharyngoesophageal diverticulum and an anterior view may be necessary.

A pharyngoesophageal diverticulum is a pulsion diverticulum, also known as a Zenker diverticulum. This occurs at Killian dehiscence, a natural weakness in the esophageal wall between the inferior constrictor muscle and the cricopharyngeus. The etiology of Zenker diverticulum is not clear, but it is likely related to reflux disease (26) and/or long-standing cricopharyngeal dysfunction (27). It is most common in the elderly population and usually presents with dysphagia with regurgitation of food that does not appear to have been digested. More subtle symptoms include halitosis, cough, or weight loss. Rarely, aspiration pneumonia may be the presenting sign of Zenker diverticulum.

Symptomatic Zenker diverticula, or those causing silent aspiration, are treated surgically with either open diverticulectomy or endoscopic diverticulotomy with cricopharyngeal myotomy (28). Open diverticulectomy is approached from a left oblique cervical incision or collar incision at the level of the cricoid cartilage. Identification of the diverticulum may be facilitated by packing of the pouch endoscopically. The entire diverticulum is removed via surgical stapling or excision with primary layered closure of the defect. Cricopharyngeal myotomy is usually performed in association with this procedure to help prevent recurrence and residual symptoms. Repositioning of the diverticulum to a more superior position (diverticulopexy) so that it does not collect food has been described for poor surgical candidates, since it purportedly takes less time than a diverticulotomy.

Endoscopic diverticulotomy is an alternative to the open approach. Specially designed bivalve diverticuloscopes have been designed to endoscopically expose the common wall between the esophagus and the pouch, which contains the cricopharyngeus muscle. Carbon dioxide laser or endoscopic stapling (29) is performed to cut the common wall between the esophagus and diverticulum. The diverticulum is not removed, but rather it is opened into the esophagus so that the pouch no longer collects food or liquid. Success rates and incidence of esophageal perforation are similar between the endoscopic and open approaches to Zenker diverticulum.

Traction diverticula occur in the middle third of the esophagus and are associated with scarring external to the esophageal lumen, for example, from chest irradiation or tuberculosis. These are rarely symptomatic. Epiphrenic diverticula are pulsion-type diverticula in the distal esophagus, associated with esophageal dysmotility. When symptomatic, epiphrenic diverticula may result in regurgitation and dysphagia.

ESOPHAGEAL EMERGENCIES

Esophageal Perforation

Violation of the esophageal wall results in perforation of the esophagus with possible mediastinal spillage. This may occur from trauma or, more commonly, from iatrogenic causes during esophageal procedures. Traumatic perforations may be due to blunt or penetrating chest trauma, severe vomiting (known as Boerhaave syndrome), caustic injury, or foreign body ingestion. Mediastinal malignancies, such as lymphoma, may lead to esophageal perforation from erosion of the tumor or from radiation necrosis. Procedures such as esophagoscopy, esophageal dilation, and nasogastric tube placement have all been associated with esophageal perforation. In the setting of esophageal diverticula or malignancies, the risk for iatrogenic perforation increases.

The most important concept in management of esophageal perforation is early recognition, since fulminant mediastinitis has a dismal prognosis. Ideally, an iatrogenic perforation is identified when it occurs, by visualization of transmural tearing, excessive bleeding, or mediastinal fat. After esophageal procedures, chest pain, fever, and subcutaneous emphysema are warning signs that a perforation has occurred. Water-soluble contrast, such as gastrografin, should be used in fluoroscopy whenever a perforation is suspected. Barium is irritating to the mediastinum and persists for years on imaging, making subsequent fluoroscopic evaluation difficult.

Small esophageal perforations may be managed medically with endoscopic feeding tube placement and *nil per os* status. Broad-spectrum antibiotics are usually initiated, to include anaerobic coverage. Fluoroscopy may be used in 5 to 7 days to evaluate for persistent leakage from the esophagus. Alternatively, surgical closure of the defect may be undertaken. Muscle flaps may be used to separate the defect from the trachea, particularly when there is risk for erosion into the trachea and creation of a tracheoesophageal fistula.

Esophageal Foreign Body

Foreign body ingestion is most prevalent in the pediatric population. Three natural compressions of the esophagus are the most common site for a foreign body to become impacted: the cricopharyngeus (most common), the compression from the aortic arch, and the LES. Drooling and dysphagia are the most common symptoms of esophageal foreign body. Compression of the trachea with subsequent respiratory distress may also occur. In children, the most commonly ingested foreign body is a coin, followed by obstructing food boluses and toys. Large food items, such as hot dog pieces, can completely compress the trachea and lead to death. Coin-shaped watch batteries are a dangerous foreign body, causing caustic alkaline injury with possible perforation. When a history or suspicion of battery ingestion occurs, endoscopic removal should be undertaken immediately. Adults have a wider variety of esophageal foreign bodies, with food bolus being the most common. This typically occurs in the setting of esophageal stricture, esophagitis, or neoplasm. Dentures are sometimes ingested during trauma or intubation. The sharp edges of dental appliances make extraction difficult and risk of perforation high.

History is the most important tool in diagnosing foreign body ingestion. Coins and other radiopaque items are readily identified on plain films. Food and plastic items, such as toys, are not typically seen on plain films and may require contrast fluoroscopy. Endoscopy is ultimately the best method for identifying esophageal foreign bodies.

Foreign bodies or food impactions are usually managed under general anesthesia with rigid endoscopy. This method helps to eliminate the potential of a foreign body dropping into the airway during extraction from the pharynx. Optical forceps are used often for extraction, allowing for simultaneous visualization and grasping of the object. The entire esophagus needs to be evaluated after the foreign body is removed to rule out esophageal injury, stricture, neoplasm, or multiple foreign bodies.

CAUSTIC INGESTION

Caustic ingestion has fortunately decreased in the past few decades in the United States because of laws regulating hazardous material labeling and improved community education. Small children who accidentally encounter caustic substances usually only ingest a small amount because the substance is so distasteful. Suicidal adults may swallow more of a caustic substance and sustain more serious injuries. Careful history and description of the substance ingested is critical in the management of patients with suspected caustic ingestion. Alkaline substances, with pH 7, are the most dangerous, including lye and laundry detergents. Strongly alkaline substances lead to deep, transmural esophageal injury from liquefaction necrosis. Acidic substances tend to cause a more superficial esophageal injury.

Examination of the lips, mouth, pharynx, larynx, and esophagus is recommended in the evaluation of caustic ingestion. Gastric lavage and emetics should not be used because further injury may occur. If esophageal injury is suspected, esophagoscopy should be performed. In the setting of significant esophageal injury, a feeding tube may be necessary.

ESOPHAGEAL NEOPLASMS

Malignant Esophageal Neoplasms

Most esophageal masses are malignant, and the gold standard for evaluating esophageal neoplasms is esophagoscopy. Larger lesions may be seen on fluoroscopy, but esophagoscopy is necessary to rule out neoplasm when suspected. Unfortunately, esophageal neoplasms are often asymptomatic until they are advanced enough to cause esophageal obstruction. Solid food dysphagia is the most important symptom. Other symptoms include weight loss, hematemesis, cough (30), and vomiting.

Adenocarcinoma of the esophagus is the most common esophageal malignancy in the United States, with its incidence increasing rapidly over the last three to four decades (31). Adenocarcinoma is found in the distal esophagus, frequently arising in the setting of Barrett metaplasia. Reflux, central obesity, middle age, and male gender are risk factors for adenocarcinoma. Squamous cell carcinoma of the esophagus is highly associated with tobacco and alcohol abuse. This neoplasm may occur anywhere along the esophagus and is most frequently found in the middle third.

Benign Esophageal Neoplasms

Benign lesions in the esophagus are rare and usually slow-growing. They are infrequently symptomatic and are usually an incidental finding on fluoroscopy or endoscopy. The most common benign esophageal neoplasm is leiomyoma, an intramural lesion covered by smooth mucosa (32). Esophageal cysts are also intramural and may be congenital. Fibrovascular polyps may originate from the postcricoid region and may become "giant." Asphyxiation from a regurgitated fibrovascular polyp can cause sudden death (33). Surgical excision via esophagotomy or endoscopy is typically performed (34). Esophageal papillomas may occur, caused by the human papilloma virus. These are usually sessile and asymptomatic but they may degrade to squamous cell carcinoma in a small percentage.

HIGHLIGHTS

- Esophageal disorders may present with head and neck symptoms, such as dysphagia, globus pharyngeus, or throat pain.
- Esophagitis due to infectious, caustic, medical, or irritant causes should be evaluated in cases of throat pain.
- Esophagoscopy is required when esophageal neoplasm is suspected, particularly in the instance of solid food dysphagia.
- Candida esophagitis is the most common type of infectious esophagitis and may be seen in immunocompetent individuals. Throat pain is a common symptom.
- Reflux may cause erosive or nonerosive esophagitis, with sequelae of strictures, motility disorders, and intestinal metaplasia.
- Eosinophilic esophagitis commonly presents with food impaction. Biopsy is necessary to confirm the diagnosis.
- Esophageal masses are predominately malignant. Benign neoplasms of the esophagus are typically incidental findings.

Management of Intractable Aspiration

60

David E. Eibling

Aspiration pneumonia accompanies a wide variety of disease states, and often contributes substantially to the impact on the patient. Inhalation of food and liquid into the lower airways is recognized as a contributing factor in the death of many patients, and is frequently the terminal event. Stroke is a well-known example, in that although aspiration risk is transitory in most stroke patients, a considerable percentage of those with persistent dysphagia (20% to 50%) will eventually succumb to aspiration pneumonia (1–3). Mitchell et al. reviewed the clinical course of 323 nursing home patients with advanced dementia and noted that more than 50% had died within 18 months, and that the combination of dementia and aspiration was particularly deadly. The *6-month mortality rate* for patients with advanced dementia who had eating difficulties was 38.6%; if they developed pneumonia the figure rose to 46.7% (4). Despite the prevalence of aspiration in many disease states, and its often grave impact on the patient, (not to mention the cost to the health care system) the evaluation and management of aspiration remain enigmatic to many, if not most, health care providers. Most aspirating patients are managed by nonsurgical means, addressed in Chapter 58. This chapter focuses on surgical management of aspiration unresponsive to conservative measures.

IDENTIFICATION OF ASPIRATION

One might suspect that clinically significant aspiration would be readily apparent to the patient's caregivers. However, the signs of aspiration are frequently attributed to the primary disease, and aspiration may remain unrecognized until the terminal phase of the disease process. Neurologic impairment masks the usual symptoms of aspiration, particularly by facilitating so-called *silent aspiration*. Common manifestations of aspiration are enumerated in Table 60.1.

Aspiration pneumonia entails substantial costs for the health care system (not to mention the patient) hence most health care facilities have introduced standard screening procedures to identify patients at risk for aspiration. These are most commonly developed and overseen by a *dysphagia team*, typically organized and led by a senior speech–language pathologist (SLP). Screening is usually performed by admitting nursing staff. Patients determined to be at risk are then evaluated by the multidisciplinary dysphagia team headed by a SLP with expertise in dysphagia who makes recommendations for further evaluation and/or intervention. In some facilities, an otolaryngologist is an integral part of the team (5); however, in others the team functions effectively without physician oversight. The Joint Commission removed the requirement for universal dysphagia screening of all stroke patients in 2010; however, other performance-monitoring organizations continue to include screening for aspiration risk in their bundles (2). High-level evidence exists that improved outcomes (reduced episodes of pneumonia) are correlated with the presence of a dysphagia team, but no clear evidence exists to guide the team activities. In other words, *paying attention* in and of itself seems to be the most critical factor in promoting improved outcomes in hospitalized patients with swallowing disorders!.

ETIOLOGY OF ASPIRATION

Otolaryngology trainees encounter aspirating patients most often on the head and neck cancer service; however, the majority of patients suffering severe aspiration are those with neuromuscular dysfunction. A retrospective review of patients with intractable aspiration who required laryngotracheal separation revealed that more than two-thirds had suffered devastating neurologic disease, such as amyotrophic lateral sclerosis, multiple sclerosis, or brainstem stroke (6). The aging baby boomer population

Weight loss

and attendant increases in the numbers of patients with dementia predict that otolaryngologists practicing in the second and third decades of the 21st century will encounter an epidemic of aspirating elderly patients. Decision making for this group of future patients will challenge today's trainees.

Increased numbers of patients with head and neck cancer will survive their disease only to suffer from long-term dysphagia and aspiration. Treatment-induced acute inflammation and mucositis, as well as long-term fibrosis, xerostomia, web formation, and stenosis (or even obliteration) of the cricopharyngeal lumen, result in severe dysphagia and often frank aspiration for many cancer survivors. Acute radiation-induced dysphagia abates several weeks following completion of therapy, only to be replaced with chronic dysphagia as fibrosis develops. This dysphagia typically increases in severity with the passage of years due to progressive fibrosis and muscle weakness (7). If recent trends in the incidence of human papilloma virus—associated oropharyngeal (OP) cancer continue, otolaryngologists can anticipate growing numbers of OP cancer survivors presenting to their offices with progressive dysphagia, possibly many years after treatment. Although recent alteration in radiation fields and dose de-escalation may reduce dysphagia rates for patients treated in coming years, for the short term at least, standard doses of combined chemotherapy and radiotherapy will likely lead to increasing prevalence of posttreatment dysphagia and even morbid aspiration.

PHYSIOLOGY OF SWALLOWING

Aspiration is a sequella of disordered deglutition, so a basic knowledge of the physiology of normal swallowing is required to understand the pathophysiologic underlying etiologies of aspiration. The reader is referred to Chapters 56 to 58 and to the classic references on the topic (7,8). Some indication of the primacy of airway protection can be seen by examining the phylogeny of the larynx (9). Humans are at particularly high risk for soilage of the lower airways during deglutition due to the caudal location of the human larynx. This location facilitates vocalization by enlarging the resonance cavity, but increases the risk of aspiration associated with relatively minor abberations in swallowing function. Effective swallowing requires that food and liquid be formed into a finite bolus and then moved rapidly and completely past the closed glottis. Failure to form a finite bolus, premature leakage of bolus material into the pharynx, delay in moving the bolus through the pharynx or incomplete emptying of the pharynx at the completion of deglutition permits material to be aspirated into an open glottis. Glottic incompetence during swallowing can lead to aspiration, particularly when accompanied by sensory changes or pharyngeal weakness. Aspiration pneumonia, therefore, is the end result of laryngopharyngeal dysfunction, and typically is due to neuromuscular disease.

Glottic Closure

Glottic closure is required for effective swallowing. Closure occurs rapidly (the glottic closure reflex is less than 25 ms in duration) and is reflexively triggered by the presence of bolus material in the pharynx. Interruption of the afferent limb through loss of sensation of the larynx and pharynx causes loss of this reflex and can lead to clinically significant aspiration. Aspiration often is associated with the effector limb of the reflex through vocal cord paralysis, atrophy, or other causes of inadequate glottic closure (Fig. 60.1). Sasaki et al. (10) have demonstrated that glottic closing pressure also impacts effectiveness of closure, and may be reduced following thyroplasty even if the glottis is anatomically closed. Surgical procedures designed to improve glottic closure can have a dramatic effect in the care of some patients (11).

Upper Esophageal Sphincter Relaxation

Relaxation of the cricopharyngeal muscle allows opening of the upper esophageal sphincter, facilitating passage of the bolus from the pharynx into the esophagus. The upper

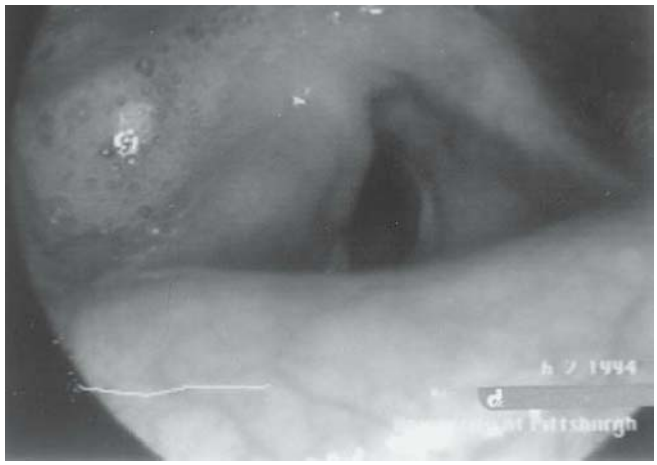

Figure 60.1 Right vocal cord and ipsilateral pharyngeal paralysis cause hoarseness and aspiration in a patient with a large glomus jugulare tumor. Saliva has pooled in the right pyriform sinus. Medialization thyroplasty was performed before tumor excision to facilitate pulmonary toilet in the postoperative course.

esophageal sphincter is actively dilatated by anterio–superior elevation of the laryngeal cartilage immediately before arrival of the bolus. Failure of either relaxation of the muscle or of hyo-laryngeal elevation will result in retained food and bolus in the pharynx.

TRACHEOSTOMY AND ASPIRATION

Aspiration has been noted in patients with a tracheostomy for nearly 50 years (12); however, controversy exists as to whether a cause-and-effect relationship exists. Sasaki (9) noted loss of the glottic closure reflex in the presence of a tracheostomy and Muz et al. (13) noted aspiration, which varied in extent depending on whether the tube was open or plugged. Several investigators (13–15) noted that plugging or placing an expiratory valve on a tracheostomy tube appeared to benefit swallowing and reduce aspiration, suggesting that subglottic air pressure played a role. Others (16) have been unable to duplicate these findings, suggesting that the specific relation between tracheostomy and aspiration varies based on patient comorbidities, age, and underlying disease.

SENSORY LOSS

Aviv et al. (17) found that stroke patients have marked reductions in pharyngeal and supraglottic sensation and that these reductions correlate with aspiration risk. Pharyngeal sensation can be measured utilizing a puff of air directed against the supraglottic structures while the larynx is observed with a flexible laryngoscope, although most examiners utilize other findings as surrogates for sensory loss (Chapter 57).

EVALUATION OF A PATIENT EXPERIENCING ASPIRATION

Once aspiration has been identified as a source of morbidity for a particular patient, additional evaluation is needed to find the cause and extent of aspiration, to assess the risk to the patient's health, and to select the optimal therapeutic course. Evaluation to identify the etiology and severity of the underlying dysphagia is integral to decision making and is discussed in detail in Chapter 57. In the past, blue dye routinely placed in tube feedings was to detect, and to some extent quantify, aspiration in patients with a tracheostomy; however, due to the risk of systemic toxicity, it is no longer utilized in this manner.

Radiographic examination (Fig. 60.2) or flexible endoscopic laryngopharyngeal examination (described in detail in Chapter 57) is the usual strategy employed to identify the etiology and evaluate the severity of dysphagia and accompanying aspiration. These studies permit real-time testing of compensatory strategies and dietary modification, which may be effective in some patients. If these strategies are not successful, then surgical approaches many be required.

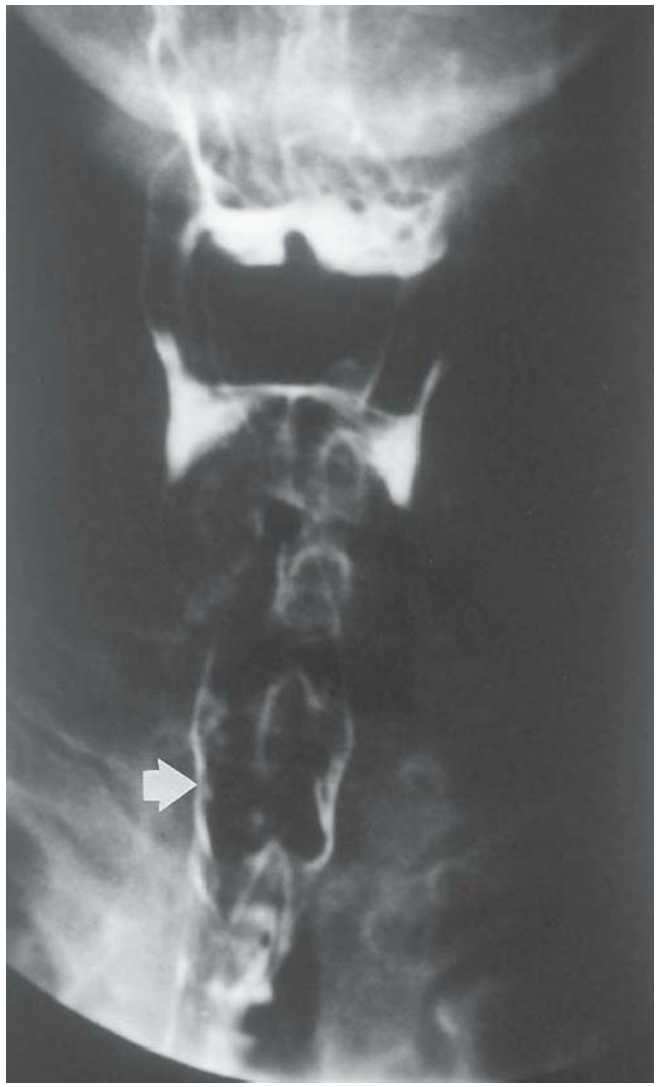

Figure 60.2 Photograph shows tracheal aspiration (*arrow*) identified during a barium swallow examination.

DECISION MAKING

Decision making in the management of intractable, morbid aspiration is typically the most complex challenge faced by the otolaryngologist. Many patients who have undergone conservation partial laryngeal surgery for cancer can be shown to aspirate on barium studies, however, actively compensate and avoid pneumonia while maintaining adequate oral intake. An understanding that the clinical effect of aspiration varies dramatically from patient to patient is required for optimal decision making in the evaluation of aspirating patients. Overall functional reserve, pulmonary status, activity level, and underlying disease processes must be considered in addition to the assessment of the extent of aspiration. The patient's overall goals and the wishes and expectations of the patient's family, as well as the role aspiration plays in the patient's overall medical status must be considered. For example, most would consider the performance of a

laryngotracheal separation on a hospice patient with terminal lung cancer who has developed severe aspiration to be inappropriate. On the other hand, there is no clear consensus on tube feeding in this setting, and decision making for each patient must be individualized. Should the same patient have glottic incompetence due to vocal cord paralysis, most surgeons would recommend performance of medialization thyroplasty, which may dramatically improve the quality of the patient's remaining life by improvements in voicing as well as reductions in aspiration. A patient who has suffered a brainstem stroke may benefit from tracheostomy and short-term placement of a laryngeal stent. This maneuver may facilitate rapid extubation and transfer out of an acute care hosptial to a skilled nursing facility merely by reducing the extent of aspiration. An understanding of the patient's disease process, the etiology of aspiration, and a knowledge of the wide range of possible solutions is essential in selecting the optimal therapeutic course. In this regard, the otolaryngologist often assumes the role of educator and facilitator in discussions with the patient and their family and care team.

THERAPEUTIC OPTIONS

Nonoral Feedings and Airway Management

Nonsurgical strategies for mild aspiration are addressed in detail in Chapter 58. Initial treatment of a patient experiencing severe aspiration is supportive and includes steps listed in Table 60.2. Elimination of oral feeding and alternative enteral access via either nasogastric tube or percutaneous endoscopic gastrostomy (PEG) are the usual initial steps in management. Surprisingly, the risk of aspiration pneumonia is not eliminated with alternative feeding. Langmore et al. (1) observed that patients who were tube-fed had a higher risk of pneumonitis (probably due to selection bias). Oral care has been shown to impact the risk of aspiration pneumonia in intubated patients (18), probably through reductions in the bacterial load contained in aspirated secretions, and should be standard in all hospitalized patients (Table 60.3).

Aspiration may become apparent in association with intubation, and often may be the trigger for placement of an endotracheal tube in a decompensating patient.

Partial supraglottic closure
Laryngeal stenting
Total laryngectomy
Laryngotracheal separation

Moreover, intubated and ventilated patients are at high risk for ventilator-associated pneumonia (VAP), at least in part due to aspiration of OP secretions through the open glottis. An evidence-based VAP—prevention bundle is now standard of care for Ventilator patients (19) (Table 60.4). Another strategy is subglottic secretion drainage utilizing an endotracheal tube designed to remove secretions from above the cuff. A recent (epub ahead of print April 2011) work demonstrates that VAP can be reduced by nearly 50% with this strategy (20).

Conversion to a tracheostomy, or elective tracheostomy with insertion of a cuffed tracheostomy tube, facilitates pulmonary toilet, although does not eliminate the risk for VAP. The presence of an inflated tracheostomy tube cuff inflation reduces but does not altogether prevent aspiration into the distal airways. Decannulation, or downsizing, plugging, or valving the tracheostomy tube after resolution of the acute process may reduce aspiration in some patients (Fig. 60.3) (14,15). The effect of these maneuvers can be assessed with either fluoroscopy (modified barium swallow) or flexible endoscopic evaluation of swallow. Employment of subglottic secretion strategies as utilized in the VAP bundle can occasionally be beneficial for patients with persistent aspiration despite use of a cuffed tracheostomy tube (20).

Procedures to Enhance Glottic Closure

Glottic closure is an integral component of normal swallowing, hence surgical procedures that enhance closure represent a critical adjunct in the management of aspiration in the patient with inadequate glottic closure. The procedures most commonly used are vocal cord augmentation or medialization with a variety of techniques, or arytenoid adduction. Evaluation of laryngeal function and performance of these procedures are discussed in detail in Chapters 69, 70, and 73. Augmenting or medializing a paralyzed cord does not completely restore glottic closing

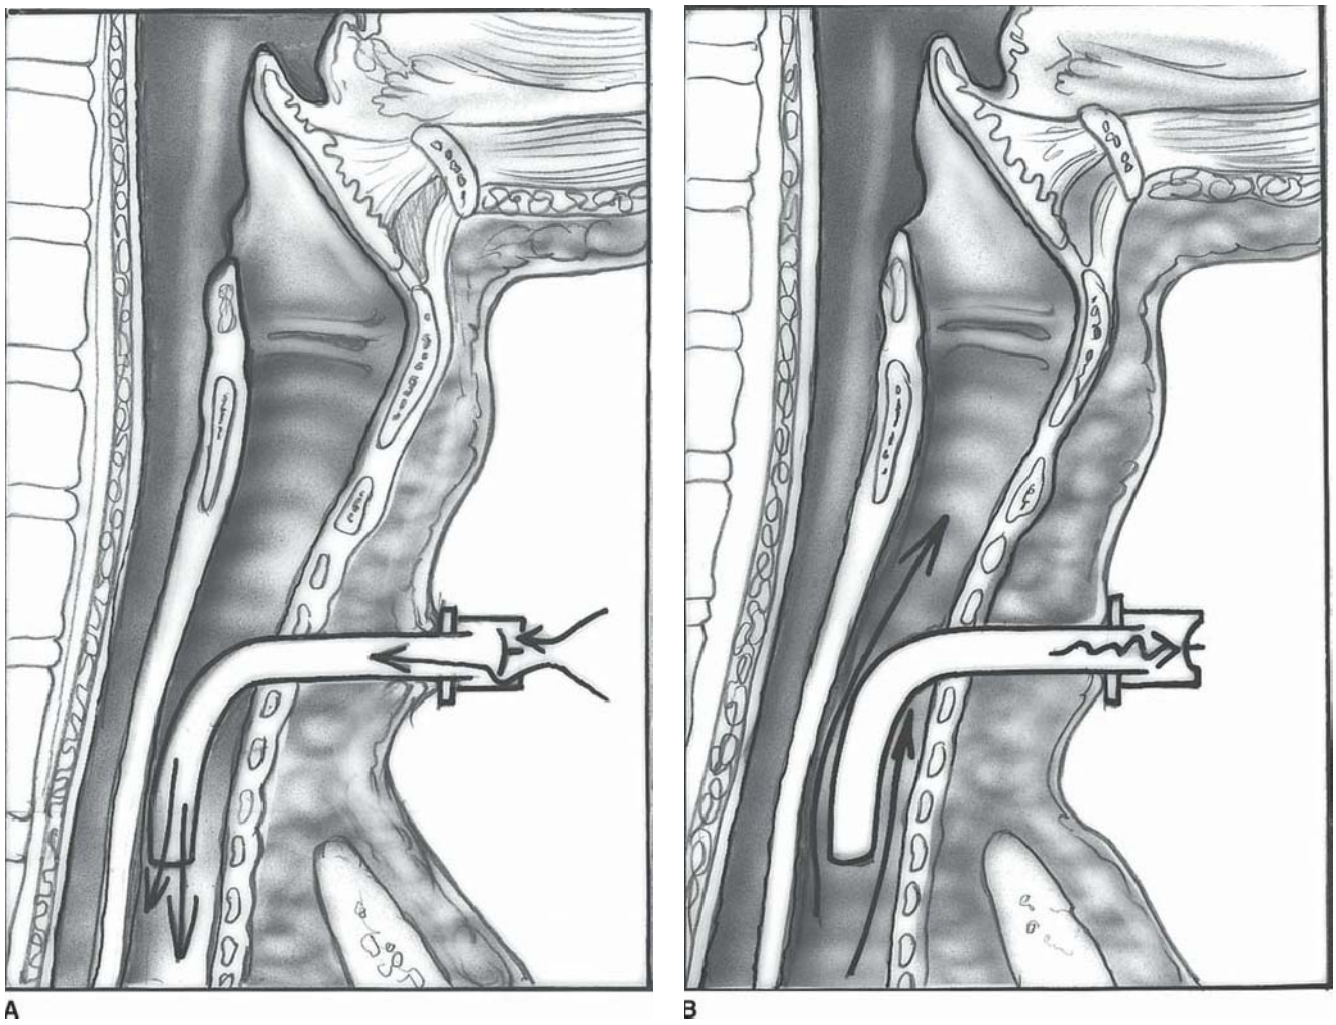

Figure 60.3 Function of expiratory speaking valve. The valve opens to allow inspiration but closes immediately to divert the inspired air out through the larynx, enabling vocalization. Use of this valve reduces aspiration for some patients with tracheostomy (10,14,15).

force since there is no active adduction on the paralyzed side (10), but typically is sufficient to thwart aspiration in cases of unilateral isolated paralysis.

Occasionally a patient experiencing severe aspiration due to severe neurologic impairment will benefit from bilateral medialization and tracheotomy. This technique can markedly diminish aspiration while maintaining vocalization, but necessitates a permanent tracheostomy.

Procedures to Enhance Esophageal Run-Off

Persistent pharyngeal residue following an otherwise intact swallow positions the airway for entrainment of food and liquid when the glottis opens for the following breath. As a result, esophageal diseases (see Chapter 59) may also contribute to intractable aspiration. Strategies to improve esophageal run-off may be the most critical management strategy for some patients.

Management of Esophageal Strictures

More than 50 years ago most esophageal strictures encountered by otolaryngologists were due to accidental ingestion of lye. Changes in product availabilty and labeling, as well as public awareness, have dramatically reduced the incidence of this devastating injury. By the end of the 20th century suicide attempts had largely replaced accidental ingestion as the cause of caustic esophageal burns.

However, the declining incidence of caustic strictures is now being replaced with stenoses secondary to organ-sparing treatment for head and neck cancer, primarily OP cancer. The average otolaryngologist can expect to encounter several in the coming decades, and most head and neck treatment centers are developing considerable experience with their management. Ongoing controversy exists as to whether the presence of a PEG during therapy contributes to the development of a stricture within the radiation field. Many Head and Neck surgeons postulate that by eliminating the need for swallowing during therapy, the repeated effective dilatation by food boluses is eliminated, permitting the raw mucosal surfaces to stenose. Esophageal dilatation has traditionally been performed in the operating suite under general anesthesia using bougies. However, many surgeons are now using balloon dilatation in an outpatient setting, and this technique seems poised to become the standard for affected patients in future years.

UPPER ESOPHAGEAL SPHINCTER

The upper esophageal sphincter is opened during the pharyngeal phase of swallowing by both passive relaxation of the cricopharyngeal muscle and active displacement of the larynx. Failure of opening results in obstruction or delay in passage of the bolus into the esophagus. Evaluation of upper esophageal sphincter dysfunction is challenging, in that failure of dilatation may be due to reduced laryngeal displacement, failure of muscle relaxation, or fibrosis. Often multiple factors contribute, and identifying the relative contribution of each may be challenging. Careful examination of the region during modified barium swallow is often instructive, but as many as one-third of elderly patients will have a persistent cricopharyngeal bar visualized on radiographic studies. Typical evaluation requires careful frame-by-frame examination of videofluoroscopic images. Occasionally the benefit of intervention can only be determined by therapeutic trial.

Cricopharyngeal myotomy may be efficacious for some aspirating patients with failure of upper esophageal sphincter dilatation during passage of the bolus, particularly when hyolaryngeal elevation is normal. An alternative to surgical division is to chemodenervate the cricopharyngeus (CP) with botulinum toxin, which may provide long-term benefit (21). The procedure can be performed as an outpatient office procedure utilizing electromyographic monitoring (Chapter 73), or can be performed in the operating suite under general anesthesia with direct visualization. Forty to fifty units of botulinum toxin are injected, with care being taken to avoid injecting too close to the postcricoid region to reduce the likelihood of posterior cricoarytenoid muscle denervation and resultant airway obstruction. Endoscopic laser division of the cricopharyngeal muscle is effective, and safe if performed in a judicious manner (22). Care must be taken to avoid entering the mediastinum in using this technique. External approaches to the CP muscle are well described elsewhere and are not reviewed in this chapter.

ZENKER DIVERTICULUM

Long-standing cricopharyngeal dysfunction may be associated with Zenker diverticulum. Large Zenker may be associated with substantial dysphagia, failure of cricopharyngeal relaxation, and resultant pooling in the hypopharyngeal pouch. Although typically not considered in the differential diagnosis of aspiration, occasionally a Zenker diverticulum will be demonstrated on radiographic studies requested to evaluate dysphagia, aspiration, and inition. Treatment of Zenker is now most commonly performed via endoscopic diverticulotomy, dividing the septum separating the pouch from the esophagus with laser, stapler device (23), or even direct incision and suture. Stapler-assisted techiques require that the pouch be larger than 2 cm, since smaller pouches do not permit complete division of the cricopharyngeus muscle. Open procedures in which the cricopharyngeal muscle is divided and the pouch either resected or inverted are also effective.

LARYNGEAL CLOSURE PROCEDURES

A number of procedures to close the larynx have been employed in reducing or preventing aspiration when more conservative strategies fail. Partial supraglottic closure converts the laryngeal introitus into a narrow tube, reducing aspiration while maintaining an aperature for phonation (24). These procedures are technically difficult, their case selection is difficult, and are probably useful in only a very small subset of patients with intractable aspiration.

Laryngeal stenting is a useful technique for severe aspiration and likely to be limited to a relatively brief period, such as in brainstem stroke. Eliachar et al. (24) reported successful control of aspiration with acceptable complications utilizing prolonged larynx stenting. Clinical experience suggests that 2 to 3 months is the typical maximum time that the laryngeal stent can remain in place. Various stents are available, as are various means for securing the stent (Fig. 60.4).

Total laryngectomy is an effective management strategy for intractable aspiration. The role of laryngectomy in the care of the aspirating patient whose larynx is nonfunctional due to prior chemoradiation, tumor destruction, or partial laryngectomy is well known. Complete laryngectomy may be required many years following successful partial laryngectomy due to aging or changes in pulmonary fuction, such as subsequent to lung surgery for a second primary lung cancer. Despite its effectiveness, the

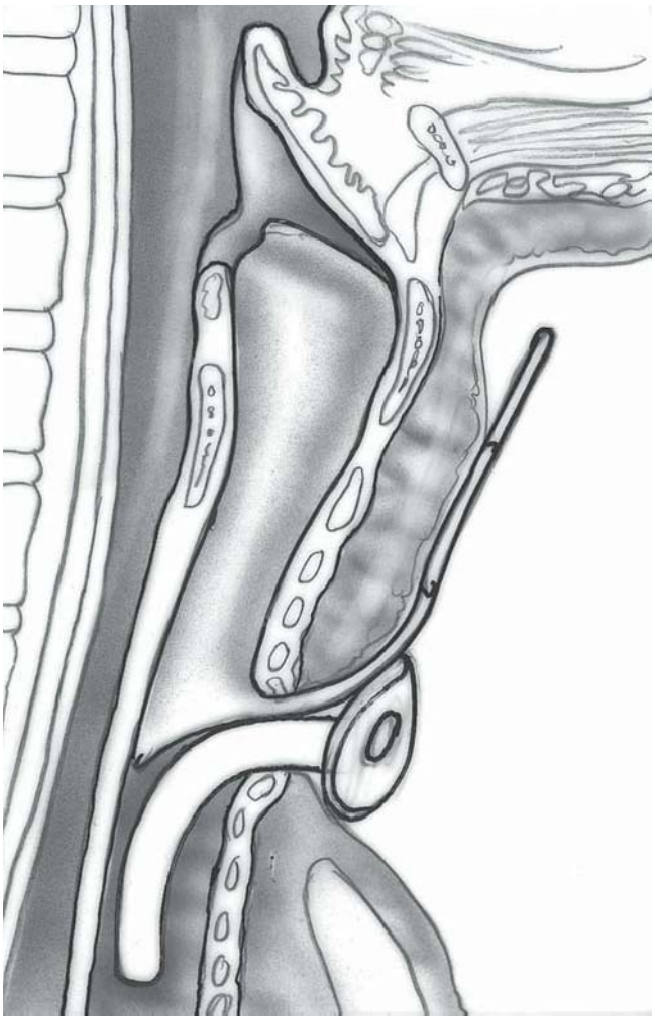

Figure 60.4 Eliachar stent in place. The stent is maintained in position by a strap that passes through the tracheostomy above the tracheostomy tube. (From *Understanding and treatment of aspiration.* SIPAC, American Academy of Otolaryngology—Head and Neck Surgery, Alexandria, VA 1993, with permission.)

procedure typically is unacceptable to patients (or their families) with intractable aspiration due to neurologic disease, even if all concerned are aware of the hopelessness of the situation, the morbidity of ongoing aspiration, and the availability of alternative techniques for voicing. The risk of wound breakdown with pharyngocutaneous fistula in the debilitated patient with poor nutritional status is not insignificant, so that preoperative nutritional support may be indicated. Alternative forms of separating the airway from the food passages are feasible and are often more acceptable to patients.

Laryngotracheal Separation

Lindeman (25) described surgical division of the trachea as a strategy for the management of intractable aspiration more than 35 years ago. As performed most commonly, the proximal tracheal stump is not anastamosed to the esophagus but is closed in a pouch (Fig. 60.5). The procedure is

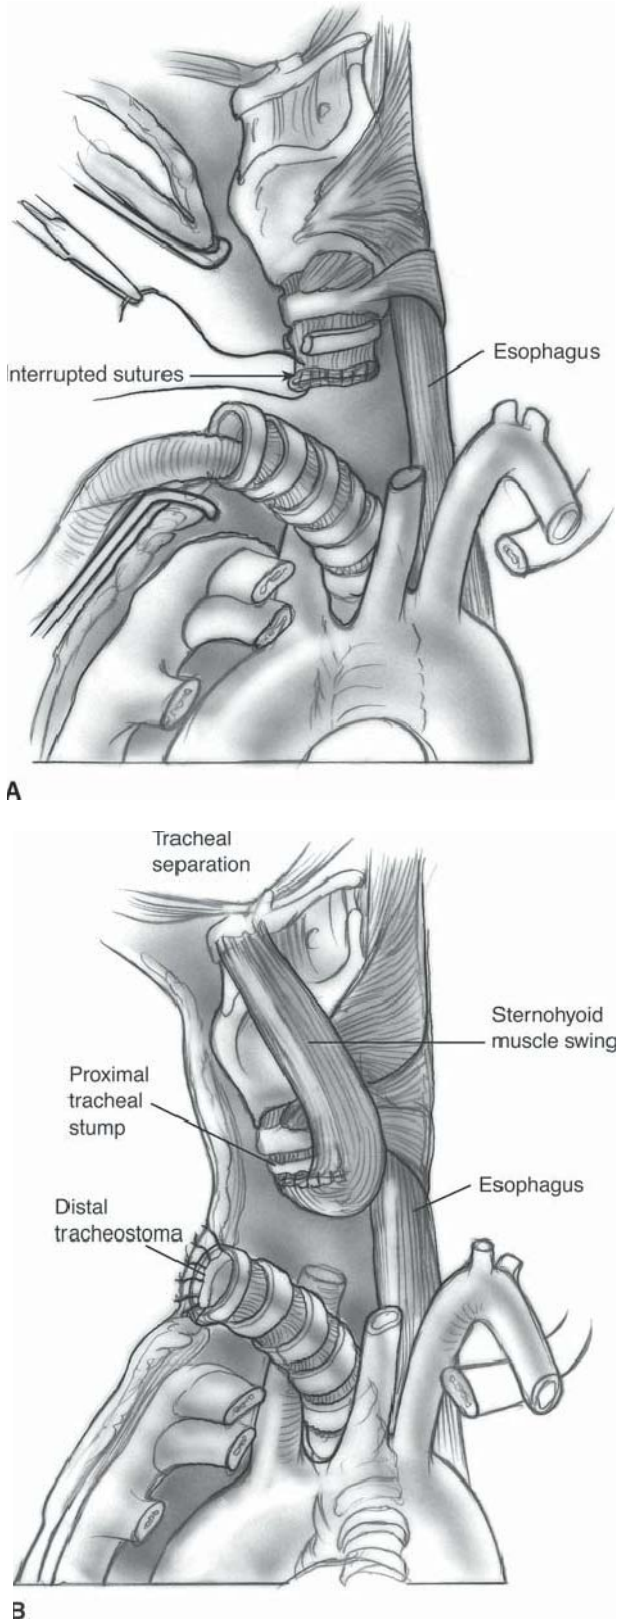

Figure 60.5 A,B: Laryngotracheal separation. The trachea is divided, and the proximal stump is closed in two layers to form a watertight subglottic pouch. The distal end of the trachea is sutured to the skin as it is in total laryngectomy. (Modified from *Understanding and treatment of aspiration.* SIPAC, American Academy of Otolaryngology–Head and Neck Surgery, Alexandria, VA 1993, with permission.)

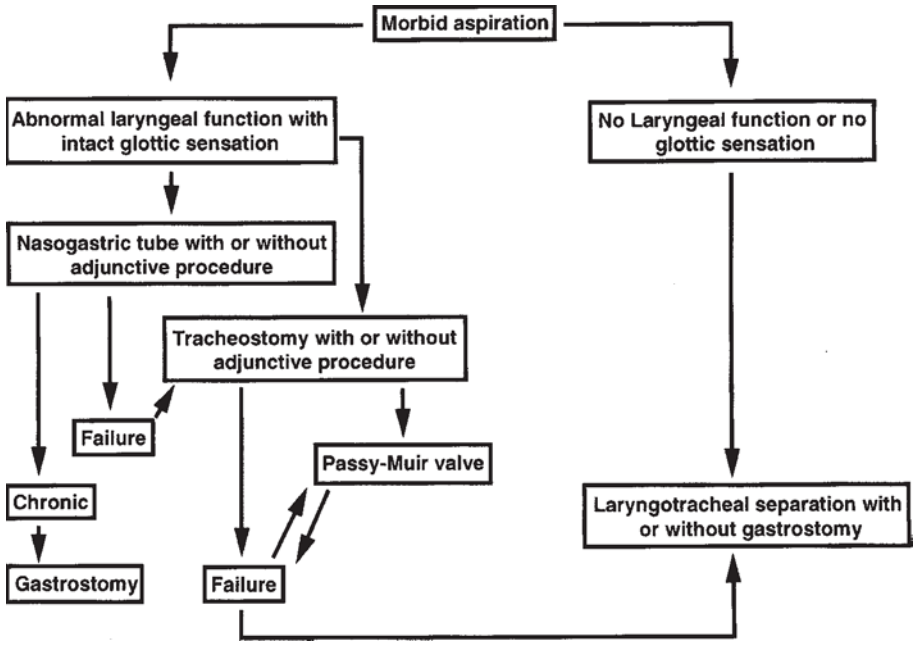

Figure 60.6 Algorithm for the management of aspiration. Adjunctive procedures, such as medialization and thyroplasty or tracheostomy tube valving, are used only in the care of patients who have a sensate functional larynx. It is more expedient to proceed directly to laryngotracheal separation if the larynx is not functional. (From Snyderman CH, Johnson JTJ, Eibling DE. Laryngotracheal diversion and separation in the treatment of massive aspiration. *Curr Opin Otolaryngol* 1994;2:63–67, with permission.)

technically easy, can be performed after tracheotomy, and is at least theoretically reversible. It has become the standard at most institutions for the management of intractable aspiration unresponsive to more conservative measures or adjunctive surgical procedures.

Laryngotracheal separation is most commonly performed following prior tracheostomy. The previous tracheostomy site is excised, the trachea dissected free, and the proximal end closed to form a blind pouch. Temporary leakage from the stump closure occurs among more than one-third of patients due to technical difficulties encountered from prior scarring, but most leakage resolves within several days with conservative therapy alone. Wound complications do occur, but tend to be self-limited. Because the larynx remains in place and is not affected by the procedure, reanastomosis of the divided trachea is feasible for the rare patient whose neurologic function returns. Tracheal reanastomosis has been reported by several authors, although the procedure can be technically challenging.

CONCLUSIONS

A decision tree useful for the management of intractable aspiration is based on whether the larynx is sensate and whether return of glottic or pharyngeal function is likely (Fig. 60.6) (26). The prognosis of the primary disease process and goals of the patient and family must take precedence over physiologic functional status. Nevertheless, if return of function is unlikely in a patient with intact cognition and otherwise acceptable quality of life, early laryngotracheal separation may provide maximal benefit. Intervention is most likely to progress in a stepwise fashion, however, with initial trials of alternative strategies prior to resorting to laryngotracheal separation. Active participation by the otolaryngologist in assisting the patient, family, and care team in difficult decision making is often invaluable in optimizing outcomes.

HIGHLIGHTS

- Morbid aspiration is a sequella of severe dysphagia.
- Aspiration accompanies many illnesses, primarily head and neck cancer and neuromuscular disease processes.
- Detection of patients at risk for aspiration is facilitated by the presence of a dysphagia team.
- Evaluation of aspirating patients should include endoscopic examination of the laryngopharynx.
- Management of aspiration should be based on assessment of the patient disease process, prognosis, swallowing physiology, and goals of care.
- A stepwise progression of theraputic interventions optimizes patient benefit while minimizing undesirable consequences.
- Procedures to enhance glottic closure and improve esophageal run-off often benefit patients with aspiration.
- Laryngectomy and laryngotracheal separation are effective interventions for aspiration, but should be considered "last resort" and utilized rarely.

61 Upper Airway Anatomy and Function

Gayle E. Woodson

The upper airway includes the nasal and oral cavities, the pharynx, and the larynx. The functional design is far from ideal because ingested food and water must traverse the upper airway to reach the alimentary tract. The pharynx must serve two conflicting functions. It must rapidly constrict to propel material into the esophagus during swallowing, yet maintain patency during the negative pressure generated by inspiration. The close proximity of the orifices into the esophagus and the lower airway present a significant risk of aspiration; therefore, the larynx has a major protective function, and breathing and speech must be interrupted during a swallow. The precarious arrangement of the airway is a product of its evolution and embryology. The trachea and lungs evolved as an offshoot of the digestive tract, and this origin is reflected in the development of human embryos. The lung buds arise from the lower pharynx.

In all nonhuman mammals, the common upper chamber for eating and breathing poses little problem, because there are functionally separate channels for breathing and eating, formed by the interdigitation of the epiglottis and the soft palate. The central channel, leading from the nose to the larynx, is for breathing, with a pathway for swallowing on either side, leading from the mouth to the esophagus. This configuration persists in human infants and explains why neonates experience such respiratory distress with nasal obstruction. In the second year of life, the larynx descends in the neck, associated with pharyngeal elongation, so that the soft palate and larynx are no longer in contact, but separated by a significant gap (1). This results in a larger hypopharyngeal space, which confers greater vocal power and diversity in articulation. But the separation of the uvula from the epiglottis abolishes the separation of air and alimentation pathways, which makes the process of swallowing considerably more complex. The purpose of this chapter is to provide the anatomic and physiologic basis for understanding the processes of breathing and speech. Because nasal and oral anatomy are covered in other parts of this text, the following section focuses primarily on the larynx and pharynx.

PHARYNGEAL ANATOMY

The pharynx is an irregularly tubular structure, extending from the base of the skull to the esophageal inlet (Fig. 61.1). The posterior and lateral walls of the pharynx are composed of three pharyngeal constrictor muscles attached to the cervical vertebrae posteriorly. The pharynx has anterior openings into the nasal and oral cavities, and inferiorly it opens into the larynx and esophagus. There are three segments: the nasopharynx, the oropharynx, and the hypopharynx. The nasopharynx can be sealed off from the oropharynx by simultaneous elevation of the soft palate and formation of a fold in the pharyngeal walls, known as Passavant ridge. Complete physical examination of the pharynx requires a mirror or endoscope, because only the posterior wall of the oropharynx is visible by transoral inspection.

The superior constrictor is suspended from the base of the skull, the medial pterygoid plate, the pterygomandibular raphe, the mylohyoid line of the mandible, and the lateral tongue. The anterior attachments of the middle constrictor are the hyoid bone and the stylohyoid ligament. The inferior constrictor attaches to the thyroid and cricoid cartilages. Activation of these muscles constricts the pharynx; there is no evidence to support the concept that they contribute to stability of the airway. Pharyngeal patency during the negative pressure generated with inspiration is maintained by muscles that dilate the lumen by pulling the base of the tongue or hyoid bone anteriorly. These muscles include the genioglossus, the geniohyoid, and the anterior belly of the digastric muscle.

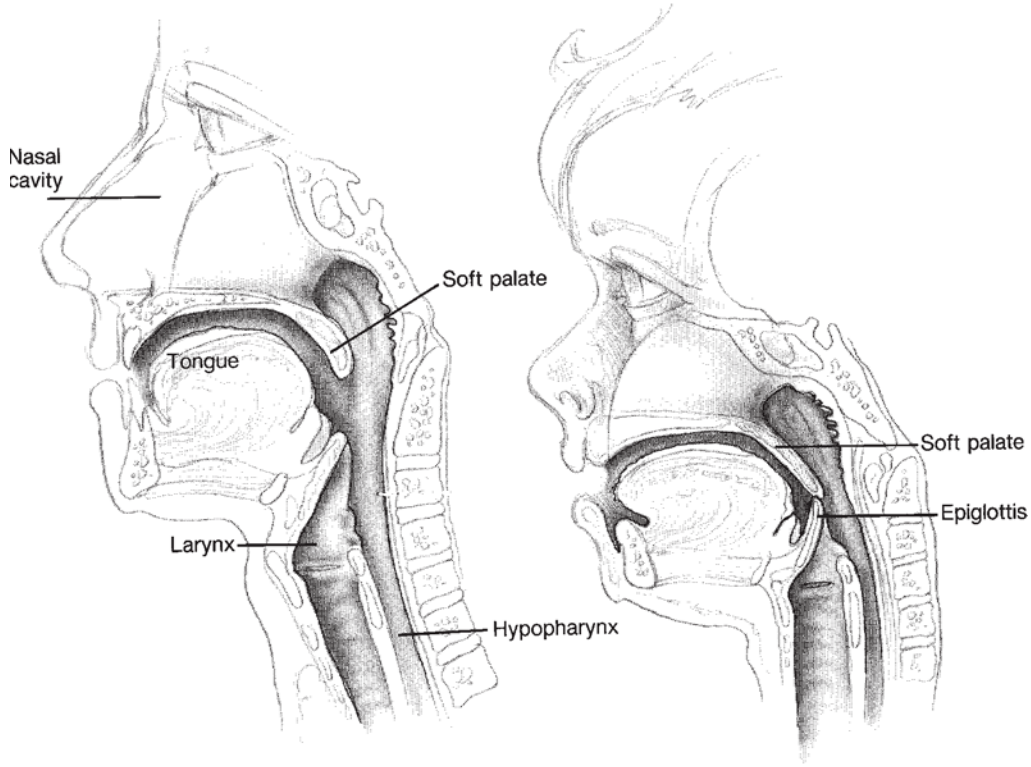

Figure 61.1 Sagittal view of upper airway.

PHARYNGEAL AIRWAY PHYSIOLOGY

Maintenance of upper airway patency is a peculiarly human problem. Some degree of airway collapse occurs during sleep in all humans, and obstructive sleep apnea (OSA) is extremely common. But sleep disordered breathing is extremely rare in any other animal (2). The instability of the human pharyngeal airway is a byproduct of the inferior displacement of the larynx during development (3). The pharyngeal walls, suspended from the base of the skull and mandible, are pliable. Some skeletal support is provided by the hyoid bone. Because its walls are collapsible, the pharynx acts as a Starling resistor. Flow through such a resistor is not determined solely by the difference between the upstream and downstream (i.e., intrapleural) pressures, but is critically influenced by the difference between the upstream pressure and the collapsing forces. In other words, if the pressure of the air inspired through the nose is not high enough to keep the throat from collapsing, no air can reach the lungs, no matter how hard the inspiratory muscles contract, and obstructive apnea results. Snoring occurs when the collapsing pressure is less than upstream pressure, but greater than downstream pressure. The airway intermittently closes, but is reopened by increased upstream pressure (2).

As mentioned above, muscles that connect the hyoid bone and tongue base to the mandible provide the force to open the pharynx. These dilating muscles are activated by the negative airway pressure generated during inspiration in the presence of upper airway obstruction. During the Mueller maneuver, which generates negative pressure in the pharynx, the dilating muscles should maintain patency. A significant decrease in the cross-sectional area of the pharynx during the Mueller Maneuver is highly predictive of OSA (4). Thus, inadequate force of pharyngeal dilating muscles is implicated in the pathogenesis of OSA.

Patients with OSA have a higher than normal activity of phasic inspiratory activity of upper airway dilating muscles during wakefulness. This suggests that these individuals require more force than normal to keep the airway patent. They are able to compensate while awake, but during sleep, airway muscle activity decreases and is inadequate to prevent collapse during inspiration. Pharyngeal patency at end expiration is also a major factor. Endoscopic observations in patients with sleep apnea demonstrate a decrease in airway cross-sectional area before an actual obstructive event. At end-expiration, with no flow, the pharyx can collapse completely. When inspiration is attempted through an already obstructed airway, the result is an obstructive apnea. Continuous positive airway pressure can stent open the collapsed segment during end-expiration. This may be one mechanism by which continuous positive airway pressure (CPAP) therapy is effective. CPAP causes a decrease in genioglossus muscle activity during wakefulness in patients with sleep apnea, but not in normals, suggesting that the increased activity in the waking OSA syndrome patient represents compensation for a mechanically obstructed airway, not defective reflexes.

LARYNGEAL ANATOMY

The most superior portion of the larynx is the epiglottis, which projects posteriorly into the pharynx. The vallecula is the pouch between the base of the tongue and the epiglottis. Interiorly, the glottis is seen as a roughly triangular opening during inspiration and a narrow slit during phonation. The true vocal folds comprise the anterior edges of the glottis. Superior and lateral to the true vocal folds are the false vocal folds. The ventricle is a narrow space between the true and false folds. The posterior glottis is formed by the two arytenoid cartilages and the intervening mucosa. The arytenoids are the posterior attachments of both the true and false vocal folds. Opening and closing of the glottis is accomplished by action of muscles that move the arytenoids. There is a mucosal bridge between the epiglottis and the arytenoid on each side, known as the aryepiglottic fold. These folds serve as levees between the esophagus and airway, by separating the piriform fossae from the glottis. The piriform fossae are mucosal-lined spaces lateral to the aryepiglottic folds but medial to the laryngeal skeleton (Figs. 61.2 to 61.4), and are the pathways by which ingested food and liquid are conveyed to the esophagus.

Skeleton

The laryngeal skeleton is made up of several cartilages and one bone strung together in series and suspended from the skull base and mandible (Fig. 61.5). Laryngeal motion can be caused by both intrinsic muscles, which arise and insert onto laryngeal cartilages, and extrinsic muscles, which connect the larynx to other structures. Also, descent of the trachea during inspiration produces widening of the glottis. This phenomenon is a result of the ligamentous interconnections of the laryngeal skeleton.

The hyoid, which supports the larynx and stabilizes the hypopharynx, is roughly U shaped, with the two free ends projecting posteriorly as the greater cornua. The lesser cornua are two small bumps on the superior anterior surface. The hyoid is connected to the thyroid cartilage by the broad thyrohyoid membrane. A bursa in this membrane enhances vertical mobility of the larynx. Laterally, the edges of the membrane thicken to form the thyrohyoid ligaments.

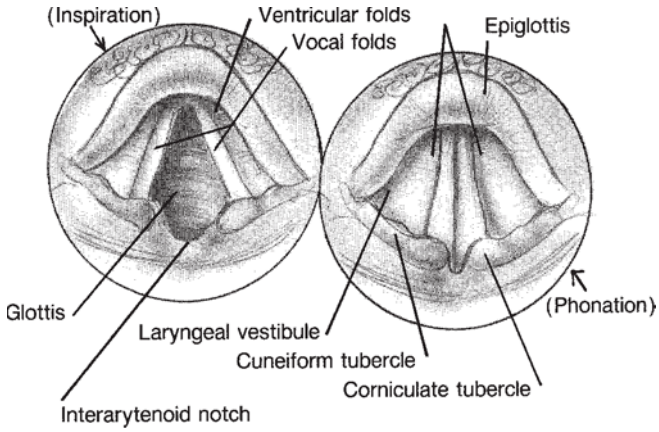

Figure 61.3 Endoscopic view of the larynx.

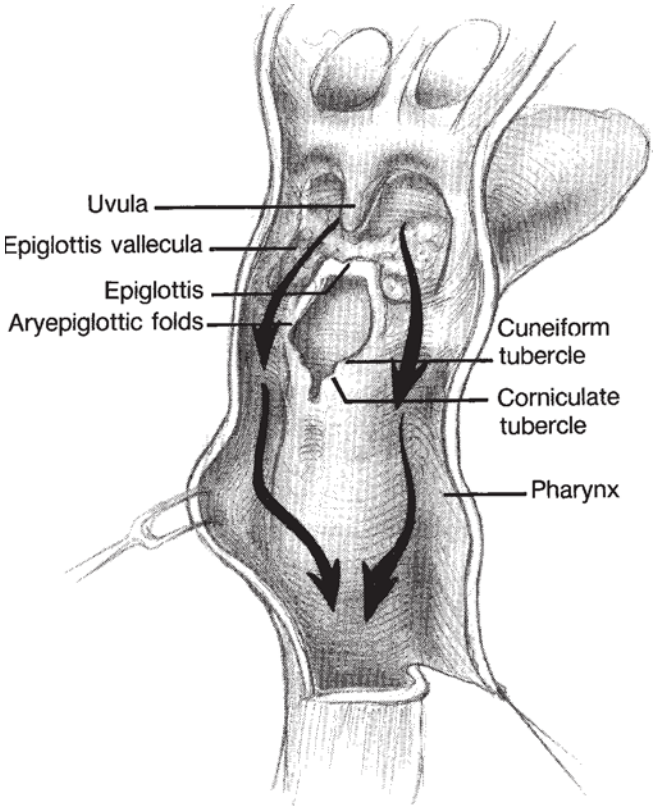

Figure 61.2 Posterior view of anterior airway.

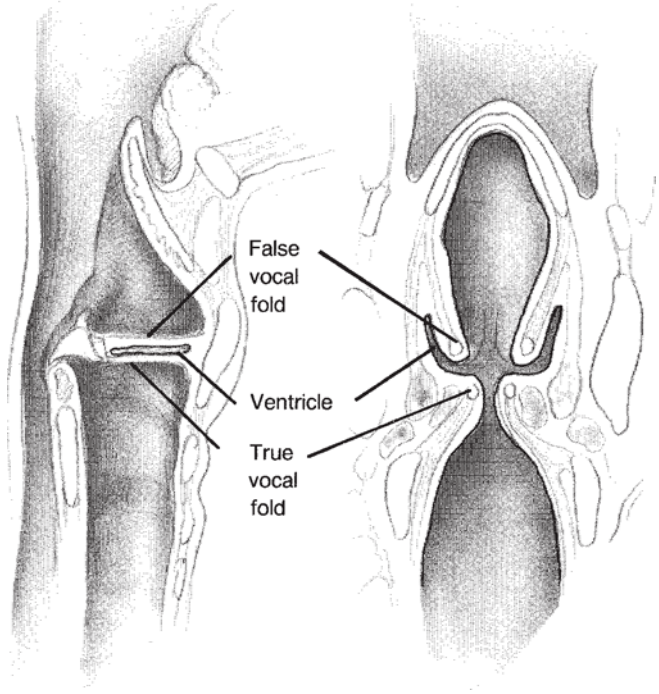

Figure 61.4 Vertical section through the larynx.

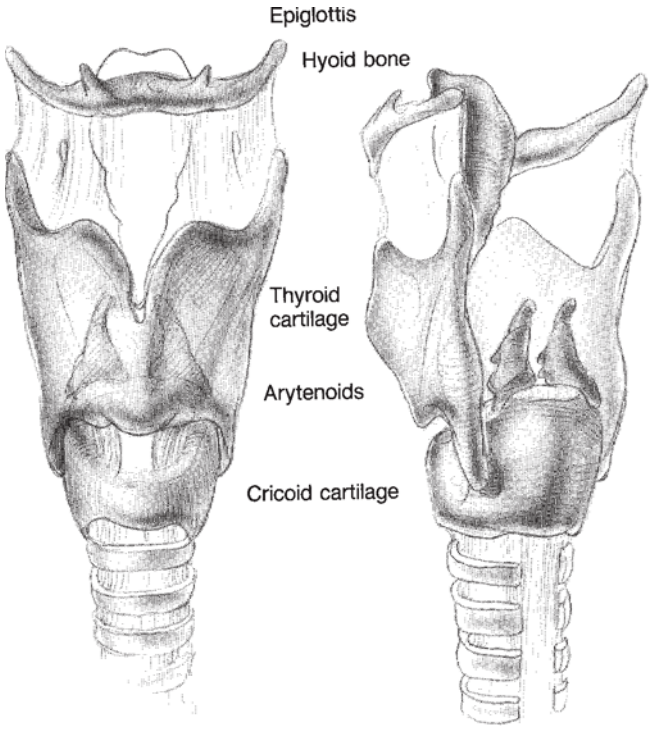

Figure 61.5 Laryngeal skeleton.

The thyroid cartilage is composed of two halves fused anteriorly at a sharp angle (90 degrees in males and 120 degrees in females). The posterior border has superior and inferior cornua. The superior cornu attaches to the thyrohyoid ligament, whereas the inferior articulates with the cricoid cartilage. The thyroid cartilage begins to gradually ossify after the age of 20. This process accounts for many age-related changes in pitch and resonance of the voice.

The epiglottis is a fibroelastic cartilage, attached anteriorly in the midline to the inner surface of the thyroid cartilage and supported by the hyoepiglottic ligament. The free end of the epiglottis projects into the hypopharynx.

The cricoid cartilage is the skeletal support of the subglottis, which is the portion of the larynx below the vocal folds. The subglottis is the only point in the airway with a completely rigid diameter. It has a smaller cross-sectional area than the trachea, so that a single foreign body that is small enough to pass through the subglottis does not cause total airway obstruction. Anteriorly, the cricoid is about 1 cm high, with a smooth curved surface. Posteriorly, it is 2 to 3 cm high, and the superior surface is flattened centrally to provide an area of articulation for the arytenoid cartilages. Posterolaterally, on each side, the cricoid articulates with the inferior cornu of the thyroid cartilage to form a visorlike apparatus, allowing rotation in a sagittal plane, which opens or closes the anterior cricothyroid space.

Each arytenoid cartilage is a somewhat pear-shaped mass. The broad base articulates with the cricoid in a complex synovial joint, which is essentially a shallow ball and socket, allowing multiaxial rotation but minimal translation (5). The vocal process, an anterior and medial projection of the arytenoid, is the posterior segment of the vocal fold (Fig. 61.6). Two other small sesamoid cartilages, the corniculate and the cuneiform, are located superior to the arytenoid and support the aryepiglottic fold.

Two fibroelastic membranes are important components of the larynx. The conus elasticus provides support to the vocal fold. From its lateral attachment to the cricoid, it extends anteriorly to the midline lower edge of the thyroid cartilage and posteriorly to the vocal process of the arytenoid. Its free edge forms the vocal ligament. The quadrangular membrane supports the supraglottis. It connects the epiglottis with the arytenoid and the corniculate cartilages. The superior free edge is draped in mucosa to form the aryepiglottic fold, whereas the inferior edge is a part of the false vocal fold (Fig. 61.7).

Muscles

Motion of the vocal folds is affected primarily by the intrinsic laryngeal muscles. It should be noted that each laryngeal muscle exerts a unique torque on the arytenoid. Physiologic motion results from the net effect of all muscles activated at any point in time (6). Thus, the vocal folds do not just open and close, but move in three-dimensional space and change shape.

The posterior cricoarytenoid muscle (PCA), the only abductor of the glottis, originates from the posterior surface of the cricoid and inserts onto the muscular process of the arytenoid. Contraction of this muscle externally rotates the arytenoid, displacing the vocal process superiorly and laterally, resulting in abduction of the glottis. However, the PCA is also activatated during phonation, presumably to stabilize the arytenoid and resist the anterior traction exerted by adductor muscles. Actually, the PCA consists of two compartments, which are innervated separately, and differ in fiber-type composition (7). The two compartments also differ in their action on the arytenoid. The horizontally oriented compartment causes rotation around a more vertical axis than does the oblique compartment (5). Potential differences in the physiologic function of the two compartments remains to be elucidated.

The lateral cricoarytenoid muscle is the primary adductor of the larynx. It originates on the lateral aspect of the cricoid and inserts onto the muscular process of the arytenoid. This muscle pulls the muscular process forward, rotating the vocal process medially. The thyroarytenoid muscle arises from the anterior inner aspect of the thyroid cartilage to insert on the vocal process of the arytenoid. The human thyroarytenoid muscle contains at least two compartments: the medial thyroarytenoid (vocalis) and the lateral muscular thyroarytenoid. The lateral portion has significant adductor action; however, isolated

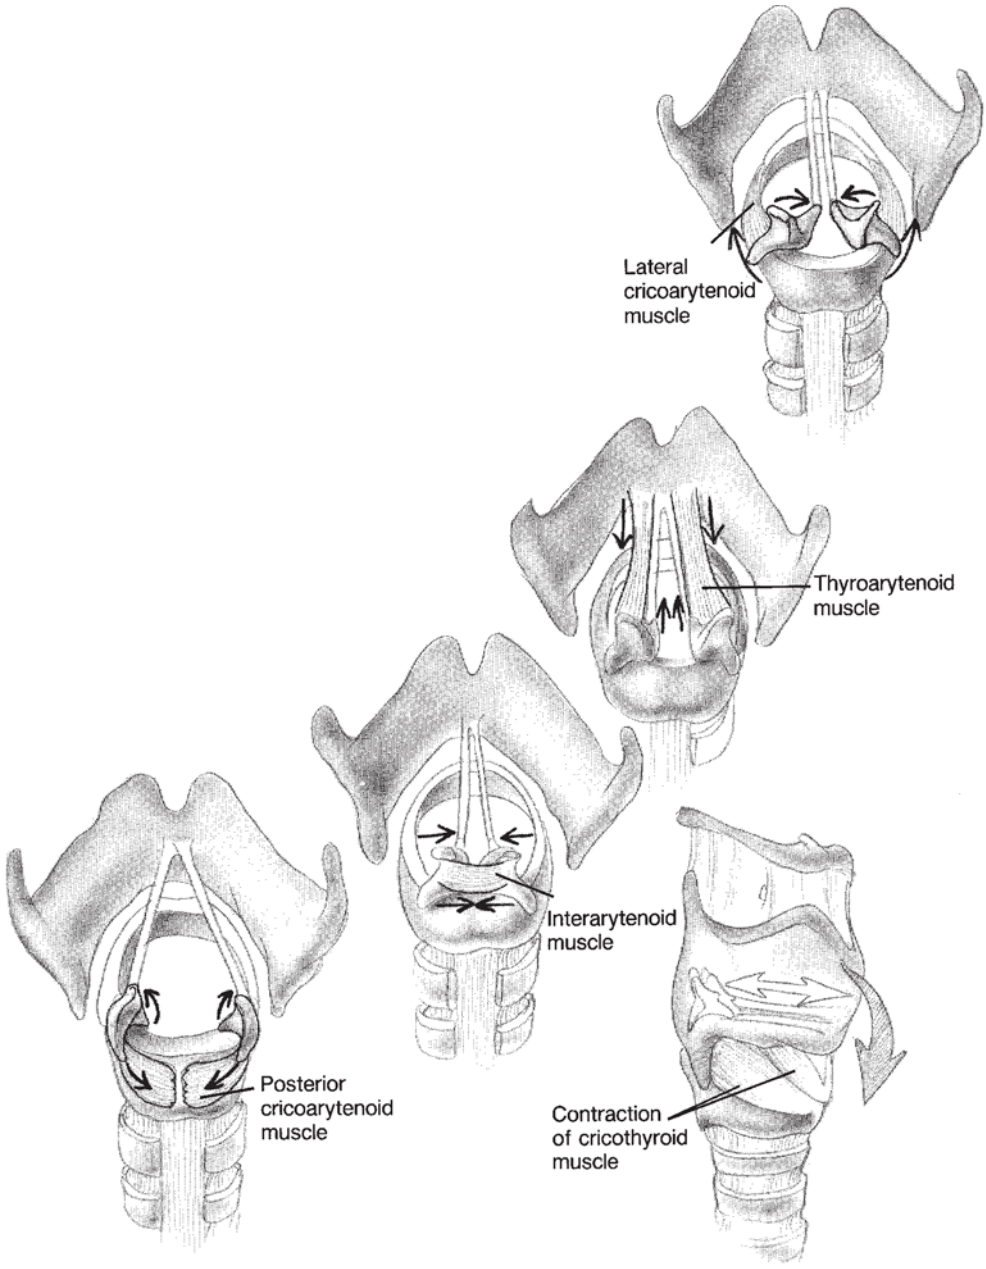

Figure 61.6 Laryngeal muscles.

contraction of the vocalis does not adduct the vocal fold, and actually produces slight abductor force (6). The vocalis does exert anterior traction on the vocal process, increasing vocal fold tension, thickness, and stiffness. In the absence of cricothyroid muscle contraction, it also reduces tension in the mucosal cover. The cricothyroid muscle pulls the cricoid and thyroid cartilages together anteriorly to increase the length and tension of the vocal folds. The interarytenoid muscle, the only unpaired laryngeal muscle, rocks the arytenoids together posteriorly (Fig. 61.6). Electromyography (EMG) studies indicate that it participates in adduction (8); however, a recent study indicated that isolated contraction of the IA abducts the vocal folds (6). The smallest laryngeal muscle, a very small band of muscle fibers between the epiglottis and arytenoid, constricts the supraglottic inlet and is probably responsible for false vocal fold adduction in functional and compensatory hyperfunction (9).

Extrinsic laryngeal muscles include the mylohyoid, digastric, and stylohyoid muscles, which suspend the larynx superiorly, and the cervical strap muscles: the omohyoid, sternohyoid, sternothyroid, and thyrohyoid. The extrinsic muscles elevate or depress the larynx or move it anteriorly or posteriorly. The extrinsic muscle activity can indirectly adduct, abduct, or tense the vocal folds or constrict the supraglottis.

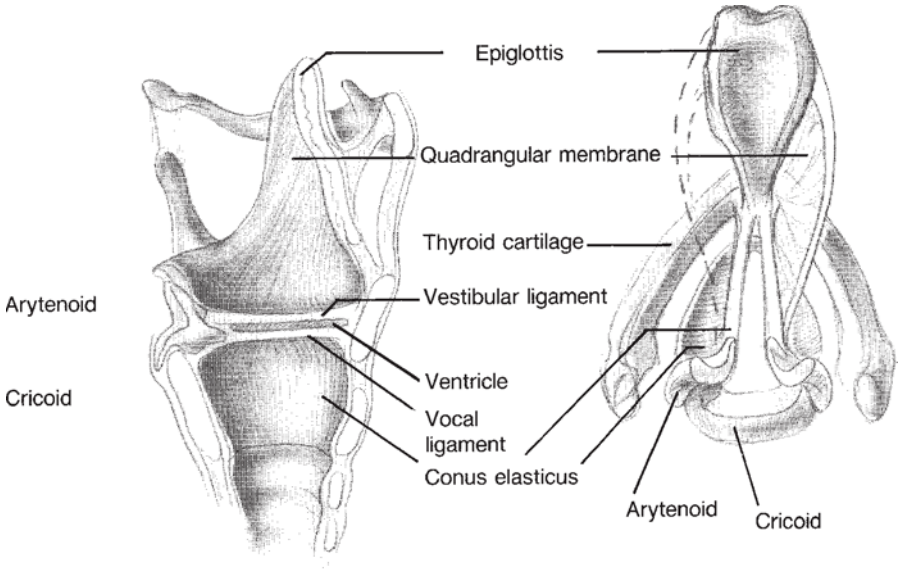

Figure 61.7 Fibroelastic membranes.

Nerve Supply

The vagus nerve supplies the larynx through two branches, the superior laryngeal nerve (SLN) and the recurrent laryngeal nerve (RLN). The SLN exits the vagus below the nodose ganglion and branches into two divisions, the internal branch, which enters the larynx laterally through the thyrohyoid membrane, and the external branch, which travels to the cricothyroid muscle. The RLN does not travel straight from the vagus to the larynx but first descends into the upper mediastinum. The right RLN curves back upward around the subclavian artery, whereas the left descends to the ligamentum arteriosum, a fibrous band connecting the aortic arch to the pulmonary artery. The nerves then ascend in or near the tracheoesophageal groove to enter the larynx. The development of the branchial arterial arch and nerve system during embryogenesis is responsible for the circuitous route of these nerves. The RLN and SLNs both contribute branches to form Galen loop, a nerve that runs submucosally along the posterolateral surface of the larynx (10).

Laryngeal mucosal sensation is mediated by both the SLNs and RLNs. The internal branch of the SLN is primarily sensory, carrying fibers from the supraglottis and vocal folds. The RLN mediates sensation from the subglottis and trachea.

A simplified view of motor innervation of the larynx is that the external branch of the SLN supplies the cricothyroid muscle, while the RLN supplies all other intrinsic laryngeal muscles. The interarytenoid muscle is bilaterally innervated, receiving motor fibers from both RLNs. However, there is a long-standing controversy regarding the possible contribution of internal SLN fibers to the motor innervation of the interarytenoid muscle. In 1929, nerve fibers from the SLN were reported to pierce the interarytenoid muscle (11). But it has been generally believed that these were sensory fibers that passed through the muscle to reach the mucosa (12). Detailed dissection using Sihler stain has provided stronger evidence that SLN fibers as well as RLN innervate the muscle and that the muscle received bilateral innervation (13). Detailed dissections have also documented that besides Galen loop, there are numerous other connections between the SLN and RLN that are variable, yet pervasive, which raise the possibility that motor control is not neatly compartmentalized between the two nerves (14). Support for this was provided by a recent EMG study in patients undergoing laryngectomy (15). In 7 of 13 patients, stimulation of the RLN resulted in a compound action potential of the cricothyroid muscle in response to stimulation of the RLN in 7 patients and in 3 patients, stimulation of the external SLN activated the posterior cricoarytenoid muscle. The variations in intralaryngeal neural connections may have significance in laryngeal paralysis and reinnervation.

Extralaryngeal branching of the RLN is also common and variable. A recent study in 579 patients undergoing thyroid or parathyroid surgery found branching on at least one side in nearly half the patients and bilateral branching in nearly 10%. Intraoperative stimulation indicated that all motor supply, both adductor and abductor, was contained within the anterior branch (16). Within the larynx, the terminal branch of the RLN supplies the transversus abdominis (TA) muscle. But the nerve supply to the PCA is not discrete and is highly variable. A recent anatomic study in 43 cadaver larynges found 1 to 5 direct branches to the PCA from the RLN and usually at least one branch from the nerve to the interarytenoid muscle. All PCA muscles received nerves arising from the anterior division of the RLN, while less than half received some innervation from the posterior branch (17). This fragmented and variable nerve supply to the PCA muscle is likely one reason why spontaneous reinnervation of this muscle is poor in comparison to that of adductory muscles (18).

Mucosal Cover

The mucosal cover of most of the upper airway is respiratory epithelium, with numerous mucous glands

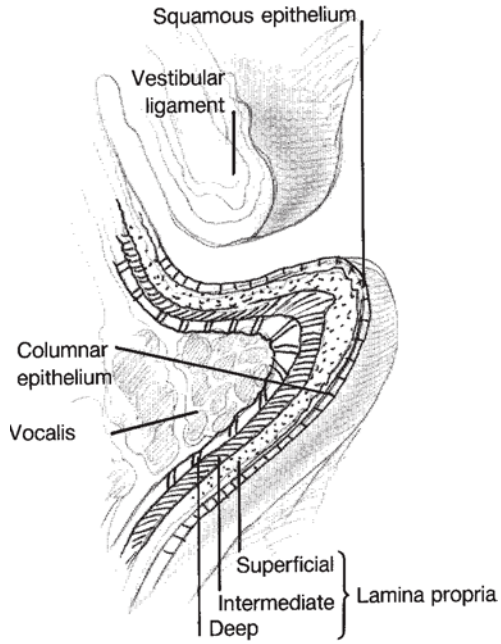

Figure 61.8 Vocal fold mucosa.

(Fig. 61.8). Over the free edge of the vocal fold, however, mucosa is adapted for periodic vibration with squamous epithelium and no mucous glands. A highly specialized lamina propria separates the epithelium from underlying muscle (19). The lamina propria serves as a shock absorber, or impedance matcher, so that the epithelium can vibrate freely, without restriction by the bulky underlying muscle. The lamina propria of the vocal fold contains three layers: superficial, intermediate, and deep. Each layer has unique mechanical properties because of varying densities of elastic and collagenous fibers. The deep layer of the lamina propria contains densely organized band of collagen fibers that penetrate superficially into the vocalis muscle. This layer is about 36% of the lamina propria. The intermediate layer occupies about half the thickness of the lamina propria. Collagen fibers are less dense and there are numerous elastic fibers. The superficial layer, immediately below the basement membrane of the epithelium, contains loosely orgainzed collagen fibers and accounts for about 13% of the lamina propria. The superficial layer of the lamina propria is often referred to as Reinke space, although it is not actually a potential space.

RESPIRATORY PHYSIOLOGY OF THE LARYNX

The most primitive function of the larynx is that of a sphincter, preventing the ingress of anything other than air into the lungs. Other functions include coughing, Valsalva maneuver, and the regulation of airflow in and out of the lungs. The larynx also serves as a sensory organ and contains receptors that influence the control of breathing and even affect cardiovascular function.

Cough

Cough ejects mucus and foreign matter from the lungs and helps to maintain patency of the pulmonary alveoli (20). Cough may be voluntary but more often occurs in response to stimulation of receptors in the larynx or lower respiratory tract. A greater stimulus is required to produce a cough during sleep, and in deep sleep a stimulus must first result in arousal to a lighter level of sleep before cough occurs.

A cough has three phases: inspiratory, compressive, and expulsive. First, the larynx opens very widely to permit rapid and deep inspiration. If the cough is voluntary, the degree of glottal abduction and inspiratory effort is proportional to the intended strength of the cough. The compressive phase is produced by tight closure of the glottis and strong activation of expiratory muscles. During the expulsive phase, the larynx suddenly opens widely, with a sudden outflow of air in the range of 6 to 10 L/s.

Valsalva Maneuver

The true vocal folds offer more resistance to inspiratory than to expiratory airflow. However, very tight closure of both true and false vocal folds enables the larynx to resist very strong expiratory forces. Forced expiration against a tightly closed glottis is known as the Valsalva maneuver. It is important in defecation because the pressure is transmitted to the abdominal cavity. Valsalva also serves to stabilize the thorax during heavy lifting by the arms.

Regulation of Airflow

The larynx is ideally located to regulate the flow of air in and out of the lungs and is better adapted than any other portion of the respiratory tract for producing sudden alterations in resistance to airflow. Observations of laryngeal movement demonstrate that the glottis widens during inspiration and narrows during expiration, and this movement with breathing varies with respiratory demand. Opening, or abduction of the larynx, facilitates breathing by decreasing resistance to airflow. Two forces contribute to inspiratory opening of the larynx: longitudinal tension on the laryngeal skeleton, caused by the descent of the trachea, and contraction of the posterior cricoarytenoid muscle. Both these forces increase during hyperpnea. Active laryngeal abduction is a primary action of breathing, because the posterior cricoarytenoid muscle consistently begins to contract before the diaphragm with each inspiration. The larynx opens more widely during inspiration with increasing effort of breathing and in response to negative upper airway pressure.

Under most conditions of breathing, respiratory rate is primarily controlled by varying the rate of exhalation. During quiet breathing, exhalation is mostly a passive phenomenon, as inspiratory muscles, including the diaphragmatic and intercostal muscles relax, and the

diaphragm and ribcage relax and recoil. The posterior cricoarytenoid muscles also relax during expiration resulting in expiratory adduction of the vocal folds, which prolongs the expiratory phase. The TA muscle is usually quiet during sleep and basal breathing. But during conscious breathing, the TA regulates the duration of expiration and the pattern of expiratory airflow. Expiratory adduction of the vocal folds also increases transglottic resistance, and can therefore provide positive end expiratory pressure in the lower airway.

As respiratory demand increases, expiratory muscles in the abdominal wall and rib cage are recruited to force air out of the lungs, accelerating the rate of expiration. Expiratory activity of the posterior cricoarytenoid muscle is also recruited during labored breathing. With increasing respiratory drive the PCA continues to contract during expiration, after the diaphragm has relaxed. This results in decreased glottic resistance and faster outflow of air, which shortens the duration of expiration and increases the rate of breathing.

In addition to dynamic control of airflow, the configuration of the static larynx exerts mechanical influences on airflow. At any given glottic aperture, resistance to airflow in the inspiratory direction is much greater than resistance to expiratory flow. Because of this, conditions that cause laryngeal obstruction, such as edema, papillomas, or laryngeal paralysis, usually produce inspiratory stridor before expiration is impaired.

Sensory Input to Respiratory Control

The larynx is not only an effector organ; it is also richly supplied with a variety of sensory receptors that exert influences on breathing and cardiovascular function. There are several times more sensory fibers from the larynx than from the lungs, which have internal surface areas of several square meters. Some responses to laryngeal stimulation are appropriate and beneficial; however, some responses such as laryngospasm and cardiovascular collapse appear maladaptive. These reflexes can be produced experimentally by electrical stimulation of the SLN. Such extreme responses probably represent an oversaturation of pathways that serve a useful function at lower levels of input. Three major types of laryngeal receptors are activated by the process of breathing and have an influence on the central control of breathing: negative pressure receptors, airflow (cold) receptors, and "drive" receptors, which are probably proprioceptors that respond to respiratory motion of the larynx (21). Laryngeal receptors also respond to touch and chemical stimuli.

Negative upper airway pressure increases the inspiratory activation of upper airway dilating muscles, including the genioglossus, the geniohyoid, the ala nasi, and the posterior cricoarytenoid muscle. Negative pressure sensation is primarily mediated by the SLN and is believed to be an important stimulus for maintaining upper airway patency.

Airflow receptors have been identified in the nose and the larynx and appear to modulate central respiratory drive. Stimulation can decrease respiratory rate or even cause apnea. Airflow receptors behave as thermistors, responding to the temperature drop induced by air flowing through. Thus, laryngeal flow receptors do not respond to air that has been warmed and humidified by the nose but are activated by air that comes in through the mouth, particularly in cold and dry weather.

A number of responses can be elicited by mechanical stimulation of the larynx, including apnea, laryngospasm, and cardiovascular collapse. Because the larynx is in a very protected position, such responses do not usually occur naturally. Laryngospasm, the forceful and prolonged closure of the larynx, is most often seen in the operating room in response to endotracheal intubation. It is most likely to occur when the patient is well oxygenated and under light anesthesia. It occurs in the conscious state under certain pathologic conditions such as upper respiratory infection. Sometimes a decreased threshold for laryngospasm can persist for many months after an infection, resulting in frequent episodes of frightening total airway obstruction. Mechanical or chemical stimulation of the larynx can produce prolonged bronchoconstriction.

The laryngeal adductor reflex is a rapid brief closure of the true vocal folds in response to appropriate stimulation of the mucosa innervated by the SLN. Sensory deficits in the laryngopharyngeal region can result in dysphagia and aspiration. Recent studies have shown the importance of sensory testing in this region, especially in predicting aspiration pneumonia risk in patients with dysphagia (22).

Apnea is a prominent response to laryngeal stimulation, prevents the aspiration of the stimulating material into the lower airway. Apnea may occur in response to such diverse chemical agents such as ammonia, phenyl diguanide, and cigarette smoke. Water in the larynx can also inhibit inspiration under certain conditions, such as general anesthesia, and during upper respiratory infections. In infants, water in the larynx can produce prolonged apnea. The typical response to water, however, in the normal conscious adult is vigorous coughing. It has been suggested that laryngeal reflexes may be implicated in the pathogenesis of sudden infant death syndrome, because respiratory reflex pathways go through a process of maturation in infancy that make laryngospasm and reflex apnea much more likely to occur during the interval of peak incidence of sudden infant death syndrome (23).

CIRCULATORY REFLEXES

Stimulation of the larynx can produce changes in heart rate and blood pressure. This effect is most noticeable during induction of general anesthesia in response to endotracheal intubation. It may also occur in natural circumstances such as OSA. When upper airway patency is not maintained

during sleep, the resulting increase in negative airway pressure can stimulate receptors in the larynx so strongly that cardiac arrhythmias occur. The direct result of laryngeal stimulation on blood pressure is hypertension. However, if laryngeal stimulation produces significant bradycardia or ectopy, the indirect result can be hypotension.

The pathways responsible for mediating cardiovascular responses to laryngeal stimulation are not clearly understood. The afferent limb is the SLN. Transection of the SLN abolishes cardiovascular responses to laryngeal stimulation, and electrical stimulation of this nerve affects heart rate and blood pressure. The efferent limb for bradycardia is clearly the vagus nerve, but the efferent limb for blood pressure elevation is not known. Intervening central connections have yet to be identified, but there is evidence that sympathetic response to laryngeal stimulation may be mediated through central respiratory control mechanisms. Recordings from cervical sympathetic roots in the neck have documented phasic activity with breathing, and this activity is suppressed by electrical stimulation of the SLN.

SPEECH

The human voice results from the coordinated interaction of the larynx, lungs, diaphragm, abdominal muscles, throat, neck muscles, lips, tongue, buccinators, and soft palate. Speech consists of three component processes: phonation, resonance, and articulation. Phonation is the generation of sound by vibration of the vocal folds. Resonance is the induction of vibration of the rest of the vocal tract to modulate and amplify laryngeal output. Articulation is the shaping of the voice into the words that characterize human speech.

Phonation

Sound is produced by the larynx when expiratory airflow induces vibration of free edges of the vocal folds as a result of the interaction of aerodynamic and myoelastic forces. Five conditions must be met to support normal phonation: appropriate vocal fold approximation, adequate expiratory force, sufficient vibratory capacity of the vocal folds, favorable vocal fold contour, and volitional control of vocal fold length and tension. Just before phonation, the vocal folds are approximated in the midline. Exhalation then causes subglottic pressure to rise until the vocal folds are pushed apart. This separation produces a rapid decrease in subglottic pressure. The vocal folds then return to the midline as a result of sudden decrease in pressure, elastic forces in the vocal fold, and the Bernoulli effect. Pressure in the trachea builds once more, and the cycle is repeated. During modal phonation, the vocal fold essentially vibrates as two masses, with the upper edge lagging behind the lower edge. This results in a traveling wave, from caudal to rostral, known as the mucosal wave. In falsetto mode, the vocal fold is thinner and vibrates as a single mass; therefore, the mucosal wave is absent.

Vocal fold position is a critical factor in phonation. When the vocal folds are loosely approximated, the mucosa can easily swing open to produce wide fluctuations in pressure. If the vocal folds are tightly compressed, more expiratory effort is required to initiate and sustain phonation. If a gap exists between the vocal folds, efficiency is markedly reduced and a higher airflow is required to induce vibration. The resulting voice is breathy, and duration of phonation is shortened. With a wide gap, the airflow requirement exceeds the expiratory capacity, and the voice may dwindle to a whisper.

In normal conversational speech, the driving force for phonation is passive exhalation, the release of energy stored in the rib cage and diaphragm. Deeper inspiration stores more energy and therefore permits louder and longer phonation. Contraction of abdominal and intercostal muscles provides additional expiratory force during greater phonatory efforts such as singing or shouting. An increase in perceived loudness of phonation during singing can be achieved by a technique known as vibrato: Expiratory effort is usually cyclically varied to superimpose slower frequency pressure changes in the vocal output.

The capacity of the vocal folds to vibrate periodically depends on the homogeneity and flexibility of the mucosa and on the integrity of the lamina propria. Edema, which increases the impedance of the submucosa, impairs vibration. Trauma, infection, or surgery can produce scars that tether the epithelium to the underlying muscle and block the normal propagation of mucosal waves.

The surface contour of the vocal folds determines the shape of the glottal tract. To support normal phonation, the medial surfaces of the vibratory portions of the vocal folds must be roughly parallel. If the vocal muscle is atrophic, then the medial surface is concave rather than convex, resulting in a convergent glottis, which is unfavorable for phonation.

Changes in vocal fold length and tension influence the fundamental frequency of vibration of the vocal folds to produce dynamic inflections of the voice. Frequency can also be controlled by changing the thickness of the fold or by limiting the length of the vocal fold segment that participates in vibration. The physical properties of a larynx determine the range of pitches it can produce. The small larynx of a child has a higher pitch range than the larger larynx of an adult. Young adult males, with longer and heavier vocal folds and a deeper supraglottis, produce the lowest human pitches. In males during puberty, the rapid increase in the size of the larynx often outstrips the capacity for adaptation, resulting in frequent sudden pitch changes. Size is not the only determinant of pitch range, however, because ossification of the thyroid cartilage with increasing age contributes to elevation of pitch.

Resonance

The sound output of the isolated larynx in no way resembles the human voice. Phonatory output is modulated by resonance, the induction of vibration in the chest, pharynx,

and head with selective amplification of certain component frequencies. Resonance not only gives the voice its characteristic acoustic pattern but can also amplify the voice. Vocal training, for singing and acting or public speaking, concentrates heavily on refining and maximizing resonance, so that the loudest and most pleasing sound can be produced with the least amount of strain or pressure on the larynx. Resonance is controlled by altering the shape and volume of the pharynx, by raising or lowering the larynx, by moving tongue or jaw position, or by varying the amount of sound transmission through the nasopharynx and nose.

Articulation

The formation of consonants and vowels is largely controlled by the lips, tongue, palate, and pharynx. The larynx also participates in articulation, by coordinating the beginnings and endings of phonation to coordinate with upper articulators, producing voiced and unvoiced sounds.

Sensory Input to Speech Control

One of the primary mechanisms for controlling phonatory output during speech is auditory feedback. However, when we speak or sing, we do not simply make a random sound and then adjust the pitch and quality; we preset the vocal tract for the intended sound. This skill, learned very early in life, uses cues that are largely unconscious. Other evidence for the involvement of nonauditory cues in voice control is the ability of deaf patients to maintain fairly normal speech patterns. Well-trained singers are able to perform with good control of pitch and loudness even when they cannot hear their own voices. Tactile sensation of induced vibration in the face, throat, and chest is important to the trained singer. The degree to which receptors in the larynx influence vocal control is not known. Stimuli such as contact of mucosal surfaces, air pressure, stretch of joint capsules, and tension in muscles are indicators of laryngeal posture and expiratory effort and can be important in speech control.

HIGHLIGHTS

- The human upper airway is distinguished from that of all other mammals by the descent of the larynx in early development, which abolishes the separation of channels for respiration and deglutition.
- Patency of the upper airway during breathing depends on active contraction of muscles that pull the hyoid and tongue base forward to dilate the pharynx.
- Vocal fold motion is controlled by muscles that act on the arytenoid.
- Tight laryngeal closure is required for the production of an effective cough.
- The mucosal cover of the vocal fold is highly specialized for phonation.
- Human speech has three components: phonation (sound production), resonance (amplification and filtering of sound), and articulation (formation of words).
- The mucosal cover of the vocal fold is highly specialized for phonatory vibration.
- The pitch of the voice is controlled by changes in length and tension of the vocal folds.
- The sound of the human voice is greatly determined by the resonance of the upper vocal tract.
- Sensation in the larynx and pharynx is very important in swallowing and deficits can lead to aspiration.
- Stimulation of the larynx can result in laryngospasm, breathing changes, bradycardia, or hypotension.

Upper Airway Stenosis: Evaluation and Management

62

Philip A. Weissbrod *Albert L. Merati*

Upper airway stenosis is an umbrella term for scarring or cicatrix of the trachea, subglottis, glottis, or supraglottis that can lead to airway obstruction. Stenosis can be limited to soft tissue scarring and fibrosis, involve cartilaginous remodeling from chondritis, or be a combination of the two. On a patient level, symptomatic stenosis is debilitating leading to significant reduction of quality of life due to obstructed breathing patterns and voice alterations (1). For many patients, especially those with postintubation-related stenosis, the difficulty breathing that comes with an airway lesion can potentiate their medical condition or significantly hinder their recovery. For all patients with airway stenosis at any level, their road to a diagnosis can often be laborious, time-consuming, and at the expense of considerable personal and societal resources. Many of them have seen numerous physicians and traveled a road fraught with misdiagnosis and unclear answers. Often patients present having been misdiagnosed with asthma, vocal fold dysfunction, or other respiratory conditions (2,3). During this period of delay between onset of symptoms and diagnosis, especially if there is significant symptomatology, their function can be limited and both their physical and mental well-being impaired limiting capacity for work and normal daily living.

In this chapter, subsites of airway stenosis including supraglottic, glottic, subglottic, and tracheal are independently addressed. Common causes, staging systems, treatment methods, and outcomes are discussed in an effort to provide overview of the current state of medical and surgical management. Etiology and evaluation of airway stenosis are discussed in general terms for all subsites, as there is significant overlap between subsites. When appropriate, specifics for each subsite are also discussed. Discussion of pediatric and congenital stenosis is not included as it is covered elsewhere in the text.

ETIOLOGY

The etiology of airway stenosis is varied (Table 62.1). While certain sites are more prone to specific disease processes, many can cause scarring anywhere between the supraglottis and trachea.

The origin of airway stenosis encompasses a broad spectrum of disease processes. Inflammation is the common link between all the disease processes. Injury to the airway can occur acutely from trauma, intubation, infection, endoscopy, or any form of surgery to the intrinsic airway that can cause mucosal or cartilaginous injury. Systemic processes such as laryngopharyngeal reflux, autoimmune disease, and neoplasm can create an environment of acute and/or chronic insult, which ultimately leads to scar and stenosis. Injury that is circumferential, in particular, can lead to greater likelihood of airway stenosis as noted by Andrews and Pearson (4) in their 2-year prospective study of intubated patients.

A number of canine models of airway stenosis have been created using drills, surgical dissection, or endotracheal tubes as the mechanism of injury. Regardless of the origin of trauma, any mucosal disruption, ulceration, or chondritis can lead to the formation of intraluminal granulation tissue and subsequently damage to the underlying cartilaginous framework, mucosal thickening with submucosal fibrosis, and ultimately, scar formation (5–8).

Trauma

The most common inciting factor for airway stenosis is trauma, most frequently in the form of postintubation injury. An endotracheal tube can create injury at two levels: the glottis due to the rigid tube's wall and the trachea due to cuff pressure (9). An endotracheal or tracheotomy tube has the potential to create a circumferential injury within the

TABLE 62.1 ETIOLOGY OF UPPER AIRWAY STENOSIS

Post radiation	

trachea (7). Injury can come from direct mucosal abrasion or from vascular compromise as a result of sustained cuff pressure (10). The vascular supply to the tracheal cartilage is derived from small intercartilaginous vessels that create a submucosal plexus (11). A number of these vessels originate from the inferior thyroid artery. Other vascular contributions to the cervical and thoracic trachea include the supreme intercostal, subclavian, right internal thoracic, and innominate artery (12,13). Increased cuff pressures, drops in systemic perfusion, cardiac bypass, and systemic vasculopathy, such as diabetes, can all contribute to local deprivation of blood supply. With ischemia come congestion, edema, and eventually ulceration (14,15). Ulceration can lead to chondritis and necrosis. Healing of necrotic compromised regions occurs by secondary intention leading to scar formation (16).

Size of endotracheal tube, length of intubation, cuff pressure, and traumatic intubation all potentially can increase the likelihood of airway stenosis (17). Postintubation stenosis arose as a frequent disease process in the mid-20th century after an increase in long-term intubation injury as related to poliomyelitis (18). It became clear that the increases in incidence of stenosis was due to injury at the tracheostoma site from surgical manipulation, the presence of a pressurized balloon, and irritation of the tip of the respiration device (19). Localized infection of the stoma and trachea also was found to be a significant risk factor in early animal studies (20).

Over time, a number of mechanisms to reduce injury of the tracheal wall were identified. Early cuff pressures were high: the balloons were initially small in size and required intraluminal cuff pressures of greater than 180 mm Hg to allow for adequate positive pressure ventilation at 20 to 25 mm Hg (21,22). By increasing the size and compliance of the endotracheal and tracheotomy tube balloon subsequently lowering the intracuff pressures, there are fewer tracheal lesions from postintubation trauma seen in the later half of the last century (23,24).

Stenosis, however, can occur with a brief intubation and small endotracheal tube. In addition to tracheal and subglottic stenosis, intubation injury can lead to trauma and scarring of the posterior glottis in the intra-arytenoid region and cricoarytenoid joints, the location within the glottis which receives the most pressure from the presence of an endotracheal tube (25).

Tracheotomy or tracheostomy is the most common form of surgical trauma causing airway stenosis. Stenosis can be at any level along the tracheotomy tube or above the stoma. Postintubation or posttracheotomy stenosis is not uncommon, ranging from 10% to 19%, but typically only is symptomatic in less than 1% of cases (26–28). It is unclear in the current literature if there are any differences in rates of stenosis between open and percutaneous dilational tracheotomy (29,30), however, conceptually, percutaneous tracheotomy may cause greater cartilaginous injury from less controlled entry into the airway leading to destabilization of the laryngotracheal framework (31,32).

Other forms of injury can include laryngotracheal trauma secondary to blunt or penetrating neck trauma, which can lead to cartilaginous framework disruption, mucosal lacerations, and tears, both of which can potentially lead to scarring at any level. Other forms of surgically induced injury along the course of the upper airway can come in the form of thyroidectomy, partial pharyngectomy, partial laryngectomy, tracheal and bronchial surgery, and any endoluminal airway procedure that can lead to inflammation and scarring.

Iatrogenic glottic stenosis can occur with bilateral de-epithelialization of the anterior commissure and anterior true vocal folds leading to anterior glottic web. Once formed, this can be difficult to treat, often requiring multiple procedures and stent or keel placement. Similarly, posterior glottic stenosis (PGS) can occur with excess manipulation of the posterior vocal folds and posterior glottis leading to scar formation and cricoarytenoid joint fixation; however, it should be restated that the most common cause is from endotracheal tubes. It has also been hypothesized that severe coughing can lead to telescoping of the cricoid cartilage over the first tracheal ring leading to vascular insult, which in the setting of poor wound healing can lead to airway stenosis (33).

Systemic Disease

Wegener's granulomatosis is a disease of unknown etiology that can involve the kidney, lungs, and upper respiratory tract. The frequency of airway stenosis in Wegener's, in particular subglottic stenosis varies depending on the series, but can

range from 8.5% to 50% (34–36). While the *subglottis* is the most commonly involved portion of the upper airway, glottic and supraglottic involvement has also been noted. Biopsy of the region can show noncaseating granulomas; however, biopsy is not always diagnostic. Antineutrophil cytoplasmic antibodies (c-ANCA) are greater than 90% positive during the active vasculitic phase of the disease and can be a useful adjunct in diagnosis (37). Adequate systemic control of disease is recommended prior to entertaining definitive treatment for stenosis. Systemic control can include medications such as methotrexate, cyclophosphamide, and in refractory cases rituximab (38).

Relapsing polychondritis is another systemic disease process that has consequences in the airway. Most commonly associated with inflammation of the cartilaginous structures of the ear, it can also involve the nose, joints, larynx, and tracheobronchial tree. In a large cohort series of patients, 31/145 patients (21%) with polychondritis had airway manifestations. Of the 31 patients with airway symptoms, 8 (26%) had subglottic stenosis, 8 (26%) had other foci of stenosis within the tracheobronchial tree, and the remainder had diffuse malacia. Forty percent required surgical intervention including tracheotomy and dilation (39).

Laryngopharyngeal Reflux

Laryngopharyngeal reflux was first suggested as a culprit of airway stenosis in the early 1980s (40,41). In recent years, there has been increasing evidence that chronic acid injury to the lining of the airway can be caustic and lead to, among other things, stenosis. There have been numerous studies aimed at teasing apart the causative role of reflux in subglottic and tracheal stenosis. Koufman (42), in 1991, studied 32 patients with laryngotracheal stenosis and noted laryngopharyngeal reflux in 78%. Others have identified similar trends in 24-hour pH probe results establishing laryngopharyngeal reflux as one of the many factors that play a role in the development of airway stenosis (43–45).

The intubated patient is at particular risk of acid-related injury given the presence of an endotracheal tube and its associated trauma. Supine position and the use of a nasogastric or orogastric feeding tube has been suggested to increase rates of reflux events, aspiration, and ventilator-associated pneumonia in the intubated patient (46,47). Currently, most ICUs place patients in a semirecumbent position (45 degrees), which has been shown to reduce ventilator-associated pneumonia and presumably gastric reflux events (48). Additionally, the widespread use of acid suppression medication in ICUs has likely further reduced acid-related injury in this patient population.

Idiopathic Stenosis

Idiopathic laryngotracheal stenosis occurs predominantly in childbearing aged women, ages 30 to 50. It is often a diagnosis of exclusion; patients usually have no history of airway trauma, systemic disease, or other identifiable etiology of stenosis. Typically, idiopathic stenosis involves a short segment of the subglottis and/or upper trachea; it manifests as a circumferential fibrous ring. These are usually isolated single level lesions as apposed to intubation injury-related stenosis, which often can have multilevel involvement (49). Interestingly, symptomatically, idiopathic stenosis patients tend to have less symptoms and individuals maintain normal respiratory effort until a critical stenosis has formed leading to relatively sudden onset of symptoms. Pathologically, idiopathic stenosis also behaves differently than stenosis from intubation trauma. Lacking is chondromalacia, a common factor seen in other forms of stenosis, and instead, there is a dense fibrotic process of the lamina propria (50).

Given the age and sex predilection, there is question as to the role of hormones in the development of idiopathic stenosis. Subglottic tissue has been evaluated for the presence of estrogen receptors; however, initial studies have failed to identify a link leaving the association still unfounded (51,52).

There is considerable debate of the role of laryngopharyngeal reflux as the underlying cause of idiopathic stenosis; however, to date there has been no definitive evidence to support this. Blumin and Johnston recently evaluated for the presence of pepsin in patients with idiopathic glottic stenosis. Pepsin serves as a highly sensitive and specific marker for the exposure of mucosal tissue to gastric contents (53). They noted 13/22 patients with idiopathic stenosis (59%) had evidence of pepsin in the stenotic tissue as apposed to controls that had no pepsin noted in biopsy specimens ($P = 0.041$) (54). Despite the relatively high rate of pepsin identified, there was not a statistically significant correlation between 24-hour pH probe and the presence of pepsin, which could relate to the deficiencies in acid testing alone or temporal limitations of testing methods.

It seems plausible that a certain percentage of patients with idiopathic stenosis may have stenosis from laryngopharyngeal reflux, but not all of this population tests positive leaving the underlying process, in many patients, still unknown. Grillo et al. (55) commented in their series of 72 patients with idiopathic stenosis, that only 5 (7%) required additional dilations despite cessation of antireflux medication further strengthening the argument that idiopathic stenosis and reflux-related stenosis are distinct entities.

Laryngitis and Tracheitis

Infection of the upper airway is a consideration in the development of tracheal stenosis. As mentioned previously, inflammatory lesions and ulcerations can lead to chondritis, granulation tissue, and scar formation. Theoretically, any intraluminal airway infection, whether viral or bacterial,

can incite an inflammatory reaction that can ultimately contribute to the development of airway stenosis, especially in cases where endotracheal intubation is necessary, as the results of multiple insults to the area could be additive. In a small but telling animal study, Squire et al. traumatized rabbit tracheas and inoculated them with *Staphylococcus aureus*. Animals were sacrificed at postoperative day 10. Those treated with antibiotics had significantly lower mean stenosis percentages as compared to those infected tracheas (50.8% vs. 85%) suggesting that infection, in the setting of airway trauma, can significantly worsen the rate and severity of stenosis (8).

Other specific infective processes have no associations with stenosis. In some tuberculosis (TB) endemic regions, TB-related airway stenosis is a common, if not the most common etiology of tracheobronchial stenosis (56). Tracheal lesions in TB can develop from lymphatic spread, direct infection of local tissue via infected sputum, or local extension from paratracheal or mediastinal lymph nodes (57).

EVALUATION

The most important component in understanding stenosis is a history that accounts for all associated risk factors and conditions. An accurate understanding of intubation history and sources of trauma can point toward a culprit etiology. In cases where there is no prior history of trauma, consideration of appropriate infectious, laryngopharyngeal reflux, autoimmune, and systemic diseases should be entertained. Other considerations should include details about the rapidity of symptom development, exercise intolerance, and the effects of airway inflammation such as upper respiratory infections. In patients who are operative candidates, special consideration should be paid to processes that could effect wound healing such as diabetes mellitus, collagen disorders, vascular disorders, history of smoking, and alcohol consumption. Patients can be followed over the time by their subjective respiratory symptoms. Self-assessment of dyspnea at rest or on exertion can be valuable clinical indicators of the need for intervention. The rapidity of symptom return can also help determine the urgency of intervention.

Physical Examination and Office Endoscopy

Physical examination should start with careful observation of both shallow and deep respiration. The presence of stridor indicates obstruction and can point toward the level of obstruction. Low pitch inspiratory stridor indicates supraglottic obstruction. High pitched inspiratory or biphasic stridor suggests laryngeal, subglottic, or tracheal obstruction. The utilization of accessory muscles, suprasternal retractions, or rapid breathing can suggest impending airway compromise and the necessity for intervention either with intubation or tracheotomy.

Examination of the airway is important for characterization as it can dictate treatment options. Flexible or rigid laryngoscopy should be an integral part of airway evaluation. For evaluation of the supraglottis, glottis, and immediate subglottis, transnasal flexible endoscopy with topical nasal anesthetic with 4% lidocaine should be sufficient. In most cases, with proper patient positioning, detailed evaluation as far distal as the subglottis is possible. For patients with heightened laryngeal sensitivity or suspected mid or distal tracheal stenosis, direct application of lidocaine to the glottis allows for transglottic views of the trachea with flexible transnasal laryngotracheobronchoscopy with relatively low risk (58). When assessing stenotic patients, all areas of stenosis and scar should be noted. Dynamic examination of the larynx is important to ensure there is no paralysis or paresis of the vocal folds, a potential source of additional obstruction. Evaluation for mucosal inflammation, edema, erythema, and other signs of laryngopharyngeal reflux should also be noted (59).

If a tracheotomy is present, careful study of the stoma in relation to the cricoid should be performed as this can have bearing on the available surgical options. Examination via trans-stomal flexible tracheoscopy is easily accomplished. If the patient is stable and has a well-established tracheotomy track, the tracheotomy should be removed and the scope retroflexed, to view the subglottis from below.

Imaging

If access to an otolaryngologist or flexible laryngoscope may be limited, plain radiograph can be helpful in outlining the silhouette of the airway. The level and length of the stenosis usually can be visualized with plain radiography, but more detailed information such as thickness of the tracheal wall, further characterization of the lumen, and presence of wall calcifications can only be identified with computer tomography (CT) (60). The presence of calcifications is often seen in cases of postintubation-related trauma; in idiopathic stenosis often there is no calcification evident (61). Noncontrast thin cut CT is a more revealing study and can be helpful in visualizing stenotic airway segments or extraluminal compression from tumors or aberrant blood vessels (62,63). In addition, in situations where there is glottic compromise, CT scan may represent a means of airway evaluation while avoiding the risk associated with transglottic endoscopy.

Despite its many benefits, CT does have limitations in airway evaluation. If the stenotic segment is thin and CT scan slice is thick, a thin stenotic segment can be missed on imaging. In addition, when compared to endoscopy, CT if significantly less accurate in predicting stenotic segment length, an important negative predictive factor in airway surgery (64).

A relatively new imaging technology, *virtual tracheobronchoscopy*, is gaining popularity. This technology takes advantage of CT spiral data acquisition and utilizes the contrast between airway and surrounding tissue to allow for virtual endoluminal navigation through the airway (65,66). In a review of 37 patients, flexible tracheobronchoscopy,

intraoperative endoscopy, CT, and virtual endoscopy all correctly estimated the Cotton-Meyer stenosis grade of stenosis in greater than 94% of cases (67). Considering this, virtual endoscopy may be of particular benefit in patients who have tenuous airways where endoscopic evaluation may be risky or in patients with severe stenosis where the airway distal to the obstruction may not be easily visualized.

Pulmonary Physiologic Testing

The use of physiologic objective testing of the airway can also be helpful. Flow volume loops (FVLs) are the standard method for assessing flow and volume characteristics of the upper airway by plotting the forced vital capacity against the rate of flow. Based on FVLs, airway obstruction can be differentiated into intrathoracic versus extrathoracic and fixed versus mobile obstruction. With a fixed obstruction, there is plateau of flow rates on both inhalation and exhalation as apposed to mobile extrathoracic obstruction which has a plateau on inspiration, and mobile intrathoracic obstruction with a plateau of flow on exhalation (68).

Despite the utility of FVLs, there are some limitations. It appears that they are a good qualitative instrument in determining obstruction but do not necessarily show the correlation between the degree of airway obstruction and severity of breathing symptom (69).

Reflux Testing

Objective reflux testing in patients with symptomatic reflux or idiopathic stenosis is also used by many practitioners (70). The gold standard for testing is dual probe 24-hour pH monitoring (71). More recently, esophageal manometry and impedance testing have been included in the diagnostic armamentarium to provide additional detail about the origin of reflux and the presence of both acidic and nonacidic reflux events. There is considerable debate regarding what represents positive testing. This discussion is outside of the scope of this chapter; however, many believe that any acidic (and even nonacidic) reflux event into the pharynx to be abnormal, especially when considering a patient with airway stenosis.

Direct Microlaryngoscopy and Operative Endoscopy

Operating room-based direct laryngoscopy is an integral part in evaluating all levels of airway stenosis. Careful preoperative planning with the anesthesia team is essential for safe administration of anesthesia and airway control. Aside from standard direct laryngoscopy techniques, advanced intubation techniques such as video-assisted endotracheal intubation and awake fiberoptic nasal intubation can be helpful in the appropriate patient. In cases of advanced glottic and supraglottic stenosis, intubation may be difficult. Rigid ventilating bronchoscopes for emergent intubation are a valuable tool in many cases. The surgical team should also be prepared for the possibility of an emergent tracheotomy if needed, preferentially at or just below the level of stenosis to limit the extent of additional airway injury. Ventilation in stenosis cases can be achieved via endotracheal tube, rigid bronchoscope, or supralesional jet.

Direct laryngoscopy and tracheobronchoscopy can serve as both a diagnostic and, when performed in conjunction with dilation, a therapeutic procedure. Diagnostic information attained from endoscopy should include the level, length, and severity of stenosis, as well as the mobility of the cricoarytenoid joints. Characterization of the stenosis is important. Multisubsite involvement complicates management considerably. Length of stenosis, granulation tissue, and thickness of stenosis are important to note as they can alter therapeutic decision making. In subglottic stenosis and tracheal stenosis, distance from the inferior margin of the vocal fold is important in ensuring that there is sufficient soft tissue proximally to perform a reanastomosis.

NONOPERATIVE MANAGEMENT

Nonoperative management is an important component of the long-term management of stenosis patients. This can include measures to prevent recurrence of stenosis or delay intervention with medical management.

Preventative measures include control of reflux, management of rheumatologic disease, and avoidance of chronic irritants that can cause an inflammatory response. For patients undergoing surgical intervention requiring intubation, the use of small caliber tubes reduces the incidence of intubation-related stenosis (14). For patients who require endotracheal intubation or tracheotomy, using low-pressure cuffs and keeping intracuff pressure less than 30 mm Hg greatly reduces airway injury (72,73). In addition, the use of lightweight swivel tracheal connectors and endotracheal tube support devices has been proven to be an effective resource in reducing incidence of intubation and tracheotomy-related stenosis in cases that require mechanical ventilation (4).

In symptomatic stenosis patients, oxygen supplementation, air humidification, systemic steroid application, and antibiotics when appropriate can all provide symptomatic relief in those who are acutely symptomatic. In patients with severe obstruction who are not candidates for dilation or resection, or who are symptomatic from an inflammatory exacerbation such as an upper respiratory infection, the use of heliox can be valuable in avoiding intubation, which could theoretically potentiate additional inflammation and worsen stenosis (74).

SUPRAGLOTTIC STENOSIS

Supraglottic stenosis leading to obstruction is most often in the region of the laryngeal inlet (Fig. 62.1). Postsurgical scarring, infection, caustic ingestion, and autoimmune diseases can lead to contractile scarring of the aryepiglottic folds, arytenoids, epiglottis, and intra-arytenoid region and

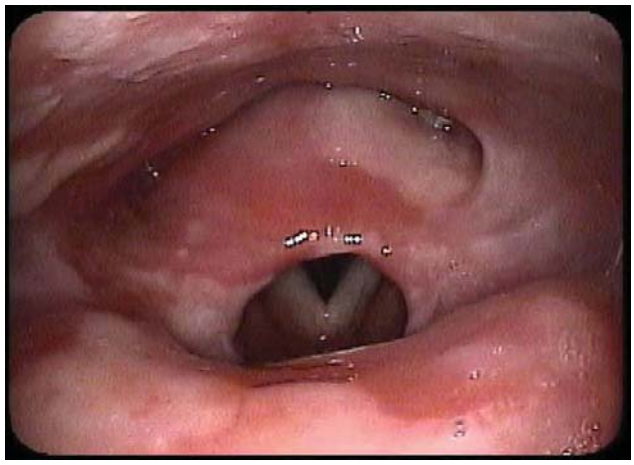

Figure 62.1 Flexible fiberoptic laryngoscopy of supraglottic stenosis in a patient with bullous pemphigus.

subsequent narrowing of the laryngeal inlet. Anterior cervical trauma that leads to injury of the thyroid cartilage and/or hyoid can displace the epiglottis posteriorly and narrow the supraglottic airway. Depending on the extent of involvement, symptoms can vary from stridor to severe airway obstruction.

Correction of supraglottic stenosis can be performed both endoscopically and via external neck incision with laryngofissure, and in extreme cases, in the form of supraglottic or suprahyoid laryngectomy (75,76). Endoscopic techniques focus on conservation of mucosa and lysis of scar via releasing procedures.

GLOTTIC STENOSIS

Glottic stenosis can be divided into three subtypes: anterior, posterior, and complete glottic stenosis. *Anterior glottic stenosis*, which includes laryngeal webs, can be congenital as seen in children and neonates, but also can form from bilateral anterior vocal fold trauma from surgery, caustic injury, infection, or malignancy (Fig. 62.2). Anterior glottic stenosis can be limited to a thin web between the anterior true folds or can be more extensive involving the false folds creating a thick web. Symptoms can range from hoarseness to varying degrees of dyspnea due to limitations of abduction.

Treatment of anterior glottic stenosis can be challenging. The technical aspects of treatment should focus on two components: division of the stenosis and prevention of restenosis. Simple web lysis with cold or laser techniques can be effective but has been associated with a high level or recurrence.

A number of techniques have been described to prevent restenosis. Most written about is placement of a keel in the anterior commissure to prevent regrowth of anterior-based scar. Initially described by McNaught (77), keels were placed through a laryngofissure and required a tracheotomy and repeat laryngofissure for removal. Keel placement was modified with the advent of endoscopic procedures. Today, silastic keels are placed endoscopically and secured to the external neck by various techniques (78–80).

Mitomycin-C can also be applied to the anterior commissure to prevent stenosis. In a canine model, Roh and Yoon showed that mitomycin-C significantly reduced the extent of web formation after vocal fold stripping procedures. Mitomycin-C–treated animals on average had stenosis that affected the anterior 31% of the vocal fold as compared to untreated animals who had a mean of 72% (81). Chitosan, a product derived from arthropod shells, has also shown promise as a topical agent in prevention of glottic stenosis in a canine laser injury model (82).

Posterior glottic stenosis is typically due to intubation injury, overzealous surgical manipulation of the posterior commissure, or relating to postinfectious scarring. Diagnosis can be difficult as scarring is not always easily visualized and signs and symptoms can mimic airway obstruction as seen with bilateral vocal fold paralysis. Fixation and ankylosis of the cricoarytenoid joint usually can only be appreciated by direct palpation under general anesthesia. While the typical finding is poor abduction, PGS has also been noted to be associated with poor adduction due to scar, a finding described as posterior glottic diastasis (83,84) (Fig. 62.3).

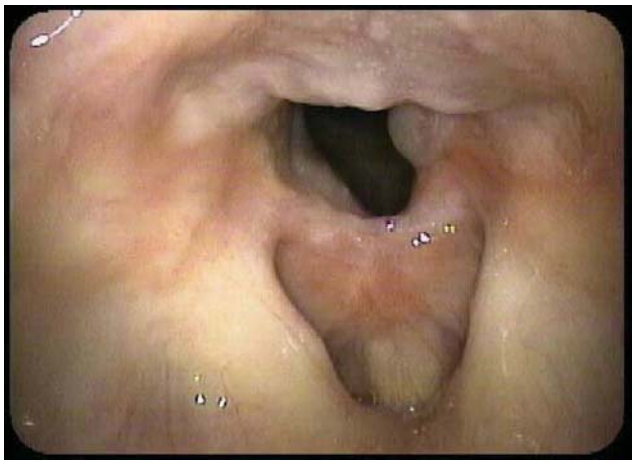

Figure 62.2 Flexible fiberoptic laryngoscopy of anterior glottic stenosis in a patient who previously underwent bilateral vocal fold polypectomy.

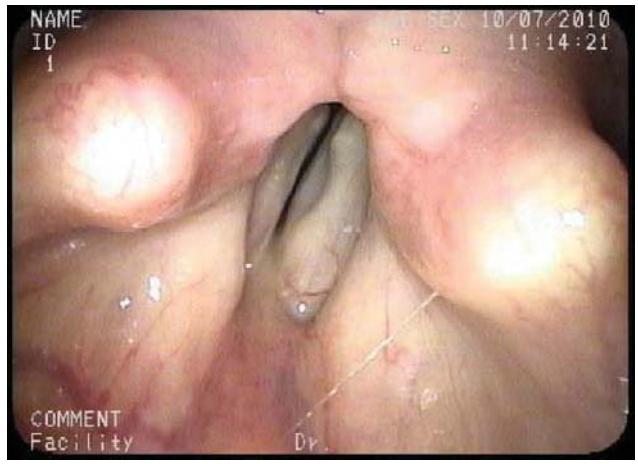

Figure 62.3 Flexible fiberoptic laryngoscopy of PGS. Note the bilateral adducted vocal folds which can be easily confused with bilateral vocal fold paralysis.

TABLE 62.2 BOGDASARIAN AND OLSON STAGING FOR PGS

Stage I	Vocal process adhesion
Stage II	Posterior commissure stenosis with scarring in the interarytenoid plane and internal surface of the posterior cricoid lamina
Stage III	Posterior commissure stenosis with unilateral cricoarytenoid joint ankylosis
Stage IV	Posterior commissure stenosis with bilateral cricoarytenoid joint ankylosis

The classic Bogdasarian and Olson staging of PGS incorporates concepts of stenosis, involvement of one or both sides, and cricoarytenoid joint fixation (Table 62.2). Electromyography can be helpful in differentiating neuromuscular paralysis from posterior glottic scarring and joint ankylosis.

A number of treatment options for PGS are available including local steroid injection, endoscopic techniques, and open techniques. For low-grade stenosis, steroid injection and endoscopic scar lysis is a reasonable first step with either laser or cold instrumentation. If the stenosis recurs, or is more advanced at the time of diagnosis there are a number of alternate endoscopic procedures available. Arytenoidectomy with or without stent placement and cordotomy (Fig. 62.4) are both options but at some expense of voice quality (85). In one of the only comparative studies of medial arytenoidectomy to cordotomy, Bosley et al. (86) reported similar postoperative voice outcomes in PGS patients treated with either technique. These procedures do not necessarily directly treat the stenosis, but rather aim to improve the symptoms of stenosis, that is, airway obstruction. There have also been a number of descriptions of endoscopic advancement flaps, which have been used over the past few decades sporadically with varying success (87,88). Langman et al. (89) describe success with endoscopic placement of a Teflon stent in the posterior glottis with decannulation in 6/9 patients.

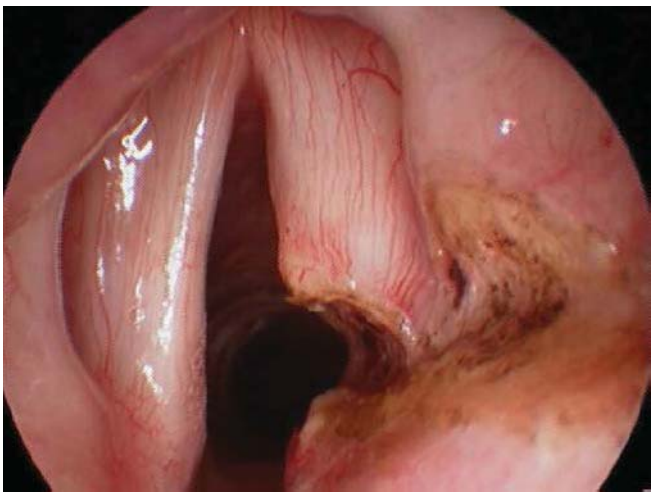

Figure 62.4 Intraoperative rigid 0-degree telescopic image of right cordotomy.

More advanced stage posterior stenosis may require open surgical intervention. In a series of 10 patients with advanced PGS, 9/10 were decannulated after laryngofissure removal of scar and skin grafting over the scar bed (90). Finally, posterior cartilage augmentation is another option for open management of PGS. Described extensively in children, costal cartilage is used to widen the posterior glottis (91). Rutter and Cotton in a series of 29 pediatric patients with isolated posterior stenosis had a 97% decannulation rate. Twelve of twenty-nine patients were treated with a single stage procedure. The 17 remaining patients had a suprastomal stent placed with a second stage required for stent removal (92). This is covered in greater detail in the pediatric airway chapter within this reference.

Complete glottic stenosis is an unusual entity that develops from severe laryngeal trauma or infection. Once the airway is secure, the larynx may be recannulated from a dual approach from both above and below the glottis if possible. Alternatively, a laryngofissure approach can be used and the stenotic region can be grafted with mucosal or skin grafting followed by stent placement (93).

SUBGLOTTIC AND TRACHEAL STENOSIS

The subglottis is found inferior to the vocal folds and includes the cricoid cartilage, a signet ring-shaped cartilaginous structure that is the only complete cartilaginous ring of the airway. In adults, the trachea is an 11 to 14 cm long by 1.6 to 2.4 cm wide tube. When cut in axial sections, it is D-shaped. It is comprised of a series of C-shaped cartilaginous tracheal rings, fibrous tissue, and smooth muscle. Most commonly associated with intubation injury (94), subglottic and tracheal stenosis are also associated with Wegener's, iatrogenic injury in the form of tracheotomy, and idiopathic subglottic stenosis. Symptoms can range from subtle hoarseness to severe dyspnea, in particular on exertion.

The Cotton-Meyer staging system (Table 62.3), while fundamentally meant for the pediatric airway is the most commonly used method of staging in the subglottis but

TABLE 62.3 COTTON-MEYER STAGING OF SUBGLOTTIC STENOSIS

Grade I	Obstruction of 0%–50% of the lumen obstruction
Grade II	Obstruction of 51%–70% of the lumen
Grade III	Obstruction of 71%–99% of the lumen
Grade IV	Obstruction of 100% of the lumen (i.e., no detectable lumen)

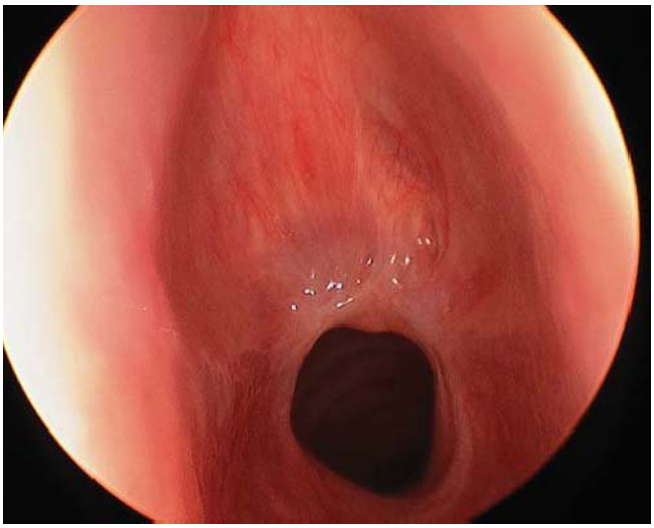

Figure 62.5 Intraoperative rigid endoscopic view of thin segment fibrous subglottic stenosis in a patient with idiopathic subglottic stenosis.

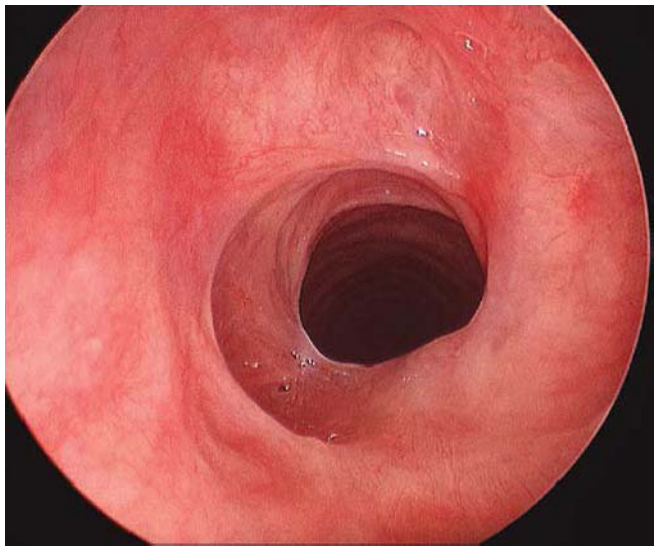

Figure 62.7 Intraoperative rigid endoscopic view of corkscrew subtype tracheal stenosis.

can be used descriptively to stage tracheal obstruction also (95). It was developed to describe subglottic stenosis in children but is easy to remember and a useful tool in characterizing adult subglottic stenosis as well. The utility of the Cotton-Meyer system in prognostication of outcomes in adult airway intervention has not been widely established. McCaffrey (96) proposed a more encompassing airway stenosis classification system that more closely reflects the challenges in treatment.

The appearance of stenosis can vary considerably: it can consist of a simple thin fibrous stenosis (Fig. 62.5), a long thick segment (Fig. 62.6), or have a "corkscrew" appearance (Fig. 62.7). There can be varying degrees of associated inflammatory tissue (Fig. 62.8) and cartilaginous collapse (Fig. 62.9).

For the purposes of this chapter, management of tracheal and subglottic stenosis will be discussed together when appropriate, given that there are many similarities and overlaps in treatment methods.

Endoscopic Management

Endoscopic management is a mainstay of treatment, which includes steroid injections, laser incisions of stenosis, dilation, and application of mitomycin-C. Many surgeons use a combination, if not all of the above procedures in treating airway stenosis patients. Endoscopic management, for most patients should be the initial surgical treatment offered as long as treatment does not further damage previously uninvolved mucosa. For many patients, an

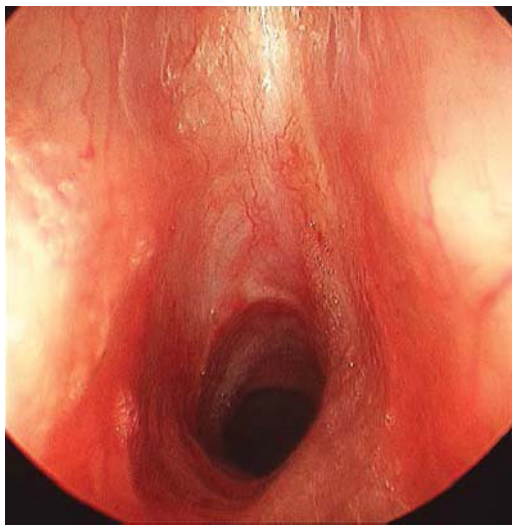

Figure 62.6 Intraoperative rigid endoscopic view of long thick segment subglottic stenosis in a patient with Wegener.

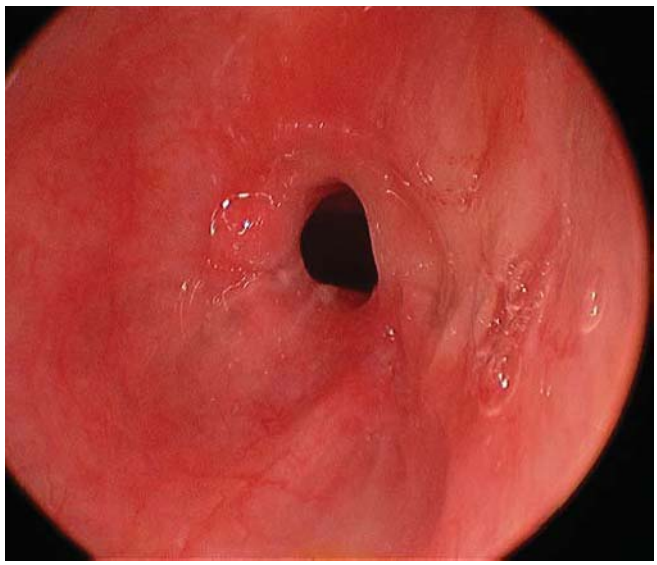

Figure 62.8 Intraoperative rigid endoscopic view of thick subglottic stenosis with associated granulation tissue.

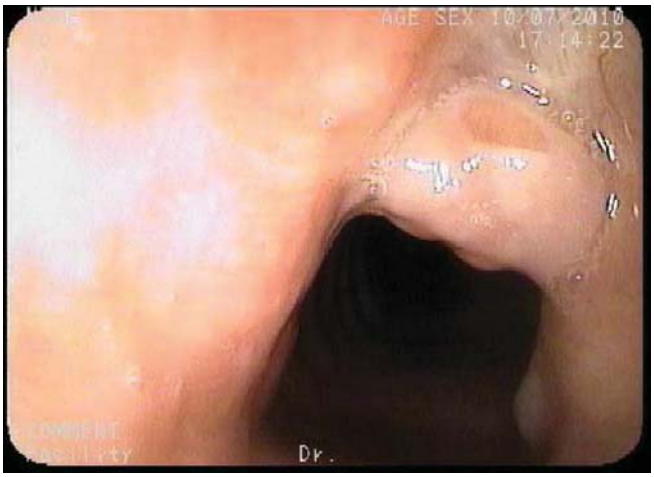

Figure 62.9 Flexible fiberoptic laryngoscopy of tracheal stenosis at a previous tracheotomy site. Note the lateral tracheal wall collapse and granulation tissue anteriorly.

endoscopic approach may be the only treatment necessary. Some may opt for multiple dilations in order to avoid surgical resection. Avoidance of open surgical repair or tracheotomy is attractive given the potential morbidity associated with open surgical complications.

Strong and Jako (97) first performed endoscopic laryngeal laser surgery in the early 1970s. A number of groups subsequently adopted using CO_2 laser to treat airway stenosis by creating radial incisions in stenotic segments with variable success (98,99). Simpson et al. (100), in a series of 60 patients with upper airway stenosis, 49 of whom who had laryngeal stenosis, determined that failure rates of endoscopic management were higher for patients with circumferential stenosis, stenosis greater than 1 cm in the vertical dimension, tracheomalacia or cartilage loss, PGS, and previous history of bacterial infection associated with tracheostomy. Valdez and Shapshay (101) also noted that length of stenosis greater than 1 cm was the most important factor in predicting failure of endoscopic management.

It is unclear how many patients who undergo endoscopic dilation require a second intervention. Recently, Roediger et al. (102), in a relatively small series of 15 patients, showed that tracheotomy can be avoided with the use of endoscopic dilation, CO_2 laser incisions, and mitomycin-C, and that only 60% of patients required repeat dilation at an average of 9 months.

Typically, following incision, kenalog is injected into the stenotic segment and then the region is dilated. There are a number of options for dilation including rigid bronchoscope, Jackson tracheal dilators, and balloon dilators. It remains unclear as to which, if any, type is superior to another in creating long lasting results.

Mitomycin-C

Mitomycin-C is an antiproliferative and antineoplastic agent produced by *Streptomyces caespitosus* that causes DNA cross-linking, suppresses inflammatory response, and prevents scar formation by inhibiting fibroblast proliferation.

Initially used as a topical medication in the eye to prevent postoperative fibrosis in pterygium surgery, it has been used over the past 15 years as an adjunct to reduce rates of restenosis (103–105).

Perepelitsyn and Shapshay in a retrospective cohort study identified 20 patients with idiopathic subglottic stenosis who underwent CO_2 laser incisions with rigid bronchoscopic dilation, laser dilation with steroid injection, or laser dilation with mitomycin-C. A successful procedure was defined as improvement of airway symptoms without recurrence of symptoms or clinical evidence of narrowing requiring intervention. The patient group with mitomycin-C was significantly more successful than the laser dilation group ($P = 0.001$) and the dilation with steroid injection group ($P \sim 0.015$) (106).

Similarly, Simpson and James, in a retrospective review, studied 36 patients with upper airway stenosis who underwent 67 procedures over a 6-year period. Patients underwent laser incision of stenosis with dilation, and a proportion, in addition, underwent topical application of mitomycin-C. Patients were followed at 2- to 4-month intervals and evaluated for dyspnea and stridor. Seven patients who underwent CO_2 laser incision plus dilation alone had a mean of 4.9 symptom-free months as apposed to 35 patients who underwent mitomycin-C application who had 23.2-month symptom-free interval ($P = 1 \times 10^{-11}$). Twenty four of 29 subjects (83%) who had mitomycin-C required only a single dilation procedure with an average of 38-month follow-up. There are a number of limitations of the study including a small sample size and no description of how it was determined which patients would receive mitomycin-C in addition to laser and dilation. Regardless, the evidence here suggests a significant advantage for patients receiving mitomycin-C (107).

In a prospective randomized double-blind placebo-controlled trial, Smith and Elstad enlisted patients with idiopathic subglottic stenosis into a treatment regimen that entailed dilation procedures every 3 months. All patients at the initial procedure underwent dilation and mitomycin-C application. The regimen varied at the second procedure in that one group had a second application of mitomycin after dilation as apposed to saline application. The third procedure was a dilation without any topical application. The recurrence rates were significantly lower at 1 and 3 years for patients who had multiple mitomycin applications, however, at the 5-year interval the benefit of mitomycin was lost suggesting that mitomycin delays but does not prevent restenosis. Ubell et al. (108) have also argued that the use of mitomycin offers a reasonable cost benefit.

Cricotracheal Resection

Most practitioners will pursue endoscopic dilation as an initial intervention for subglottic and tracheal stenosis. In patients who fail endoscopic management, open resection

is indicated for many patients. There are a number of applicable open techniques for management of subglottic stenosis. When considering open surgical resection for subglottic stenosis both *augmentation* of stenotic regions and *resection* of stenosis should be considered.

Cricotracheal resection is indicated when there is a circumferential scar within the subglottis. The entire anterior cricoid, inferior thyroid cartilage, and posterior cricoid inferior to the cricoarytenoid joints can be resected when necessary; in most cases, however, the anterior cricoid is the only part of the laryngeal complex that is removed. Anastomosis of the trachea directly to the inferior thyroid cartilage and posterior cricoid allows for reapproximation of the airway. Sufficient tissue inferior to the glottis must be present to allow for placement of anastomatic sutures.

In high subglottic stenosis, the mucosa overlying the inferior posterior cricoid plate often needs to be resected. In this situation, a sleeve of tissue can be included from the inferior tracheal segment as described by Grillo (109,110) (Fig. 62.10).

Outcomes using this single stage laryngotracheal and reconstruction technique have been impressive with a 90% success rate in regards to airway symptoms with a mean of 8-year follow-up. Despite the improvements in airway symptoms, voice suffers due to the resection of the cricothyroid muscle, which is responsible for lengthening of the vocal folds and pitch elevation. In Grillo et al.'s series of 72 patients, only 26% of patients reported no change in their voice and 64% noted changes in their singing voice and projection (52). Smith et al. measured voice frequency change in a series of 14 patients who underwent cricotracheal resection. In their paper, the mean fundamental frequency for their female patients lowered from 186 to 165 Hz, which is in the male range. Patients must be counseled about this expected change (111).

Alternatively, anterior augmentation of the cricoid cartilage via a laryngocricoid fissure can provide an option to performing an end to end anastomosis, especially in the presence of high subglottic involvement when a high anastomosis would make cricotracheal resection prohibitive.

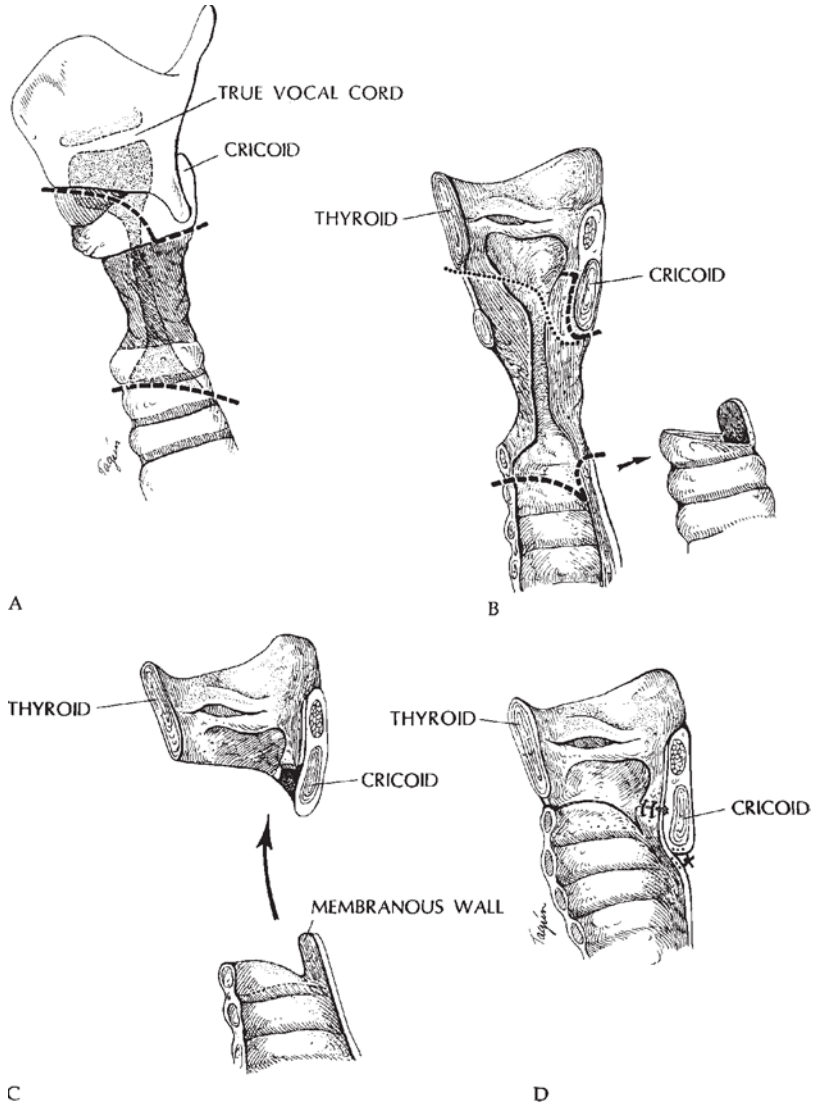

Figure 62.10 Technique of laryngotracheal resection in the presence of circumferential stenosis involving the subglottis. (Used with permission from Grillo H. Primary reconstruction of airway after resection of subglottic laryngeal and upper tracheal stenosis. *Ann Thorac Surg* 1982;33:3–18.)

Augmentation procedures with costal cartilage have been studied extensively in children with noted good success (112). In adults there have been few studies that address the efficacy of this procedure. Terra et al. describe a series of 20 patients who underwent anterior and posterior glottic/subglottic augmentation for highly advanced laryngotracheal stenosis. Fifteen of the patient had grade IV stenosis and six required simultaneous cricotracheal resection in addition to augmentation. All patients temporarily retained a tracheotomy and glottic stent postoperatively which was switched to a T-tube at 6 weeks post op. Ultimately, 80% of patients were decannulated at a mean of 23 months (113).

Cui et al. describes using thyroid cartilage as an alternative to costal cartilage in a series of adult patients. For patients with grade II Cotton-Meyer stenosis, no scar was removed, with grade III, the scar was removed submucosally, and with stage IV the scar was excised. Nine of twelve patients were decannulated after a mean of 12.3 months. Two of the three patients who failed decannulation had previously failed laryngotracheal reconstruction. In this series, most patients had a T-tube placed in order to stent the airway during the healing process (114).

Tracheal Resection

When the neck is extended approximately one-third of the trachea is extrathoracic, making it amenable to surgical resection without a thoracotomy. For mid-tracheal lesions, partial sternotomy can increase exposure to the mid-trachea and improve mobilization, although this is not always necessary. For distal tracheal lesions that approach the carina, sternotomy is essential.

Resection and primary anastomosis of the trachea in adults can include up to 50% of the length of the trachea or 6 cm when releasing procedures are employed. Longer segments should be managed with stents or other reconstructive methods, which will be discussed later. Laccourreye et al. (115) suggested that 3.5 cm represents the safe limit of tracheal resection without releasing maneuvers. Surgical principles for tracheal resection revolve around tension-free closure and minimization of blood supply disruption, which explains the limitations that relate to length of resection and extent of paratracheal dissection.

Most tracheal lesions are amenable to end–end anastomosis. The procedure is performed through a horizontal anterior neck incision. If a tracheotomy is present preoperatively and to be removed, the stoma site should be included in the incision line. The strap muscles are divided in the midline. If present, the thyroid gland is transected in the midline and swept off the anterior trachea. Typically the recurrent laryngeal nerves are not identified; however, the tissue in the tracheoesophageal groove is treated with care, in particular near the insertion point of the recurrent laryngeal nerve at the cricothyroid joint. The area of stenosis is entered anteriorly and only trachea with involved stenosis is removed. The precision of the entry point may be enhanced with endoscopic "marking" as described by Lichtenberger et al. (116). Conservation of healthy uninvolved trachea is of paramount importance. After resection of diseased trachea, anastomosis is performed with either absorbable suture such as Vicryl, or permanent suture such as Prolene. Careful closure of the anastomosis is important to prevent seeding of tracheal secretions into the neck which could cause infection, or air which could lead to subcutaneous emphysema (Fig. 62.11), pneumomediastinum, or pneumothorax. Finally, many surgeons place a stitch from chin to sternum or use a cervical collar to encourage neck flexion and avoid tension on the anastomosis. In the authors' institution, this is referred to as the "Grillo stitch" for the late Hermes Grillo. Other than anastomotic complication and dehiscence, common complications include wound infection, pneumonia, vocal fold paralysis or paresis, tracheomalacia, and hemorrhage (117).

Figure 62.11 Sagittal view x-ray of subcutaneous emphysema following anastomotic leak post cricotracheal resection.

In a large review from Grillo's series at the Massachusetts General Hospital, 901 tracheal resection patients were reviewed, and among those, 589 with postintubation stenosis, 208 with tumor, 83 with idiopathic stenosis, and 21 with tracheoesophageal fistula. They analyzed prognostic factors, which predict anastomotic complications that included granulation requiring debridement, symptomatic stenosis, and separation. Results showed that diabetes (OR = 3.32), long segment resections of greater than 4 cm (OR = 2.01), age less than 17 (OR = 2.26), laryngotracheal resections (OR = 1.8), and the presence of a tracheotomy preoperatively (OR = 1.79) are all important risk factors

for anastomotic failure. Idiopathic stenosis patients had an anastomotic complication rate of 2.4%, an overall complication rate of 6.6%, and a "good" outcome in 98.8% of cases. Complication rates for postintubation-related stenosis were considerably higher with anastomotic complications in 11% and the necessity for postprocedure airway appliance in 4.8% of patients (118). Within the otolaryngology literature, Lano et al. (119) reported on the Vanderbilt open airway surgery experience, also noting the increased failure rate in diabetic patients, acute inflammation, and those with multiple level stenoses (119).

Releasing Procedures

Most tracheal lesions are amenable to primary resection and reanastomosis. Most authors cite that 50% of the adult trachea can be resected and reanastomosed primarily which can be up to 6 cm in some individuals (120). Tension-free closure, as noted above, is important to anastomotic success. In situations where there is undue tension at the anastomotic site, releasing procedures can be used to gain extra length during tracheal mobilization. Resection of greater than 50% of the trachea for extended lesions is challenging. Long segments need to be managed with stent placement; however, advances in bioengineering are bringing tracheal transplantation options ever closer.

Laryngeal releasing procedures are employed for extended resections that involve the proximal trachea, and can allow for closure of defects up to 5+ cm (121). Frequently discussed, they are a rarity for busy stenosis practices and in most cases, good results can be attained without (122). In a series of 521 operations, Grillo et al. (123) only utilized releasing procedures in 6.4% of primary cases and 29% of revision cases. Dedo and Fishman (124) originally described the thyrohyoid, or infrahyoid release, which involves transecting the thyrohyoid muscle and membrane and mobilizing the superior cornu of the thyroid cartilage to allow the larynx to drop inferiorly. This technique has largely fallen out of favor due to significant postoperative swallowing issues.

More commonly used is the suprahyoid technique described by Montgomery (125). In this technique, the muscular attachments on the superior surface of the hyoid are released. The stylohyoid ligament and hyoid cartilage are then divided medial to the digastric tendon attachments separating the body of the cartilage from the greater cornu bilaterally. The suprahyoid musculature is divided between the anterior bellies of the digastric muscles allowing the body of the hyoid, larynx, and proximal tracheal to drop inferiorly. This technique is associated with fewer postoperative swallowing deficiencies because it preserves laryngeal elevation during swallow.

There are a number of intrathoracic releasing techniques that are rarely required by otolaryngologists during the care of proximal or mid-tracheal stenosis. These all require a combined cervical and mediastinal approach and can add significant complexity to the surgical procedure. Grillo describes a cadaveric study of 40 specimens where a number of thoracic releases were performed and their effects measured. By combining mobilization of the right hilum with pulmonary ligament division, dissection of the pulmonary vessels, and division of the intercartilaginous tracheal ligament, defects greater than 6 cm can be primarily anastomosed. Mobilization of the hilum can produce 3.0 cm mobility, division of the left mainstem bronchus can produce 2.7 cm, and freeing the pulmonary artery from the pericardium can produce an average of 0.9 cm in length (126).

TRACHEAL STENTS

Stent placement can be an effective means in select patients to maintain a patent airway in patients with subglottic or tracheal obstruction from malacic segments and extraluminal encroachment. While associated with high rates of complications, stents are particularly useful for palliation in patients with poor long-term prognosis, patients who have failed prior dilations and open surgical repair, those with long segment stenosis, or airways where there is a lack of framework support. They are also highly effective in treating airway narrowing for extraluminal compression from tumors. Stents come in two basic forms: silicone or metal (127). The principal argument against stent use in benign stenoses is the tissue damage incurred in previously noninvolved airway segments.

Metallic stents, while easy to place, become integrated into the tracheal wall and mucosa. This tendency serves as both a benefit and hindrance. Incorporation into the wall prevents migration and mucosalization allows for mucociliary clearance over the stent. Alternatively, metallic stents are notoriously difficult to remove and tend to form granulation tissue (128). They are typically placed via flexible bronchoscopy or under fluoroscopic guidance, easily conform to varying airway dimensions, and have a more favorable internal–external diameter ratio (129). In a review of the literature pertaining to metallic stents which included 497 patients, 34% of patients were noted to have complications (130). The most common complication was granulation formation, which represented 27% of the complications. Other complications included restenosis, migration, stent fracture, erosion, bleeding, infection, and death in 13/497 patients.

Silicone stents have been used effectively for distal tracheal and bronchial airway stenosis as well as refractory high tracheal cases. Silicone is relatively inert, produces minimal granulation tissue, and is capable of providing structure to make it sustain patency in the face of scar or external compression. Silicone stents are easier to place, move, and remove as compared to metal stents, and can be tailored to fit any airway length. Downsides to silicone stenting include the need for general anesthesia for placement and their tendency to migrate (131). To some extent, migration of silastic stents has been reduced by the presence of external studs on the outside of the stent, as in the case of Dumon stents (Bryan Corp, Woburn, MA) (132).

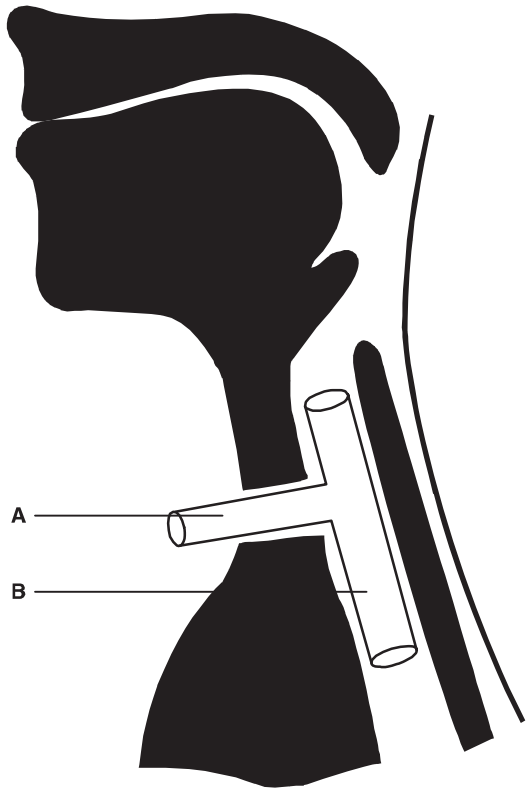

Figure 62.12 Schematic view of T-tube. "*A*" marks the horizontal, and "*B*" the inferior tracheal limb. (Used with permission from the *British Journal of Anaesthesia.* Touma O, Venugopal N, Allen G, et al. Emergency airway management in a patient with a Montgomery t-tube *in situ*. *Br J Anaesth* 2011;107:107–108.)

For tracheal and high subglottic stenosis, particularly in cases with multiple level involvement, silicon T-tubes can provide an additional option. Designed and popularized by Montgomery in the 1960s, T-tubes have a superior and inferior limb, which serve as a tracheal and subglottic stent, as well as horizontal limb that serves as a tracheotomy tube (Fig. 62.12). These can be highly effective for refractory stenosis case, but require meticulous care by the patient to keep them clean and free of crusting. They are subject to obstruction because of the unhumidified air inhaled through the horizontal segment when uncapped and the lack of inner cannula. If a tube becomes obstructed, they are removed emergently by the patient. Also, unlike regular tracheotomy tubes, these require a trip to the operating room with general anesthesia for tube changes.

Autografts

The popularity of the "augmentative" approach to airway surgery is on the decline. There are many inherent advantages, including avoiding lateral dissection which is always necessary in resection cases. Nonetheless, this approach for open stenosis management is still necessary in some cases.

Historically, a number of materials have been used to reconstruct defects of the trachea including allografts, autografts, prosthetic grafts, and now, bioengineered tracheal grafts. In clinical situations where primary anastomosis and releasing procedures are not options, autografting provides a viable alternate option. Autograft options have included fascia lata, tracheal wall, pericardium, periosteum, bony fragments, and auricular cartilage to name a few. For small defects, these can be used as the sole repair. For large defects, the materials can be used in conjunction with an additional material for support such as wire or Marlex mesh, or silicone or polyethylene stents, all of which can prevent airway collapse (133). Each autogenous technique conceptually holds promise but most have relatively high failure rates due to poor graft take and restenosis or narrowing due to scar or granulation tissue formation, in addition to various other donor site morbidities. Alternate autogenous graft options include local, regional, and free flaps. Radial forearm free flap reconstruction has been used with moderate success by a number of authors (134,135).

TRACHEAL TRANSPLANTATION/TISSUE ENGINEERING

Considerable work is currently being conducted to identify techniques for tracheal transplantation or replacement. As mentioned previously, there are limitations to the amount of trachea that can be resected and reanastomosed. While tracheal stenting is a valuable contribution to dealing with long segment stenosis, use is fraught with complication. It is for this reason, considerable effort is currently being put into identifying means of long segment tracheal reconstruction with allografting, and more recently bioengineered tissues. A transplantable or reconstructive prosthesis should be easily accepted by the host with minimal inflammatory reaction, provide airtight anastomosis and adequate rigidity to maintain the shape of the three-dimensional construct of the airway, and ideally permit ingrowth of the respiratory epithelium in the endoluminal lining (136).

Allograft

Allograft tracheal transplantations have been in large part relatively unsuccessful. Early transplantation mainly failed due to donor tissue rejection (137,138). Even with immunosuppression, nonvascularized allograft transplantation continued to fail due to poor vascular supply leading to extensive fibrosis of transplanted trachea (139).

Direct tracheal vascular anastomosis is not possible due to the nature of the network of small vessels that supply the trachea. In canine models, donor trachea has been vascularized by wrapping the donor tissue in omentum. Cyclophosphamide has been shown to adequately suppress tissue rejection (140). Interestingly, cryopreservation, storage of donor tissue at −196°C for 1 to 6 months, has been suggested in animal models to reduce acute tissue rejection as compared to naïve trachea (141,142).

Allograft transplantation in human subjects has been limited. A few scattered cases and techniques have been described. In 1979, Rose et al. (143) transplanted trachea that had been revascularized in sternocleidomastoid

muscle. Surgery was successful but no long-term follow-up was provided. Levashov et al. (144), in 1993, attempted a single staged allograft transplant wrapped in omentum. This failed at 4 months. Klepetko et al. suggest a staged procedure for omental free tissue transfer. In the first stage, the allograft is implanted into the abdominal cavity and wrapped in omentum. The second stage entails microvascular transfer into the neck with tracheal and microvascular anastomosis. In one patient, they performed the first stage successfully but ultimately did not need the allograft due to success of primary anastomosis (145).

Bioengineered Tissue

Bioengineered tissue is rapidly becoming a reality in tracheal transplantation. Ideal candidate tissue should be functional in that it can clear mucosal secretions, semi-rigid so that it can maintain the three-dimensional structure of the airway yet remain compliant during breathing, not require immunosuppression, and allow for angiogenesis to improve tissue survival (146). Current models of bioengineered tissue rely upon a scaffolding that becomes populated by the patient's own cells. Many suitable products have been tested for use. Experimental scaffolds have included synthetic material and decellularized natural matrices that support the growth of cellular material derived from recipient chondrocytes and epithelial cells (147).

Omori et al. have used a Marlex scaffold and polypropylene spiral that is encompassed by a collagen sponge scaffold derived from porcine dermal type 1 and 3 collagen. This has been well tolerated in a canine model (148) and in 2002 was used for the first time in a human subject with invasive thyroid carcinoma. At 2-year follow-up, the implant was well mucosalized and the patient experienced no complications (149).

Recent work has shown that use of the detergent enzymatic method (DEM) (150) allows for human trachea to become nearly completely acellular. By applying 25 DEM cycles, Baiguera et al. (151) generated a human acellular scaffolding that is completely devoid of cellular elements save for a few chondrocytes, while preserving the angiogenic factor basic fibroblast growth factor without destroying the histoarchitecture of the extracellular matrix or compromising the basement membrane. In 2004, using the above concept, a 30-year-old female with post-TB tracheal and bronchial stenosis, who had failed prior open subglottic stenosis and bronchial stenting, underwent a left main bronchus resection, which was replaced with bioengineered human trachea (152). The trachea was removed from a donor and underwent processing with the decellularization process described above. Using autologous bone marrow and bronchial mucosa, the acellular tissue scaffolding was populated with the patient's own cells using a complex bioreactor and finally implanted. The limitation of this procedure was the long technical processing required to construct the prosthesis.

In 2010, the same group performed a similar procedure in a 12-year-old boy (153). A 7 cm segment was transplanted, the longest section ever transplanted. Instead of a long prosthesis incubation period, this case used a decellularized trachea which *in vitro* was seeded with stem cells from bone marrow and respiratory cells. The group utilized a number of factors including erythropoietin, granulocyte-stimulating factor, and beta-transforming growth factor to encourage stem cell growth and differentiation. A temporary absorbable stent was used to provide additional airway support during the first 2 months.

An alternate method was described by Delaere et al. (154). Tracheal allograft was buried under the forearm for the revascularization of the donor tissue. The membranous tracheal wall mucosal lining of the donor trachea was removed and replaced with a buccal mucosal graft from the recipient. The graft was transferred to the trachea with its neo blood supply, the radial artery. Endoluminal graft biopsy revealed donor respiratory mucosa as well as recipient buccal squamous mucosa, and viable chondrocytes. Immunosuppression was discontinued after the confirmation of recipient cells within the airway and shortly thereafter, there were no additional donor cells noted on subsequent biopsy.

The field of regenerative medicine holds exciting promise for tracheal and subglottic reconstruction. For patients with long segment stenosis, these techniques will be life altering as they become more readily available.

HIGHLIGHTS

- Postintubation injury is the most common cause of airway stenosis.
- For many patients, endoscopic management is the only treatment necessary. This may include dilation, laser incision of stenosis, injection of steroid, and application of mitomycin-C.
- For open tracheal resection, diabetes, stenotic segments of greater than 4 cm in length, age less than 17, laryngotracheal resections, and the presence of a tracheotomy preoperatively all increase the rates of anastomotic failure.
- For tracheal resection segments longer than 5 cm, stents, flaps, and bioengineered tissue are all management options.
- The lack of dynamic motion of the scarred or damaged larynx makes many endoscopic airway surgery decisions almost arithmetical; increasing airway leads to loss of vocal and/or swallowing function, for example.

63 Complex Upper Airway Problems

Jay B. Tuchman *Deepak K. Mehta*

The proper approach to any problem involves a well-constructed systematic plan, combined with diligent preparation and careful attention to detail, to successfully achieve the desired outcome. The principles of this methodology should certainly be adhered to when confronted with the complexities of airway management, and particularly when presented with the scenario of the difficult airway. The practitioner's margin of error dwindles in patients with deteriorating clinical status and those at extremes of age or with a predisposition toward oxygen desaturation. An organized and focused preoperative airway evaluation, resulting in the advanced recognition of an impending difficult airway, can help avoid a catastrophic situation. Assessment should include a determination regarding possible difficulties with ventilation, intubation, patient cooperation, and/or tracheostomy (1). Failure to intubate a trachea will not result in a patient's death, but inadequate preparation, allowing the consequences of "can't intubate" to proceed along the slippery slope toward "can't ventilate" may very well do so. Routine preparation and planning includes the availability of multiple sizes of basic equipment, optimal positioning for successful ventilation and intubation, and supplemental oxygenation (especially prior preoxygenation) throughout the airway management. The benefits of the proliferation of airway devices over the past few years should surely not be underestimated, but it is critical to realize that the choice of a particular advanced airway device does not constitute an adequate plan, and is undoubtedly not a panacea for avoiding the frightening "can't intubate, can't ventilate" clinical scenario. The development of the difficult airway algorithm of the American Society of Anesthesiology (ASA) is an embodiment of this multidimensional approach to management of the difficult airway (2). Basic management decisions include (a) awake intubation versus attempts after induction of general anesthesia, (b) noninvasive versus invasive initial approaches to intubation, and (c) preservation or ablation of spontaneous ventilation (1).

The algorithm includes a section for the awake approach to intubation, as well as an approach to situations involving failed intubation attempts after the induction of general anesthesia (Fig. 63.1). At all times, communication between services, involving a discussion of the multifaceted nature of the plan, as well as highlighting the particular involvement of each member of the operating room staff is of paramount importance in thwarting the development of this precarious scenario.

There are a multitude of pathologic characteristics associated with difficult airway management, including congenital features such as micrognathia, mandibular hypoplasia, macroglossia, cervical instability, limited mouth opening, midface hypoplasia, and facial distortion, as well as acquired conditions associated with infection, obesity, tumors, trauma, burns, and arthritis (3). The technique chosen must be tailored to the distinct disease presentation associated with the difficult airway. However, even within each situation, there may be multiple reasonable approaches, and it behooves the practitioner to be flexible and capable of changing course with alacrity, should the primary attempts prove unsuccessful. Utilizing the ASA difficult airway algorithm as a guide, we attempt to elucidate in this chapter the benefits of specific approaches, techniques and devices for particular airway scenarios, while simultaneously emphasizing the importance of a comprehensive plan for the management of each patient.

A decision to follow the pathway of awake airway management prior to anesthetic induction includes both the possibility of securing the airway via surgical access, or via noninvasive approaches such as flexible fiberoptic intubation, utilizing sedation, and topicalization of the airway (4).

In a patient with upper airway obstruction and acute respiratory distress, an urgent tracheostomy utilizing minimal sedation and maintaining spontaneous ventilation, with

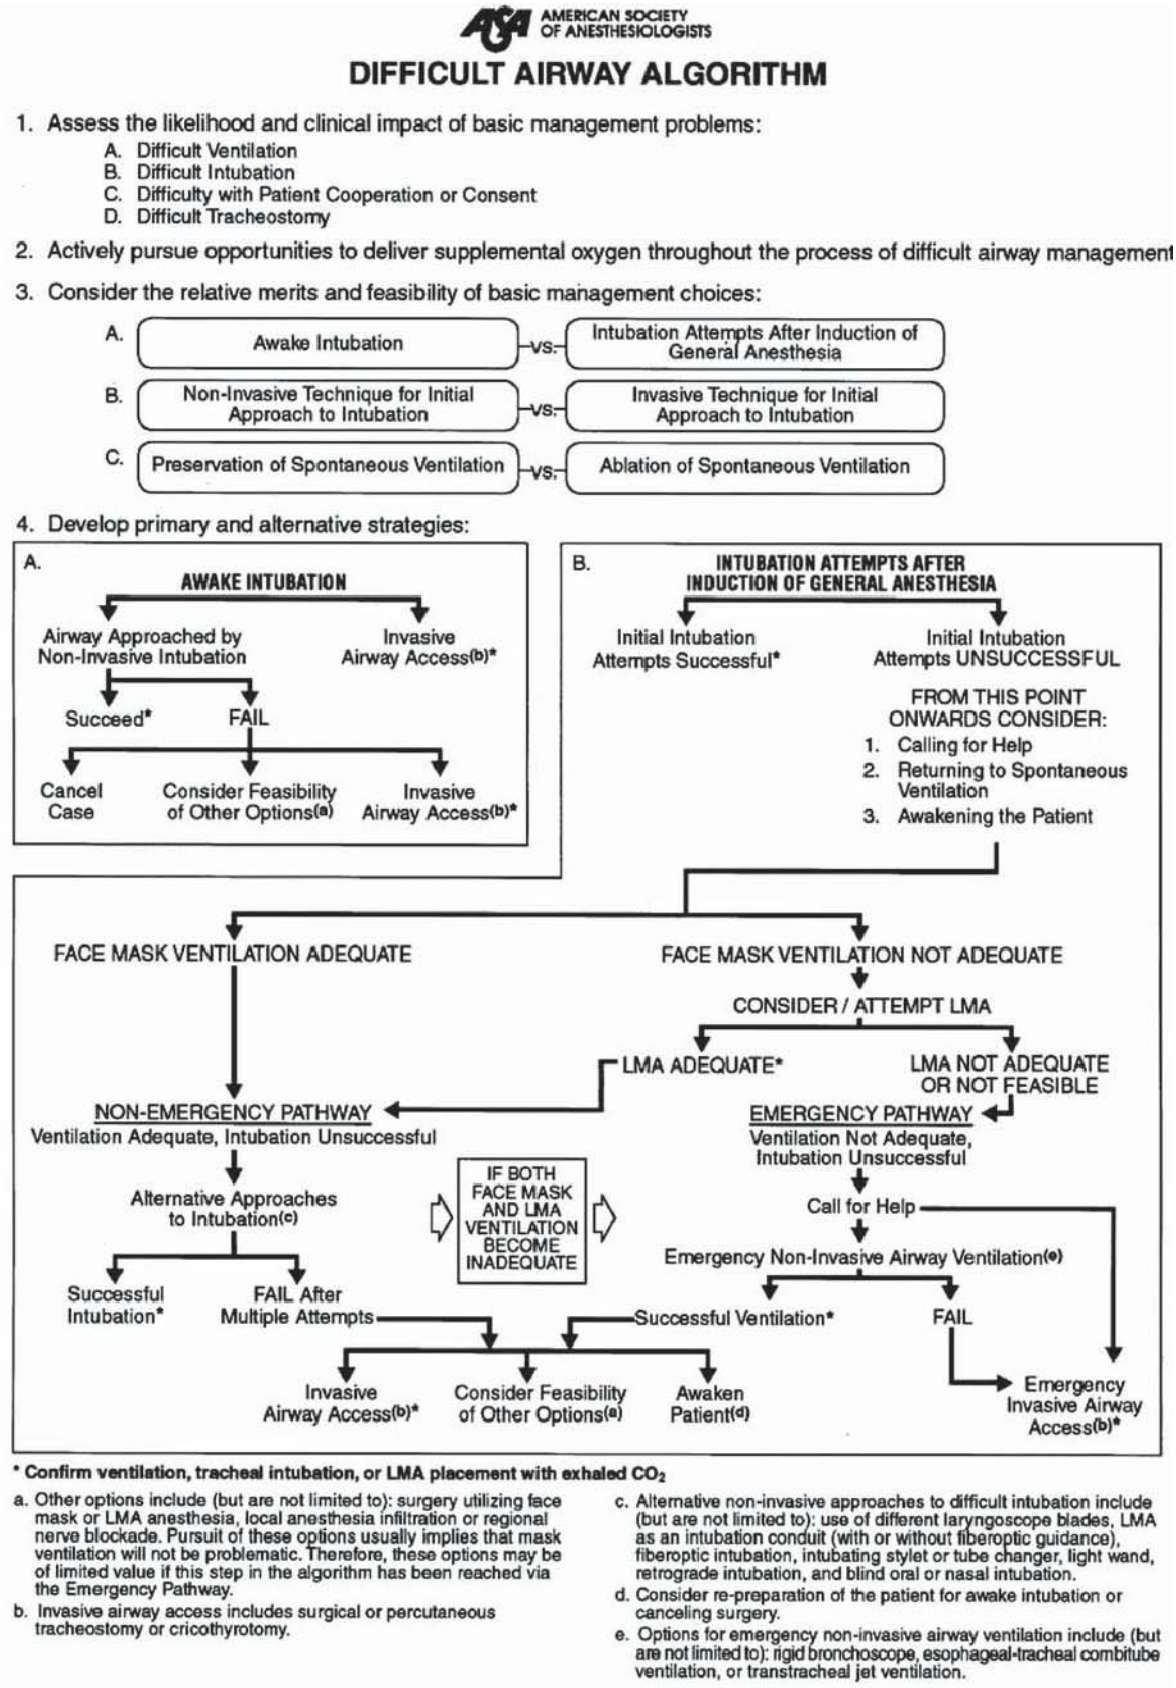

Figure 63.1 ASA difficult airway algorithm. Reproduced from American Society of Anesthesiologists Task Force on Management of the Difficult Airway. Practice guidelines for management of the difficult airway: an updated report by the American Society of Anesthesiologists Task Force on Management of the Difficult Airway. *Anesthesiology* 2003;98(5):1269–1277, with permission.

infiltration of local anesthetic, might be appropriate. Other situations mandating an awake tracheostomy include patients unable to tolerate general anesthesia, or patients with supraglottic abscesses or masses, which may lead to aspiration of purulent material or airway distortion complicating endotracheal intubation. There are scenarios, however, where surgical access via tracheostomy may not be feasible, such as patients undergoing neck *s*urgery, those with *h*ematomas or abscesses of the neck, *o*bese patients, and those with prior *r*adiation or *t*umors (mnemonic SHORT) (5). It is always instructive to recognize that in the rare situation where airway manipulation may be so disastrous and lead to complete decompensation, the option of femoral–femoral cannulation under local anesthesia as preparation for possible cardiopulmonary bypass should be considered (6).

The noninvasive approach of awake or sedated flexible fiberoptic intubation may be facilitated by the administration of small titrated doses of benzodiazepines, narcotics, ketamine, an antisialogogue such as glycopyrrolate, and a new agent, dexmedetomidine, resulting in a patient with reduced anxiety, decreased secretions, yet without respiratory depression. The antisialogogue also improves the effectiveness of topical anesthetics, by removing the barriers to mucosal contact. When combined with local anesthetic administered via injected nerve block techniques such as the Glossopharyngeal Nerve (GPN), Superior Laryngeal Nerve (SLN), and Recurrent Laryngeal Nerve (RLN) blocks, this may help achieve anesthesia of the nasopharynx, oropharynx, and hypopharynx in an awake, sedated patient. This allows for uncompromised airway exchange and oxygenation via spontaneous ventilation, maintenance of normal muscle tone with increased size and patency of the oropharynx, and improved upper and lower esophageal sphincter tone with intact protective airway reflexes, reducing the risk of severe gastroesophageal reflux and aspiration (3). The concern for pulmonary aspiration is a strong argument for the awake approach to intubation in patients with a difficult airway and full stomach, or those with obesity (7). However, limitations to the awake approach to intubation include young children, those with an allergy to local anesthetics, or others with an inability to cooperate due to mental retardation or dementia. Caution must also be exercised in situations where the possible negative consequences of awake attempts may be manifest, such as cardiac ischemia, increased intracranial or intraocular pressure, or neurologic damage from cervical spine instability (3).

A specific scenario of preemptive airway control unique to the fetal/neonatal population is the *Ex Utero* Intrapartum Treatment (EXIT) procedure (Fig. 63.2). Infants with a very low probability of survival, as suggested by prenatal ultrasound, due to tracheal obstruction or other airway abnormalities such as cystic hygroma, cervical teratoma, congenital goiter, or congenital high airway obstruction syndrome, are managed by maintaining uteroplacental circulation with only partial delivery. This allows time, prior to clamping of the umbilical cord, for procedures such as

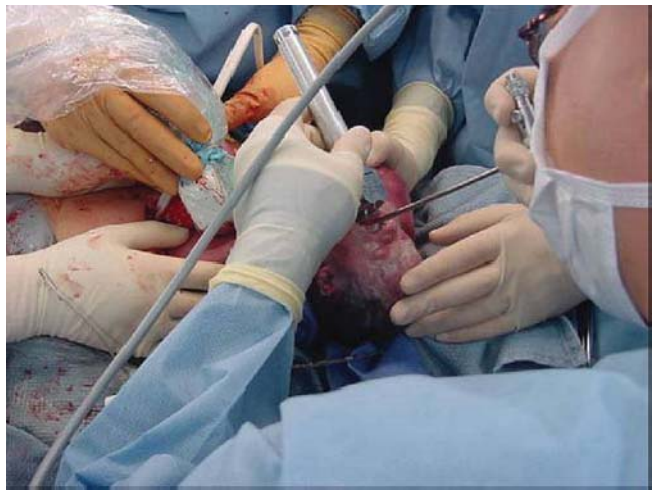

Figure 63.2 Bronchoscopy performed during EXIT procedure to secure fetal airway prior to delivery.

direct laryngoscopy, bronchoscopy, intubation, and tracheostomy to secure the airway and maintain continuous oxygenation, improving the chances of neonatal survival (8).

When the decision has been made to attempt intubation after the induction of general anesthesia, and despite an appropriate plan, the initial approach has been unsuccessful, it is prudent to repeatedly consider calling for help, returning to spontaneous ventilation if not present, and possibly even awakening the patient. The advantages of assisted spontaneous ventilation include the maintenance of oropharyngeal muscle tone, avoiding total airway obstruction, and serving as a guide to locate the glottis. If face mask ventilation is still adequate despite unsuccessful intubation, alternative approaches to intubation should be considered (1).

If further attempts are made with a standard laryngoscope, *o*ptimum *e*xternal *l*aryngeal *m*anipulation or *b*ackward, *u*pward, *r*ightward *p*ressure on the thyroid cartilage may improve the grade of laryngoscopic view. Placing a flexible stylet inside the endotracheal tube (ETT) in a hockey-stick shape may facilitate ETT placement, even when only the epiglottis or arytenoid cartilages are seen. Particularly in children with micrognathia or macroglossia, where routine rigid laryngoscopy has been previously unsuccessful, the retromolar approach to direct laryngoscopy may be useful. The head is turned slightly to the left, and a straight Miller 1 blade (even in older children) is introduced while the right corner of the mouth is retracted (Fig. 63.3). Sweeping the tongue to the left, the laryngoscope is advanced between the tongue and lateral pharyngeal wall, overlying the molars, until the epiglottis is visualized (Fig. 63.4). The movement of the head and lateral placement of the blade allows for bypassing the tongue, a reduced need for soft tissue displacement, and improved line of site visualization (9).

Flexible fiberoptic bronchoscopy remains the gold standard for management of the difficult airway. Advantages of flexible fiberoptic bronchoscopy include those related to the

Figure 63.3 Placement of laryngoscope blade for retromolar technique. Courtesy of Larry Borland, MD.

device and to the technique itself. The flexible bronchoscope allows flexibility and adaptability to varying airway anatomy with minimal manipulation, is applicable to both oral and nasal approaches in all age groups, and gives the practitioner the ability to provide both oxygen and topical anesthesia during intubation (10). The specific technique as described below decreases the trauma and cardiovascular response to airway instrumentation, has a consistently high success rate, and allows for confirmation of position. Improved digital technology obtains clearer images, even in the neonatal population, with the smallest scope sized 2.2 mm, and able to fit through a 2.5 ETT (9). Light sources and video systems have been incorporated into the newer bronchoscopes, allowing for increased portability, as well as the ability to display a larger image of the airway. The improved technology still comes at a high cost, with frequent maintenance necessary due to the fragility of the flexible scopes. There is a significant learning curve with the fiberoptic scope and maintenance of one's skills requires continuous utilization (11).

Optimal positioning for fiberoptic bronchoscopy requires the patient's head to be slightly extended at the atlanto-occipital joint, while a jaw thrust, and at times tongue traction, is performed by an assistant, opening the posterior pharynx for an ideal view of the laryngeal opening. The flexible bronchoscope must be kept rigid, placing the tip of the scope in the midline. Specially designed oral airways may help facilitate midline placement during oral fiberoptic intubation, whereas nasal fiberoptic bronchoscopy will intrinsically allow for easier midline placement (10). The approach of choice for the pediatric patient is generally the nasal fiberoptic; however, due to the distinct possibility of adenoid shearing or epistaxis, premedication with topical vasoconstrictors is ordinarily undertaken. Nasal fiberoptic intubation can be greatly assisted by the modified nasal trumpet (Fig. 63.5), allowing spontaneous ventilation and the administration of volatile anesthetic, while fiberoptic intubation ensues via the other nares (Fig. 63.6). The modified nasal trumpet technique has

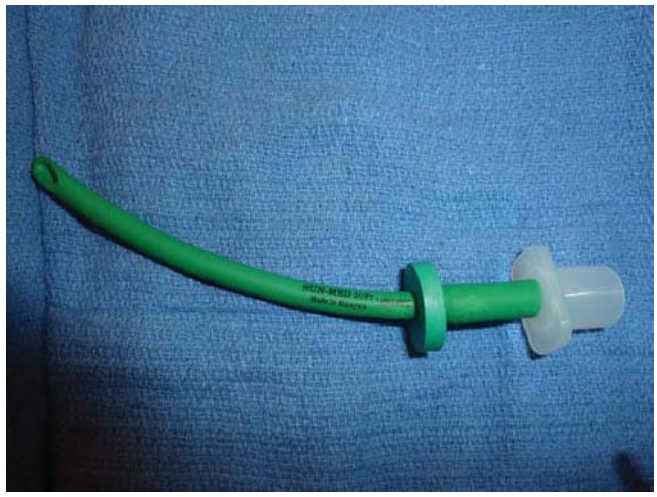

Figure 63.5 Modified nasal trumpet to help facilitate spontaneous ventilation while maintaining anesthetic depth for flexible fiberoptic laryngoscopy.

Figure 63.6 Flexible fiberoptic laryngoscopy facilitated by modified nasal trumpet.

great utility in the pediatric population, or those with an inability to cooperate and tolerate an awake approach to intubation (9). Despite successful placement of the fiberoptic scope into the trachea, the practitioner may experience resistance to the ETT upon attempted advancement into the trachea. A helpful hint to avoid catching the ETT on the arytenoid cartilages is to place the ETT bevel *d*own on the fiberoptic scope for *o*ral intubations and bevel *u*p for *n*asal intubations *(mnemonic UNDO)* (12). The major drawback of the fiberoptic scope is that excessive secretions or bleeding may render the scope completely unusable, particularly with the neonatal scope, which lacks a channel for suctioning or administering local anesthetic (10). This weakness argues strongly in favor of mandating the clinician to master a number of other techniques, as part of the comprehensive approach to airway management we have described above.

Aside from the standards of direct laryngoscopy and flexible fiberoptic laryngoscopy, this chapter focuses on six other main categories of devices that may be utilized, avoiding the need to resort to a surgical airway such as a cricothyroidotomy or tracheostomy. These include indirect laryngoscopes, rigid fiberoptic stylets, intubating or lighted stylets, video laryngoscopy, laryngeal mask airway (LMA)–guided intubation, and rigid fiberoptic bronchoscopy.

The first indirect rigid fiberoptic-enhanced laryngoscope (Fig. 63.7), the Bullard (Gyrus ACMI, Norwalk, OH), was originally designed for use in the difficult pediatric airway and is available in both adult and pediatric sizes. Although still quite expensive, this instrument, as well as other similar models such as the WuScope (Pentax, Orangeburg, NY) and Upsherscope (Mercury Medical, Clearwater, FL) cost less than the flexible scope, and are less prone to damage (13). The Bullard is the most versatile of these devices, and may be utilized for both oral and nasal intubations in syndromic patients with mandibular hypoplasia, as well as those with limited neck extension, prominent upper incisors, or mouth opening as little as 6 mm. The utility of these devices, however, may be limited in patients with absent midline structures, due to their dependence on normal supraglottic anatomy and lack of panoramic view. Oxygen insufflation, instillation of local anesthetics, and improved suctioning of secretions versus the flexible scope may be achieved through the working channel, but suctioning through the suction channels in these devices still remains suboptimal. The device should be placed in the mouth at the midline, and then positioned like a laryngoscope blade to pick up the epiglottis (Fig. 63.8). The fiberoptic bundle located on the posterior aspect of the blade provides a 55-degree field of view at the level of the larynx, improving visualization around the base of the tongue, without the need for physical alignment of the oral, pharyngeal, and laryngeal axes. The ETT is loaded on the rigid stylet positioned to the right of the viewing lens and specifically designed to match the indirect laryngoscope, advancing the ETT into the trachea from right to left under direct visualization. Loading the ETT backwards on the original wire stylet with the bevel directed right, or aiming the stylet at the middle-third of the left vocal fold may help avoid the right arytenoid when attempting to pass the ETT off the stylet. Practice remains very important, as the method of visualization is vastly different than standard laryngoscopy, with a significant learning curve necessary to achieve consistent success (13).

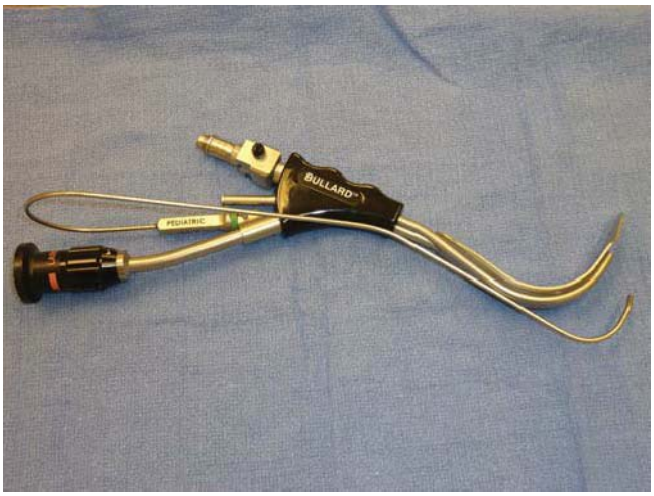

Figure 63.7 Bullard laryngoscope.

Figure 63.8 Intubation performed by anesthesiologist with the Bullard laryngoscope.

Figure 63.9 Airtraq optical laryngoscope.

The Airtraq (Prodol Meditec, Vizcaya, Spain) is a newer disposable rigid optical laryngoscope that may also be utilized without aligning oral, pharyngeal, and laryngeal axis, with a guide channel included to enable direction of the ETT toward the vocal cords. The image is transmitted to a proximal viewfinder through a combination of lenses and a prism, rather than fiber optics (Fig. 63.9). The device includes a built-in heater, which prevents fogging of the distal lens, and a low-temperature LED light source which may last up to 90 minutes, but both require at least 30 seconds of preparation. The Airtraq may be beneficial in patients with cervical spine disease, but requires a larger mouth opening of up to 16 mm and may be difficult to insert in patients with a short jaw or large chest (14,15).

The Shikani optical stylet (SOS; Clarus medical, Minneapolis, MN) (Fig. 63.10) was initially designed by an ENT surgeon, and is a rigid, yet malleable metal stylet with a fiberoptic light source, which delivers an image to an eyepiece or video camera. This device has a preformed hockey-stick shape and may be used in both adult and pediatric patients for oral intubation, with or without direct laryngoscopy. Neck extension is not required for this technique and offers the advantage of displacing soft tissue and enabling oxygen delivery during intubation attempts (Fig. 63.11). One must exercise caution, however, when utilizing this oxygen-delivery system in infants and neonates, due to concerns of pneumothorax (16,17). Unlike the Shikani stylet which utilizes a midline approach, the Bonfils Intubation Fiberscope (Storz, Tuttlingen, Germany) is an optical stylet without a malleable stylet, utilizing a retromolar approach, as the fixed 40-degree curvature is inadequate when utilizing a midline approach (18). As with other fiberoptic techniques, these devices require a significant learning curve, may be quite fragile, and attempts to secure the airway may be complicated by fogging, bleeding, and secretions. A benefit of the optical stylet over flexible fiberoptic laryngoscopy is the ability to visualize the tip of the ETT passed into the trachea and improved maneuverability of the stylet's tip (17).

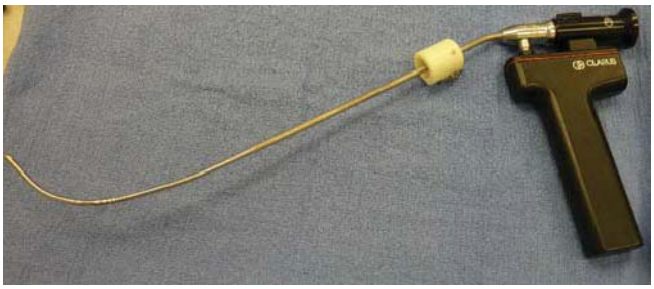

Figure 63.10 Shikani optical stylet.

Figure 63.11 Intubation performed by anesthesiologist with the Shikani optical stylet.

An alternative approach under general anesthesia involves an intubating stylet used as an introducer or guide for placing the endotracheal tube. The Eschmann Tracheal Tube Introducer (Portex Limited, Hythe, UK) or "gum elastic bougie" is a 60 cm long 15 Fr catheter with a "j" tip at the distal end and was originally described by MacIntosh in 1949. Generally, when standard direct laryngoscopy has only achieved visualization of the epiglottis, the bougie is hooked under the epiglottis and advanced into the trachea until a clicking sensation is felt over the tracheal rings. If the bougie is placed correctly, it will lodge in a distal airway at the 30 to 35 cm mark. The ETT is then slid over the

bougie into the trachea, and may sometimes be facilitated by a jaw thrust or by rotating the bevel of the endotracheal tube posteriorly to avoid catching structures of the laryngeal aperture. If the bougie has been incorrectly placed in the esophagus, the entire bougie will advance without any resistance. Confirmation of correct placement is confirmed by routine methods of capnography and auscultation of breath sounds. A similar device, the Cook Airway Exchange Catheter (Fig. 63.12) (Cook Inc., Bloomington, IN), was originally designed as a tube exchanger for use in the difficult airway, but may have the additional advantage of ventilation in an emergency situation, due to its hollow lumen and proximal port adapter (19).

A lighted stylet (light wand), equipped with a high-intensity light at the tip, may also be utilized to secure the difficult airway using the principle of transillumination (Fig. 63.13). Due to the technique's ability to achieve

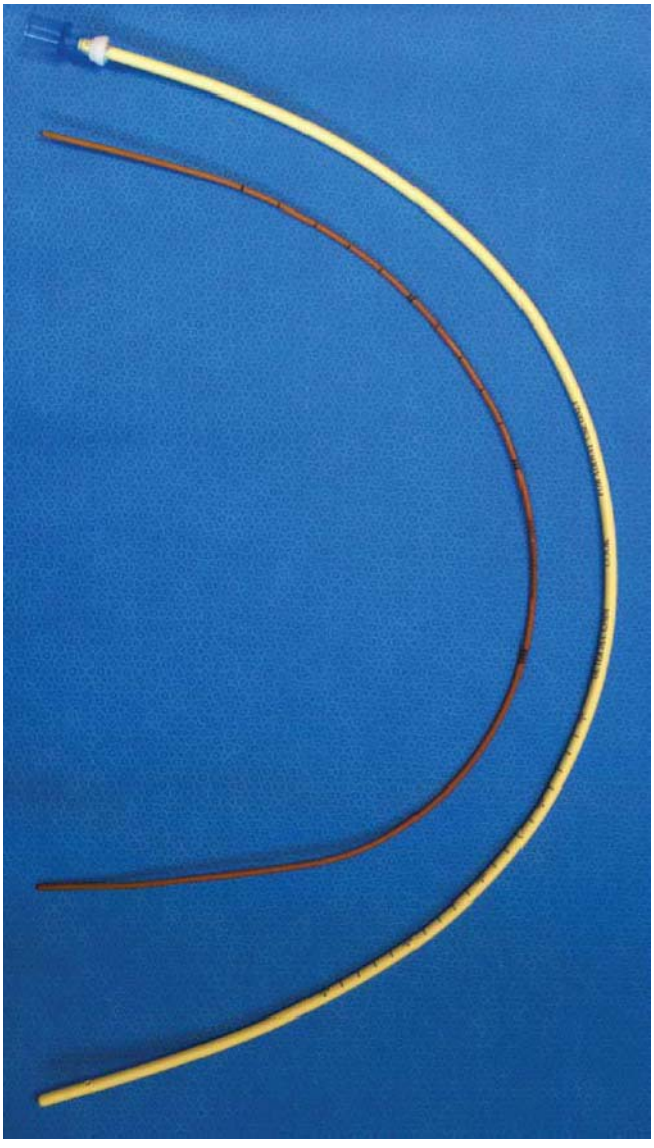

Figure 63.12 Intubating stylets: Gum Elastic Bougie and Cook Airway Exchange Catheter.

Figure 63.13 Light wand.

intubation without neck movement, the light wand may be particularly helpful in patients with cervical spine fractures. Similarly, the device may be utilized in patients without intrinsic laryngeal or oropharyngeal pathology, where there may still be difficulty obtaining a laryngoscopic view, such as micrognathia or temporomandibular joint (TMJ) abnormalities. Successful placement may be achieved by dimming the lights and curving a well lubricated lighted stylet 45 to 90 degrees, while carefully maintaining the tip of the stylet within the tip of the ETT to avoid airway trauma. The stylet is passed along the curvature of the tongue until the middle of the neck is transilluminated by a clearly circumscribed circular light, signifying appropriate positioning for gently sliding the ETT off the stylet into the trachea. If the ETT is caught on the epiglottis, the stylet may be withdrawn and placed more posteriorly, allowing placement of the ETT underneath the epiglottis, or the bevel of the ETT may be rotated. Drawbacks to this technique include the blindness of the approach and its consequent risk of bleeding, as well as the large diameter of the stylet, restricting the approach to larger children and larger ETTs. The light wand may also be less successful in obese patients and should not be utilized to secure the airway in the presence of airway tumors, laryngeal injuries, or retropharyngeal abscesses (19).

Video-assisted laryngoscopy is a versatile new technology, with earlier designs incorporating an ultrathin fiberoptic bundle into an angulated blade (AVIL) or coupling a light source, video processor and monitor with a MacIntosh laryngoscope (Storz DCI) (13). More recently, the Glidescope (GVL, Verathon, Bothell, Washington), with a miniature video chip embedded into a modified MacIntosh laryngoscope and a blade angled 60 degrees upward, has been extensively studied. The extraordinary ability to achieve improved laryngeal exposure with less force upon laryngoscopy and minimal cervical manipulation (Fig. 63.14), while simultaneously placing these images in real-time on display monitors, greatly increases the success of intubation even in the difficult airway, while facilitating both teaching and learning (20,21) (Fig. 63.15). At times, an awake Glidescope laryngoscopy after topicalization with nebulized 4% lidocaine may avoid the need for an awake intubation (22). The advantages of a similar skill set to routine direct laryngoscopy, reduced fragility of the fiberoptic element, no need for an external light source have made the Glidescope a ubiquitous presence in both the perioperative and prehospital settings (13). The most notable drawback to the Glidescope is that despite the improved laryngoscopic view, significant difficulty may still be encountered in placing the ETT through the vocal cords. All of these devices require at least some mouth opening to pass the device, and may be complicated by fogging, bleeding, and secretions. Midline placement of the blade and utilization of a preshaped ETT conforming to the convex curvature of the blade or the rigid stylet which accompanies the device will improve the rate of converting

Figure 63.14 Improved laryngoscopic view obtained utilizing Glidescope.

a good laryngoscopic view into a routine intubation using the technology of video laryngoscopy (23,24). At times, it is necessary to retract the stylet or manipulate the ETT 180 degrees to avoid the anterior tracheal wall (25). It is important to watch both insertion of the blade and later the ETT into the mouth, to avoid injury to the oropharyngeal

Figure 63.15 Intubation performed by anesthesiologist utilizing Glidescope.

structures, thereby guarding against the tendency to focus too extensively on the monitor (26). The Glidescope may also be utilized for scenarios where continuous glottic viewing may be beneficial such as confirmation of ETT exchange or visualization of laryngeal function, as well as for viewing passage of nasogastric tubes, transesophageal echocardiography probes, or upper gastrointestinal equipment (13).

For the pediatric population, a multitude of new video laryngoscopes that do not require neck extension have been designed, including those with camera integration into the laryngoscope blade, such as the Glidescope Cobalt (Verathon, Bothell, Washington) and Storz video laryngoscope (Karl Storz, Tuttlingen, Germany), as well as those utilizing prisms and mirrors, such as the Airtraq optical laryngoscope described above (Prodol Meditec, Vizcaya, Spain) and Truview EVO2 (Truphatek International, Netanya, Israel). Each of these new devices has their own particular advantage. The Glidescope Cobalt has multiple sizes of blades for different ages of children, as well as a warming device at the tip of the blade to reduce fogging. The Storz Video Laryngoscope can be used for direct laryngoscopy and converted to video laryngoscopy; a particularly useful tool in the suspected, but unconfirmed difficult pediatric airway. The particular advantage of the Airtraq is its portability and one time disposable use, making it well suited for nonoperating room use. The Truview EVO2 provides a wide angle magnified view, and provides an infant blade with a port for oxygen insufflation (27,28).

Despite the effectiveness of video laryngoscopy in managing the difficult intubation, its utility is surpassed by that of the LMA. The LMA is a minimally invasive airway device inserted blindly into the hypopharynx, sitting over the laryngeal opening, with its tip overlying the esophagus. The supraglottic device consists of an inflatable mask fitted against the periglottic tissues, to form a seal above the glottis, achieving ventilation of the lungs via a tube exiting the mouth (29). The concept of the LMA as a supraglottic ventilatory device was introduced into mainstream clinical practice in 1988 in the United Kingdom, approved by the Food and Drug Administration in 1991 in the United States, and has now become ubiquitous in the practice of anesthesia, emphasizing its ability to support ventilation without the need for endotracheal intubation. The LMA has proven to be beneficial in the management of difficulty with both intubation and ventilation and was added to the most recent edition of the ASA's difficult airway algorithm in 2003 (2). The LMA is routinely used in remote locations to administer anesthesia, as well as to facilitate bronchoscopy and tracheobronchial stent placement, awake craniotomy and stereotactic procedures and transesophageal echocardiography (30). Perhaps the most useful attributes of the LMA, are its utility in patients who cannot be ventilated by conventional mask ventilation, as well as serving as a conduit for endotracheal intubation either blindly, with an intubating stylet (31) or fiberoptic technology (32), or even for high-frequency jet ventilation (33).

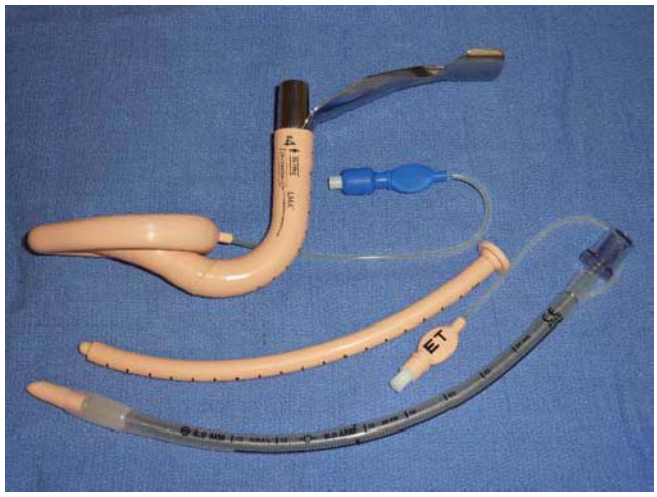

Figure 63.16 Fastrach intubating LMA with endotracheal tube.

The classic LMA does not protect the airway from regurgitation or aspiration, cannot be utilized in situations of subglottic obstruction, and cannot be used with airway pressures greater than 20 to 25 cm H_2O (34). Other supraglottic airway designs have incorporated gastric tubes or room for placement of separate gastric tubes through their device to reduce the possibility of aspiration (35). The Fastrach LMA is designed as an intubating LMA (Fig. 63.16), through which an ETT may be passed blindly into the trachea, and after which the LMA may either be left in place or removed using a specially designed pusher. This device was developed due to the shortcomings of the sizing of the classic LMA and need for specialized maneuvers to successfully pass the ETT through the LMA when used to facilitate intubation (36).

Although the Fastrach cannot be used for the pediatric population below 30 kg, a classic LMA may still be used as a conduit for insertion of the ETT (37). The LMA may serve as an adjunct for ventilation, while proceeding with attempts to secure the airway via intubation. Proper placement places the classic LMA with its distal opening overlying the glottis facilitating blind intubation; however, the most successful method for LMA-guided intubation in children utilizes the flexible fiberoptic scope as a stylet (Fig. 63.17) to advance the ETT through the LMA. The inability to pass the pilot balloon of a cuffed ETT may limit the feasibility of this technique in the younger age groups. However, the practitioner may cut the pilot balloon to facilitate placement of the cuffed ETT and then reconstruct the pilot balloon by inserting an IV catheter into the cut end of the tubing, removing the needle and attaching a one way Luer lock valve port adapter to the end of the IV catheter (Fig. 63.18). Another approach utilizes the specialized Air-Q LMA, with a wider and shorter tube than the standard LMA, accommodating the pilot balloon and minimizing the risk of accidentally pulling the ETT when removing the LMA (Fig. 63.19). A stabilizer bar is provided

Figure 63.17 Flexible scope used as a stylet to facilitate LMA-guided fiberoptic intubation.

Figure 63.19 Comparison of the wider and shorter shaft of the new Air-Q LMA with the classic LMA.

by the manufacturer to wedge inside the ETT, allowing successful removal of the LMA without catastrophic removal of the ETT (27).

Finally, ventilation utilizing an anterior commissure scope or rigid bronchoscope should be considered before proceeding with a surgical airway, such as a cricothyroidotomy or tracheostomy. These may also be helpful in ventilating the patient while a surgical airway is created. Alternate utilities of the rigid bronchoscope include the facilitation of endotracheal intubation by passing the rigid Hollinger telescope (Fig. 63.20) through the lumen of an appropriate sized endotracheal tube and under direct visualization passing the endoscope through the larynx for placement of the endotracheal tube. A gum elastic bougie or a Cook Airway Exchange Catheter may also be passed through the lumen of the bronchoscope, followed by removal of the bronchoscope and securing of the airway (38). Clearly, in difficult situations, preparation for a surgical airway should be considered, and at times initiated with possible life-saving results.

The major indication for cricothyroidotomy is the inability to establish an airway through orotracheal or nasotracheal intubation, which may be due to difficult patient anatomy, excessive bleeding in the mouth or nose, massive facial trauma, or airway obstruction resulting from angioedema, trauma, burns, or a foreign body obstructing the airway. The rate of failed emergency department intubations and subsequent surgical airway management is lower than 0.6%. In the emergency department, cricothyroidotomy has been used for 1.0% to 2.8% of all intubation attempts in patients with trauma. Whenever possible, cricothyroidotomy should be performed by physicians fully trained and skilled in carrying out the procedure, such as emergency physicians, surgeons, and intensivists. Surgical

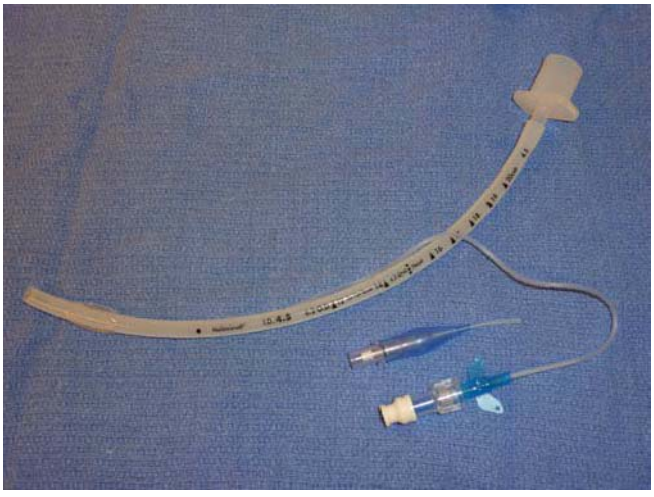

Figure 63.18 Reconstruction of the pilot balloon after LMA-guided fiberoptic intubation with a cuffed ETT.

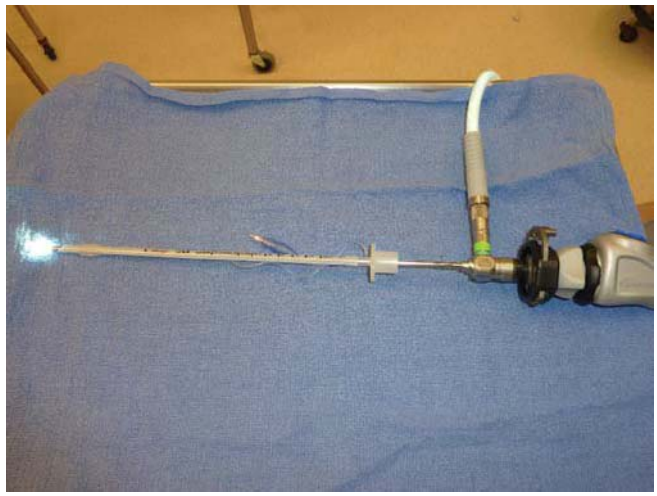

Figure 63.20 Hollinger telescope.

cricothyroidotomy involves inserting a tracheostomy tube into the trachea through an incision in the cricothyroid membrane. In needle cricothyroidotomy, a catheter is placed over a needle that penetrates the membrane, allowing ventilation by a pressurized stream of oxygen. Because the catheter has a smaller diameter, it is less effective in providing adequate ventilation and should be used only as a temporizing measure while preparation is made for surgical cricothyroidotomy or tracheostomy. Needle cricothyroidotomy is the preferred method of establishing an emergency airway in children younger than 10 to 12 years, since the larynx is more easily damaged by surgical cricothyroidotomy in this age group, with a higher incidence of postoperative airway complications.

To perform cricothyroidotomy, stabilize the larynx with your thumb and middle finger, and use your index finger to palpate the thyroid cartilage. Move your index finger down until you palpate the cricoid cartilage. The space between the thyroid and cricoid cartilages is the cricothyroid membrane. Use the scalpel to make a 2.5-cm vertical incision through the skin and subcutaneous tissue. Use the curved hemostat to make a blunt dissection in the subcutaneous tissue. Next, use the scalpel to make a horizontal incision through the cricothyroid membrane. Extend the incision laterally, turn the blade, and extend it in the opposite direction. Once the trachea has been entered, make sure the blade stays within the incision, so that communication with the trachea is never lost. Insert a tracheal hook, and pull upward on the distal portion of the incision, elevating the larynx. Once the tracheal hook is in place, you may remove the blade. Insert a Trousseau dilator and open the membrane vertically, then insert the tracheostomy tube. The anesthesia circuit is then connected to confirm the position of the tube within the airway (39).

In conclusion, the key to success when presented with difficult airway is preparation and a systematic approach for unexpected failure. In an unanticipated difficult tracheal intubation after routine induction of an adult or pediatric patient, each practitioner should become comfortable with a number of difficult airway tools to secure the airway, without the need to resort to surgical management. The key to success is utilization of these devices in routine intubations to achieve a high degree of comfort, allowing a degree of confidence to be present when greeted with the unexpected.

In our experience, utilizing video laryngoscopy in the manner described in this chapter should provide an improved laryngoscopic view to facilitate intubation. If difficulty is still encountered in placing the ETT despite the improved view, an intubating stylet or flexible fiberoptic scope may be employed to achieve tracheal intubation (40). Should these methods still prove unsuccessful, or in the desperate situation of failed intubation, increasing hypoxemia and difficult ventilation, the LMA Fastrach should be placed for adults, with the ETT passed into the trachea (41). In the pediatric population, the Air-Q LMA may be placed to facilitate ventilation, with a flexible fiberoptic scope or intubation catheter passed through the LMA to serve as a guide for the endotracheal tube to secure the airway. Clearly, a continuous dialogue and communication between the anesthesiologist and ENT surgeon, while simultaneously following an orderly and structured plan is critical for safety and success. Utilizing the ASA's Difficult Airway algorithm can help both the surgeon and anesthesiologist in avoiding the disastrous situation from developing, as well as grappling with unforeseen and challenging circumstances with a calm demeanor and appropriate focus.

64 Advanced Airway Management—Intubation and Tracheotomy

Karen M. Kost

INTUBATION

History

The history of intubation is much more recent than that of tracheotomy. Up until the 19th century, tracheotomy, although considered to be dangerous, was also the most reliable method of achieving tracheal intubation.

The human glottis was first viewed in 1854 by Manuel Garcia, a Spanish vocal pedagogue, with a tool he developed using two mirrors and the sun as an external light source (1,2).

In 1858, a Parisian pediatrician, Eugene Bouchut, reported on a small straight metal tube he had developed that could be advanced into the larynx. He used this new nonsurgical orotracheal intubation device to bypass laryngeal obstruction resulting from diphtheria in seven cases. He went on to develop a set of tubes that could be used as an alternative to tracheotomy for cases of diphtheria, despite severe criticism from his colleague Armand Trousseau (3).

In 1878, Wilhelm Hack of Freiburg published two papers describing the use of nonsurgical orotracheal intubation (a) in the removal of vocal fold polyps and (b) to secure the airway in a patient with acute glottic edema (4). Visualization of the glottis had been indirect, through the use of mirrors, until 1895 when Alfred Kirstein performed the first direct laryngoscopy, using a modified esophagoscope he called an "autoscope" (5).

In 1913, Chevalier Jackson developed a new laryngoscope. It included a sliding removable portion for introduction of an endotracheal (ET) tube or bronchoscope as well as a light source at its distal tip (6). In the same year, Henry Janeway, an American anesthetist, designed a laryngoscope with several modifications specifically for tracheal intubation. His goal was to deliver volatile anesthetics through direct intratracheal insufflation. The intubating laryngoscope he developed had batteries within the handle to power the distal light source, a notched blade for keeping the tracheal tube midline during intubation and a slight curve at the distal tip of the blade. His work is largely credited with the subsequent incorporation of direct laryngoscopy and tracheal intubation into the specialty of anesthesia (7).

Subsequent noteworthy contributions included the work of Sir Ivan Whiteside Magill, who introduced the technique of awake blind nasotracheal intubation. The Magill forceps he designed for this purpose continue to be widely used in many hospitals across North America (8,9). In 1943, Sir Robert MacIntosh developed the Macintosh curved laryngoscope, which has withstood the test of time as the most popular laryngoscope blade for orotracheal intubation (10). MacIntosh also developed the precursor to the current ET tube introducer (often referred to as a "stylet"), used for difficult intubations.

Indications

Intubation is the placement of a flexible tube (most often made of polyvinyl chloride) into the trachea to maintain an open airway or to serve as a conduit through which certain drugs can be administered. Patients are usually intubated for controlled mechanical ventilation since an ET tube will provide a good seal for controlled ventilation with consistent inspired volumes and pressures compared with noninvasive methods.

Intubation is frequently performed in critically injured, ill, or anesthetized patients to facilitate ventilation of the lungs. Nonoperative indications (Table 64.1) include, but are not limited to the following: (a) head injury with loss of gag or cough reflex; (b) airway obstruction from laryngeal edema, epiglottitis, oropharyngeal, or laryngeal neoplasms; (c) neck trauma or multisystem trauma; (d) pulmonary toilet; and (e) respiratory failure, as may occur with pneumonia, emphysema, chronic obstructive pulmonary disease, and even asthma. Operative indications for ET intubation

TABLE 64.1 NONOPERATIVE INDICATIONS FOR INTUBATION

- Head injury with loss of gag or cough reflex
- Airway obstruction from laryngeal edema, epiglottitis, oropharyngeal, or laryngeal neoplasms
- Neck trauma or multisystem trauma
- Pulmonary toilet
- Respiratory failure from pneumonia, emphysema, chronic obstructive pulmonary disease, or asthma

(Table 64.2) include (a) protection of the airway from aspiration; (b) surgical procedures of the head and neck; (c) all situations involving the use neuromuscular paralysis; and (d) procedures that may involve intracranial hypertension.

Airway Assessment

In order to avoid unpleasant surprises and potential complications, patients should be carefully evaluated prior to proceeding with intubation. A history should be taken to assess past surgical procedures, comorbidities, and current medications. The airway history (Table 64.3) should be detailed and should include inquiries into the following conditions that may affect the intubation technique: (a) prior intubation, difficult or complicated intubation; (b) prior airway surgery, airway trauma, and head and neck neoplasms; (c) prior radiotherapy to the neck; (d) presence of dentures or loose or capped teeth; (e) trismus, temporomandibular joint problems, or difficulty opening the mouth; (f) cervical spine disease or instability; and (g) diagnosis of sleep apnea.

The physical exam (Table 64.4) will help in further identifying any problems and begins with vital signs, including heart rate, respiratory rate, blood pressure, and oxygen saturation. Stridor, use of accessory muscles, and/or cyanosis should be noted. Following a general physical exam and evaluation of body habitus, emphasis should be placed on evaluation of the head and neck. Assessing the oropharynx is helpful in predicting ease of intubation. The Mallampati system has been designed for this purpose and divides patients into four classes based on visualization of the oropharynx. This evaluation should be conducted with the mouth widely open, the tongue protruded, and the neck extended.

TABLE 64.2 OPERATIVE INDICATIONS FOR INTUBATION

- Protection of the airway from aspiration
- Surgical procedures of the head and neck
- All situations involving neuromuscular paralysis
- Procedures that may involve intracranial hypertension

TABLE 64.3 AIRWAY HISTORY PRIOR TO INTUBATION

- Prior difficult or complicated intubation
- Prior airway surgery, airway trauma, head and neck neoplasms
- Prior radiotherapy to the neck
- Presence of dentures or loose or capped teeth
- Trismus, temporomandibular joint problems, or difficulty opening the mouth
- Cervical spine disease or instability
- Diagnosis of sleep apnea

Mallampati Classification

Class I: The tonsillar pillars are visible in their entirety—intubation is likely to be straightforward

Class II: The uvula is visible, but the tonsillar pillars are partially or completely obscured

Class III: Only a portion of the uvula and soft palate are visible

Class IV: The tongue obscures the tonsillar pillars, uvula, and soft palate. Only the hard palate is visible—intubation is likely to be difficult (Fig. 64.1)

Additional findings that may affect planning and technique of intubation include the following:

(a) Facial deformities.
(b) Trismus—ideally the mouth opening should be at least three fingerbreadths.
(c) Limited neck mobility.
(d) Thyromental space—the distance from the mandible to the thyroid should be three fingerbreadths (6 cm) or greater. It is reduced in conditions such as retrognathia.
(e) Tissue compliance—the tissue should be soft, pliable.
(f) Poor dentition with mobile or fractured teeth or prominent or large teeth may all render intubation difficult.

TABLE 64.4 PHYSICAL EXAM PRIOR TO INTUBATION

- General: body habitus, vital signs, presence of stridor
- Assessment oropharynx (Mallampati classification)
- Facial deformities
- Trismus—mouth opening should be ≥3 fingerbreadths
- Limited neck mobility
- Thyromental space—should be ≥3 fingerbreadths (6 cm)
- Presence of retrognathia
- Tissue compliance
- Poor dentition: mobile or fractured teeth, prominent or large teeth
- Large tongue and/or high arched palate
- Impaired cognition

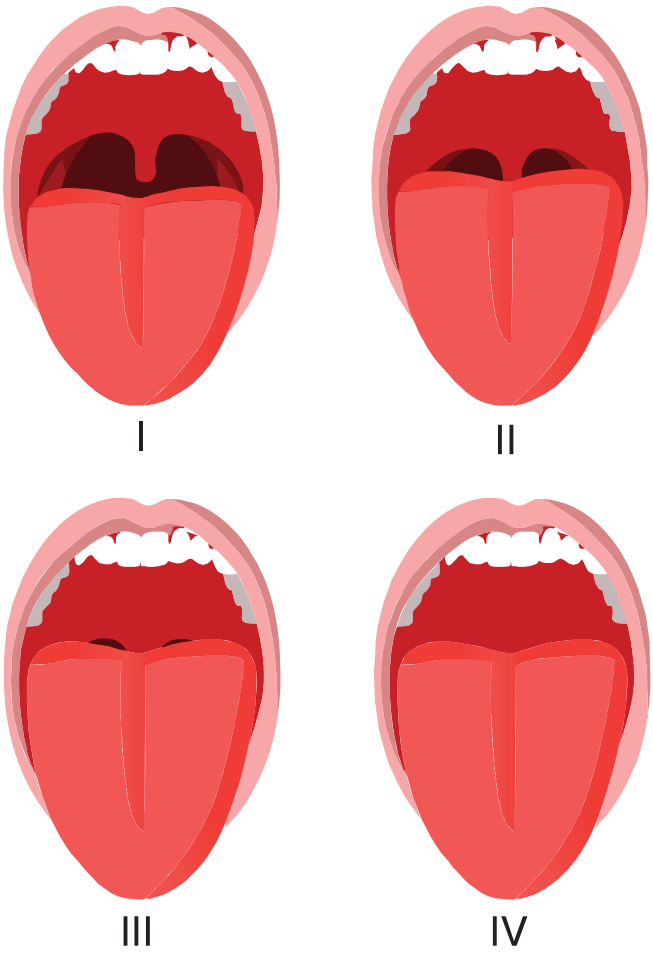

Figure 64.1 Mallampati classification.

(g) Large tongue and/or high arched palate—this may affect use of the laryngoscope or reduce visualization of the glottis. Ideally the oral cavity should be large and the tongue small.
(h) Impaired cognition.

Special Considerations

The decision to intubate or proceed to tracheotomy (Table 64.5) in any given situation must be based on a thorough review of several factors. These include the following: (a) Anticipated duration and need for mechanical ventilation. Patients with conditions such as epiglottitis, or laryngeal edema, who require short-term ventilator support are best managed with intubation. Conversely, patients with severe respiratory illnesses or head injuries who are likely to require prolonged ventilator support will benefit from early tracheotomy. (b) Skill of the anesthetist and skill of the surgeon. There are many conditions where it is appropriate to secure the airway with either ET intubation or tracheotomy. Pertinent otolaryngology examples include patients with deep neck space infections, severe facial trauma or neck trauma, and upper airway obstruction

TABLE 64.5 FACTORS IN DECISION MAKING: INTUBATION VERSUS TRACHEOTOMY

- Review of all pertinent clinical information
- Anticipated duration and need for mechanical ventilation
- Condition of the patient: for example, respiratory distress
- Skill of the anesthetist and skill of the surgeon
- Communication between anesthetist and surgeon
- Establishing a clear plan of action

from laryngeal edema or neoplasms. The decision in these cases must be predicated on the condition of the patient, the skill and experience of the anesthetist and surgeon, and review of all pertinent clinical information including the history, physical exam, imaging studies, and laboratory data. Communication between the surgeon and anesthetist is critical in establishing a clear and safe plan of action. For example, in the case of a deep neck space infection, each of the following scenarios may be correct: (i) a skilled and experienced anesthetist may feel comfortable attempting an awake fiberoptic intubation with the surgeon on "standby," scrubbed and ready to intervene with a tracheotomy; (ii) a less experienced anesthetist may defer to the skill of the surgeon in establishing the airway; and (iii) the anesthetist and surgeon may decide to proceed directly to tracheotomy because it is neither safe nor possible to attempt intubation.

Endotracheal Tube Selection

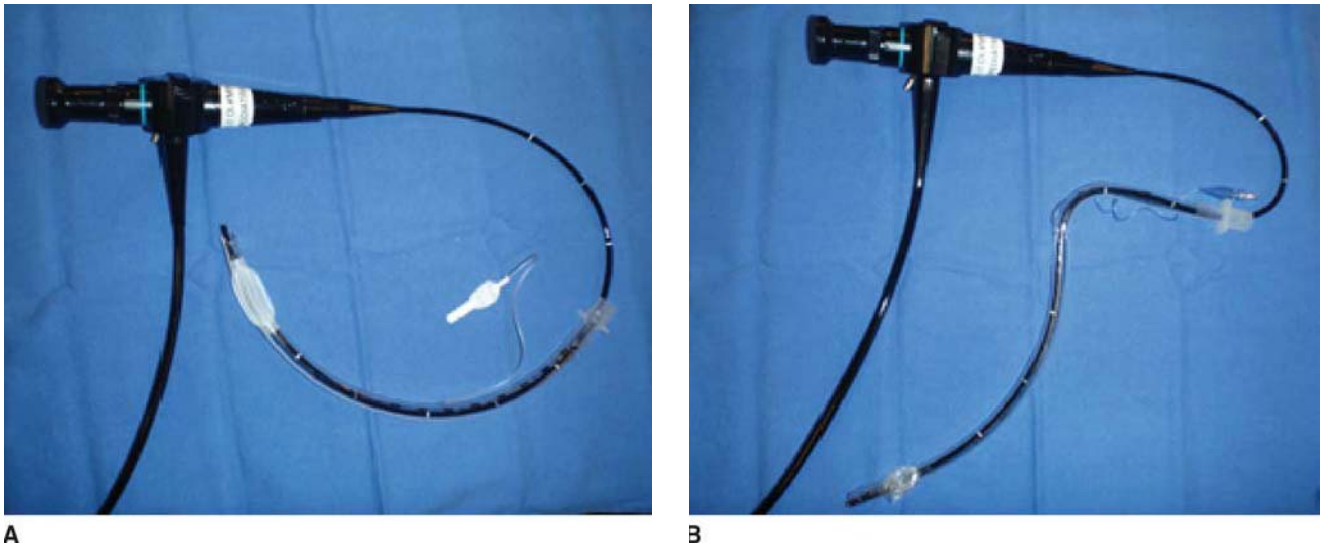
The ET tube size should be determined based on the patient's gender and clinical needs. In general, smaller tubes with an internal diameter (I.D.) between 6.5 and 7.5 are preferred in adult females while slightly larger tubes with an I.D. of 7.0 to 8.0 are used in males. In patients with airway compression or narrowing, smaller tubes may be chosen. Obese patients generally require slightly larger tubes to compensate for the increased weight on the chest and higher ventilation pressures. It is prudent to have several sizes available. There are several different types of ET tubes, including commonly used polyvinyl chloride tubes, armor tubes, and laser-resistant tubes. Specific tube shapes have been developed for nasotracheal and orotracheal intubation, and particular surgical situations such as tonsillectomy (Fig. 64.2).

Orotracheal Intubation

The most widely used route for intubation is orotracheal, in which an ET tube is passed through the mouth and vocal folds into the trachea. It is the simplest technique and that with which anesthetists and critical care physicians have the greatest experience and familiarity. It is appropriate for many operative otolaryngology cases including sinonasal and otologic procedures. It may also be used

Figure 64.2 *Left to right*: orotracheal tube, nasotracheal tube, tonsillectomy tube, armor tube.

for parotidectomy, excision of neck masses, and neck dissections provided the tube is secured away from the surgical side and access to the oral cavity is not required. Orotracheal intubation may be accomplished blindly or with the help of fiberoptic scopes. In the majority of cases, however, a rigid curved MacIntosh laryngoscope is used to facilitate the intubation.



Prior to initiating the intubation, the patient should be positioned with the neck slightly flexed on the chest and the head slightly extended on the neck. The patient should be preoxygenated by delivering O_2 through a well-fitted mask. The pharynx and oral cavity should be thoroughly suctioned. The right-handed physician stands at the head of the bed, and holds the MacIntosh laryngoscope in the left hand. The right hand gently opens the mouth, being careful not to impale the lips on the teeth, and the left hand introduces the laryngoscope into the right side of the mouth, displacing the tongue over to the left as the tip is advanced into the vallecula. The larynx is lifted anteriorly to expose the glottis. The ET tube, held in the right hand, is advanced into and through the glottis. Pressure on the cricoid cartilage may be used to facilitate intubation in an anteriorly positioned larynx and has the added advantage of decreasing the risk of aspiration by closing the opening to the esophagus. Following intubation, air entry into both lungs is verified and the tube is secured in position with tapes.

In difficult cases where the first few intubation attempts fail, a different approach should be considered. This may include using intubation aids such as the GlideScope, or switching to a different technique altogether, such as intubation over a flexible fiberoptic bronchoscope.

In patients with limited mouth opening, or a narrow airway from whatever reason, awake intubation over a flexible fiberoptic bronchoscope (Fig. 64.3) provides direct visualization of the glottis and adds a measure of safety. This technique is one of the cornerstones of difficult airway management. Patient comfort is greatly improved with good topical anesthesia of the oral cavity and pharynx and the addition of a superior laryngeal nerve block. Use of an oral airway prevents biting on the ET tube and bronchoscope. Flexible fiberoptic intubation is very useful in cases of laryngeal edema, deep neck space infections, laryngeal papillomatosis, and other neoplasms.

Nasotracheal Intubation

Nasotracheal intubation is another means by which the airway can be protected. It is very useful and provides unhindered access for major head and neck oncologic procedures involving the oral cavity and oropharynx. It may also be used when orotracheal intubation is not possible or otherwise contraindicated. Nasotracheal intubation is

A B

Figure 64.3 **A:** Fiberoptic orotracheal intubation. **B:** Fiberoptic nasotracheal intubation.

best used for short-term airway protection because of the high incidence of sinusitis, serous otitis media, acute otitis media, and the risk of alar necrosis associated with the more prolonged use of these tubes. It is contraindicated in patients with midface fractures involving the cribriform plate or fovea ethmoidalis because of the risk of entering the brain.

Nasotracheal intubation may be performed blindly, or with the use of rigid or flexible laryngoscopes. Retrograde techniques are also described but are beyond the scope of this chapter.

In the awake patient, nasotracheal intubation is better tolerated than orotracheal intubation. Adequate preparation of the patient is a wise investment in time and will ensure a smooth procedure. A quick look at the nose with a nasal speculum will help identify septal deviations or other anatomic abnormalities that may interfere with the intubation. Good topical anesthesia and vasoconstriction can be achieved by packing the nose with cotton wool impregnated with lidocaine and a decongestant. Alternatively, topical sprays may be used. Topical anesthesia of the pharynx can be obtained by using lidocaine which is either gargled or nebulized. A superior laryngeal nerve block can also be a helpful adjunct. With good topical anesthesia and vasoconstriction, the nasal cavity can be dilated with progressively larger nasal "trumpets." Ideally the tube should be warmed prior to use to make it more pliable. The warmed, lubricated nasotracheal tube is inserted into the nasal cavity and advanced to the pharynx. At this point, an intubating laryngoscope in the left hand is placed in the right side of the oral cavity and advanced to the vallecula. The tip of the nasotracheal tube, visible on the posterior pharyngeal wall, is grasped with a Magill forceps held in the right hand, and advanced through the glottis. Good air entry to both lungs is verified, and the tube is secured.

When a difficult intubation is anticipated, fiberoptic nasotracheal intubation (Fig. 64.3) is a good choice. It is an extremely important and successful technique in patients with difficult airways. In particular, it should be considered in patients with limited neck mobility, limited mouth opening, and a short thyromental space. Intubating patients having received prior radiotherapy or surgery to the head and neck can be extraordinarily difficult. In these cases, fiberoptic nasotracheal intubation is likely to be successful, and is especially attractive because it can be performed on the awake, spontaneously breathing patient. The nose and upper airway are prepared with topical anesthesia as previously described. The nasotracheal tube is threaded over the fiberoptic bronchoscope. A size 7 ET tube is the smallest size that will accommodate an adult bronchoscope. A pediatric bronchoscope must be used with size 6 or 6.5 ET tubes. The bronchoscope is introduced into the nose and advanced through the glottis. The nasotracheal tube then follows over the bronchoscope down through the glottis and into the trachea.

Blind nasotracheal intubation is a rarely used "rescue technique" when advancing the tube with the help of a laryngoscope or when fiberoptic intubation or orotracheal intubation is not possible. Patients must be breathing spontaneously. Topical anesthesia is used as much as the situation permits. The tube is introduced through the nose, and advanced into the hypopharynx, with the operator listening for breath sounds as the tube approaches the glottis. The tube is advanced through the glottis just as the next inspiration is begun. Air entry is verified, and the tube is secured. Tips to facilitate passage through the glottis include external pressure on the neck and use of a stylet through the ET tube after it has passed through the nasopharynx. It must be emphasized that this technique is difficult, requires skill and experience, and is associated with higher complication rates than other techniques.

Intubation Aids in the Difficult Airway

In difficult cases where the first few intubation attempts fail, a different approach should be considered. This may include using intubation aids (Table 64.6) such as the GlideScope, or switching to a different technique altogether, such as intubation over a flexible fiberoptic bronchoscope. Repeatedly attempting to intubate orotracheally after a few failed attempts may lead to airway edema, trauma, and bleeding, rendering both visualization and ventilation by any means difficult. What started as a routine intubation becomes a potentially life-threatening emergency.

The most frequently used intubating instrument is the MacIntosh laryngoscope (Fig. 64.4) with the curved blade. This laryngoscope, in its original design, is intended to be held in the left hand. A mirror image of the MacIntosh blade is available for left-handed operators to hold in the right hand leaving the dominant hand for intubation. It is introduced into the left side of the mouth and may also be used in patients with right-sided facial abnormalities or injuries. The English MacIntosh laryngoscope has become the preferred instrument in many centers, because of the continuous curve along the entire length of the blade, and the distal extension of the vertical step and flange. Considered together, these modifications provide a better view of the glottis in many cases. A very large number of subtly modified curved blades, all with intended specific uses, have also been developed (11).

TABLE 64.6 INTUBATION AIDS IN THE DIFFICULT AIRWAY

- Intubation over a fiberoptic bronchoscope
- Use of a stylet or a lighted stylet
- Use of a GlideScope
- Straight laryngoscope blades
- Fiberoptic viewing laryngoscopes

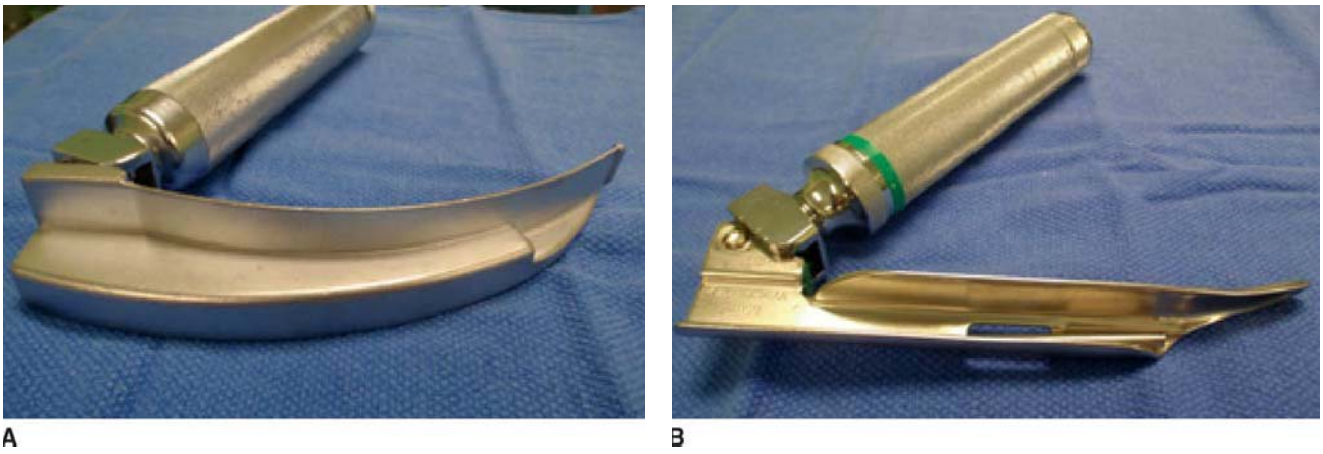


Figure 64.4 **A:** Curved MacIntosh blade. **B:** Straight Miller blade.

An impressive variety of straight blades also exists, of which one of the earliest and still most commonly used is the Miller laryngoscope blade (Fig. 64.4). It is straight, with a gradual curve 5 cm from its narrow tip, and a smaller vertical step compared to the MacIntosh blade. Straight blades are intended to "entrap" and lift the epiglottis, in contrast to the curved blades. Straight blades are especially useful in patients with limited mouth opening as is often the case in previously operated or radiated necks. In these situations, the slimmer blade fits more easily between the teeth, and the distal curved tip allows visualization of the laryngeal inlet. Because the space for maneuvering the ET tube is limited with this type of blade, use of a stylet is recommended (11).

A number of stylets are available to facilitate intubation. They are long, thin, malleable devices that are inserted into ET tubes and bent or adjusted to a desired shape and curvature. They may be entirely within or extend beyond the ET tube. Some even have a small light at the distal end. The curve of the ET tube afforded by the stylet is helpful when the larynx rests in an anterior position.

The occasional failure of direct laryngoscopy to provide an adequate view for tracheal intubation in the difficult airway led to the development of alternative devices such as the lighted stylet, and a number of indirect fiberoptic viewing laryngoscopes, such as the fiberscope, Bullard scope, Upsher scope, and the WuScope. A detailed discussion of each of these devices is beyond the scope of this chapter. Though these devices can be effective alternatives to direct laryngoscopy, they each have certain limitations, and none of them is effective under all circumstances. One important limitation commonly associated with these devices is fogging of the lens.

The introduction of digital technology has led to the development of several video laryngoscopes designed to facilitate tracheal intubation. The GlideScope emerged in 1991 as the first of several similar devices. The GlideScope incorporates a high-resolution digital camera, which is connected by a video cable to a high-resolution light crystal display monitor (Fig. 64.5). The high degree of success in intubating difficult airways with the GlideScope is the result of five special features. (a) The sharp 60-degree angulation of the blade reduces the need for displacing the tongue anteriorly, thereby improving the view of the glottis. (b) Instead of being at the tip of the blade, the CMOS APS digital camera is located at the point of angulation of the blade, providing a better view of the field in

Figure 64.5 GlideScope with recessed position of digital camera and light crystal display monitor.

front of the camera. (c) The recessed position of the video camera shields it from blood and secretions that might otherwise obstruct the view. (d) The video camera has a relatively wide viewing angle of 50 degrees. (e) The incorporated heated lens helps prevent troublesome fogging of the lens. The blade of the GlideScope is introduced as for a MacIntosh blade, and advanced through the oropharynx with the operator viewing the procedure on the monitor. When the optimal view is achieved, the ET tube is introduced and guided into the larynx, with the help of the image from the monitor. The use of a stylet precurved at approximately 60 degrees facilitates access to the glottic opening.

The GlideScope has been shown to improve laryngeal views compared with direct laryngoscopy with high success rates of intubation in normal airways, following failed direct laryngoscopy, and in predicted difficult airways (12). In the latter situation, the success of the GlideScope is approximately 92% on the first attempt, and increases from 96% to 100% after more than one attempt. In contrast, increased laryngoscopy attempts are associated with increased morbidity. The most important predictors for failure with the GlideScope include a thyromental distance of less than 6 cm and abnormal neck anatomy such as a neck mass or history of prior irradiation. Important predictors of failure for direct laryngoscopy include the combination of a high Mallampati score and reduced thyromental distance, as well as abnormal neck anatomy (12). This highlights the importance of careful preoperative patient assessment, and discussion between the anesthesiologist and surgeon to come up with a thoughtful plan that includes alternative techniques such as flexible fiberoptic intubation.

In summary, there exists a large and ever-expanding array of intubating aids and devices for management of the difficult airway. Although each has its place and utility, it should be emphasized that fiberoptic orotracheal or nasotracheal intubation remains a cornerstone in the management of the patient with a difficult airway.

The Hunsaker Tube and Jet Ventilation in Microlaryngeal Surgery

Microlaryngeal surgery involves sharing the airway. A balance must be achieved between airway control and ventilation and the need for adequate laryngeal visualization and exposure.

In 1967, Sanders introduced jet ventilation for use during rigid bronchoscopy (13). In the 1970s, the concept was adapted for use in microlaryngeal surgery as a means of providing adequate ventilation and maximizing exposure. The technique involves positioning and suspending a laryngoscope to expose the glottis. An injector cannula, tightened to the laryngoscope, allows for the high-pressure delivery of air from above the vocal folds. Exhalation is passive, and requires an unobstructed airway. The technique offers excellent exposure of the larynx at the expense of airway control.

TABLE 64.7 ADVANTAGES OF HUNSAKER TUBE IN MICROLARYNGEAL SURGERY

- Can be used with stylet
- Excellent exposure
- Laser safe
- Versatile

The technology has been further modified for supraglottic, subglottic, and transtracheal jet ventilation.

Several tubes have been developed for subglottic ventilation, but their use was limited by problems such as misalignment, inadequate ventilation, inability to monitor airway pressures, and the risk of airway fires with laser use.

In 1994, Hunsaker introduced a special laser-safe subglottic tube designed specifically for microlaryngeal surgery (14). Airway pressures and end-tidal CO_2 could be monitored through the tube that was attached to a dedicated jet ventilator.

The Hunsaker Mon-Jet tube offers excellent laryngeal visualization and anesthetic safety. It is very versatile and can be used in patients with comorbidities, obesity, and difficult airways (Table 64.7). It provides excellent laryngeal exposure for a wide range of endolaryngeal procedures using laser, cold steel, or the microdebrider (15,16). When used with the laser, it is important to keep oxygen concentrations as close to room air as possible in order to prevent airway fires. In addition, the subglottic position minimizes vocal fold movement during surgery.

The tube itself is 35.5 cm long with an inner diameter of 2.7 mm and an outer diameter of 4.3 mm. Because it is made with a nonflammable fluoroplastic material, it can be safely used with lasers. A metal stylet adds some rigidity to the tube, thereby facilitating intubation. The green basket at the end of the tube helps center the tube within the trachea, and prevents the jet port from coming into direct contact with the mucosa (Fig. 64.6). There is a 1-mm port for monitoring airway pressures and end-tidal CO_2 that opens 3.2 cm above the jet port.

The intubation technique is the same as for orotracheal intubation with a MacIntosh laryngoscope. Once in proper

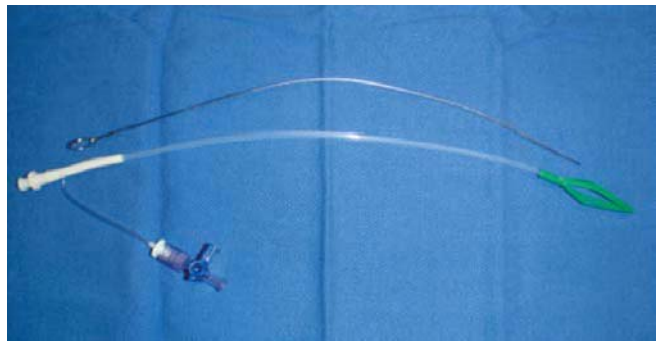

Figure 64.6 Hunsaker tube. Note *green* basket and metal stylet.

TABLE 64.8 COMPLICATIONS FROM JET VENTILATION WITH THE HUNSAKER TUBE

- Hypoxia and/or hypercarbia
- Bleeding into the trachea from the surgery
- Barotrauma

position, the jet port and monitoring port of the tube are attached to the jet ventilator. An automated jet ventilator is preferred because of the automatic "shut-off" if airway pressures exceed preset limits. The tube should be secured at the corner of the mouth and supported in order to avoid kinking. When the laryngoscope is not in position or the patient's mouth is closed, an oral airway should be used to allow passive exhalation.

Complications from this technique (Table 64.8) are seen in less than 2% of cases and consist mostly of hypoxia and/or hypercarbia and rare bleeding down the trachea from the surgical procedure. In all these cases, the Hunsaker may be exchanged for a laser-safe ET tube. Appropriately securing the tube is important to avoid kinking. Barotrauma can be largely prevented with an automated jet ventilator (16).

The Laryngeal Mask Airway

The laryngeal mask airway (LMA) was developed in the 1980s by Dr. Archie Brain as a supraglottic airway device that could be used as an alternative to (a) the more invasive ET intubation, or (b) face-mask ventilation, which is difficult to control. The LMA consists of an inflatable mask attached to a tube that exits through the mouth and can be connected to a ventilator (Fig. 64.7). The mask contours the periglottic tissues while occupying the hypopharyngeal space. Once inflated, it forms a seal above the glottis in contrast to an ET tube, which forms a seal within the trachea. It requires some training, but is relatively easy to insert, can be used blindly without accessory instruments, and is associated with infrequent complications. An important limitation is that it does not protect against abdominal contents and aspiration. Many modifications of the original device have emerged to adapt to particular clinical situations and expand the indications for use. The LMA, or one of its modifications, can be used in the following situations: (a) as a routine airway or ventilation device, (b) in emergency cases with a "cannot intubate, cannot ventilate" scenario, and (c) with the modified LMA Fastrach, as a conduit for ET intubation (17).

Figure 64.7 Classic LMA.

The original device, the "LMA Classic," is useful for short, elective, nonotolaryngology cases requiring general anesthesia in the supine position. Because a fiberoptic endoscope can easily be passed through the LMA, it is useful in otolaryngology for diagnostic evaluation of the larynx and during percutaneous tracheotomy. The LMA Classic has also been shown to be very useful in the emergency or nonemergency management of patients with difficult airways. Examples include patients with the following conditions: (a) cervical spine immobility or instability; (b) morbid obesity; (c) micrognathia; (d) congenital syndromes such as Treacher-Collins, Pierre-Robin, and Down syndrome; and (e) unexpected failed intubation with difficult face-mask ventilation (Table 64.9). Indeed, the LMA has been incorporated into the "Practice Guidelines for the Management of the Difficult Airway" by the American Society of Anesthesia (ASA) Task Force on Management of the Difficult Airway (17).

A modified version, the intubating LMA Fastrach, was introduced in 1997 and is intended to facilitate blind or fiberoptically guided ET intubation in difficult airways such as C-spine injuries, where head position must remain neutral (18). It consists of a hollow 13-mm stainless steel tube connected distally to the laryngeal mask. Proximally, a handle helps with insertion and placement. Once it is positioned, a special ET tube can be advanced through the

TABLE 64.9 ADVANTAGES OF THE LARYNGEAL MASK AIRWAY

- Less invasive than ETT
- Can be used blindly without accessories
- Can be used with fiberoptic scope
- Useful in difficult airway. For example, C-spine instability, obesity, micrognathia
- Useful in emergencies. For example, failed intubation
- Few complications

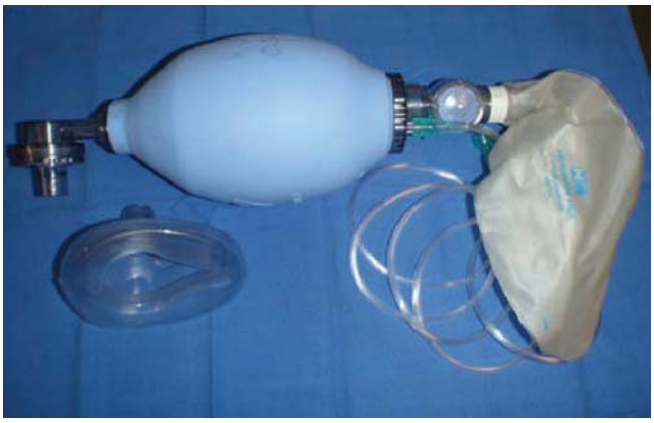

Figure 64.8 Mask and resuscitation bag.

lumen into the trachea either blindly or over a fiberoptic bronchoscope. The intubating LMA Fastrach is a well-recognized "rescue device" for difficult airways. The C-Trach represents an additional modification with a camera integrated into the LMA, allowing the operator to visualize the ET tube being introduced through the glottis (18).

Noninvasive Ventilation

This approach relies on the use of a well-fitted mask covering the nose and mouth, along with a self-inflating resuscitation bag (Fig. 64.8). Maintaining a proper seal between the mask and the patient's face is necessary for adequate ventilation. This may not be possible in patients with facial trauma or severe facial deformities. In obese patients or those with difficult anatomy, the use of nasopharyngeal and oropharyngeal airways may be helpful. Although useful as a temporizing solution prior to definitive airway protection, the bag and mask technique provides no protection from aspiration, and maintaining an adequate seal quickly becomes tiring for the operator.

Complications of Intubation

Many if not most complications are preventable with careful planning, selection of the appropriate intubation technique, and attention to technical detail. Not surprisingly, complications are much more frequent following difficult or traumatic intubations (Table 64.10).

Nasal trauma may occur during nasotracheal intubation with possible injury to the mucosa, septum, turbinates, and adenoids. Nasotracheal tubes kept *in situ* postoperatively increase the risk of nasal alar injury, sinusitis, and otitis media. Long-term sequelae include nasal synechia as well as scarring and distortion of the nasal tip and/or ala. Although some epistaxis is common with nasotracheal intubation, it is usually self-limited. Nasal trauma can be minimized by maximally decongesting the nose, using nasal trumpets for dilatation, and warming and lubricating the nasotracheal tube.

TABLE 64.10 COMPLICATIONS OF INTUBATION

- Lip injury
- Dental injury
- Nasal trauma (nasotracheal intubation)
- Mucosal injury
- Macroglossia
- Laryngeal/tracheal trauma
- Bronchial intubation
- Esophageal intubation
- Esophageal/pharyngeal/pyriform sinus perforation
- Intracranial intubation
- Pulmonary edema
- Barotrauma (with jet ventilation)
- Airway obstruction
- Nerve injuries
- Cervical spine injuries
- Corneal abrasions

Lip trauma usually occurs on the right upper lip as a result of inattentive laryngoscopy during intubation. It is usually self-limited and requires only comfort measures.

Dental injuries occur in approximately 1 in 4,500 cases and usually involve the maxillary central incisors. These injuries are most common in young children, in patients with preexisting periodontal disease, and in cases where intubation is difficult. Chipped or cracked teeth should be located and removed to prevent tooth aspiration.

Macroglossia, or massive tongue swelling, has been reported, and is thought to result from venous and lymphatic obstruction of the tongue. It is associated with prolonged procedures and compression of the tongue by the ET tube. Less commonly, it may be seen with angiotensin-converting enzymes. In extreme cases the airway may need to be secured with a long nasal trumpet or nasotracheal tube.

Mucosal injury to all areas of the oral cavity and pharynx is possible and may occur from the laryngoscope, oral airway, ET tube or any other device that is used. Up to 40% of patients complain of sore throat following intubation, with even larger numbers in cases of traumatic intubation. Fortunately, most symptoms resolve in 24 to 48 hours.

Laryngeal trauma from intubation may occur in up to 6% of cases and is most likely following traumatic intubation. Injuries may include vocal fold lacerations or hematoma, arytenoid dislocation or subluxation, vocal fold paralysis, and granuloma formation. Use of large tubes, particularly in females, results in tissue ulceration of the posterior larynx and increases the risk of posterior glottic stenosis. The risk is even greater in agitated patients with nasogastric tubes and gastroesophageal reflux.

Tracheal trauma may be related to several factors. An overinflated cuff that exceeds capillary perfusion pressures

results in local tissue hypoxia, necrosis, and eventual healing with malacia or stenosis. Use of large ET tubes, especially in females, may similarly result in stenosis. Intubating stylets, tube exchangers, and malpositioned tubes may also result in tracheal injury. In young children, edema in the subglottic area following extubation increases airway resistance and may result in croup-like symptoms.

Bronchial intubation, especially of the right mainstem bronchus, is relatively common and may manifest as absence of breath sounds on the left side and asymmetric chest expansion. It is even more common in children and may be undetected until hypoxia, atelectasis, or even pulmonary edema further complicate the situation.

Inadvertent esophageal intubation is not uncommon, and, provided it is recognized, can be quickly rectified without adverse effects such as hypoxia. Preoxygenation prior to intubation provides a "safety cushion" of 6 to 9 minutes before hypoxemia occurs. Presence of an end-tidal CO_2 is crucial in confirming placement of the ET tube.

Perforation of the esophagus, pharynx, and pyriform sinus are all possible, particularly with difficult intubations. These are serious complications that may progress to neck abscesses, subcutaneous emphysema, pneumothorax, mediastinitis, sepsis, and death. Early recognition and treatment are important because the mortality associated with mediastinitis is at least 50%.

Intracranial intubation is a rare but disastrous complication that usually results from attempted nasotracheal intubation in the presence of skull base fractures or facial trauma.

Pulmonary edema may occur following sudden relief of chronic airway obstruction. It may manifest in the operating room (OR), or later in the recovery room following extubation. Hypoxia, difficulty ventilating the patient, and pink foamy fluid in the ET tube should arouse suspicion as to the cause. The diagnosis is confirmed with a chest radiograph. Treatment usually consists of mechanical ventilation with positive end-expiratory pressure (PEEP) and diuretics.

Barotrauma is usually associated with jet ventilation techniques such as those used in microlaryngeal surgery. High-flow insufflation through catheters distal to the glottis may result in air tracking into peribronchial tissues. Unrecognized, the situation may progress to pneumomediastinum or tension pneumothorax. As discussed previously, use of Hunsaker tubes with automated jet ventilators is helpful in minimizing the risk of these injuries.

Airway obstruction may occur from occlusion of the tube from blood or secretions. Other potential causes include kinking of the tube or, more rarely, cuff herniation over the tip of the tube. Tubes may also become dislodged or disconnected, particularly when they are hidden under surgical drapes. Early recognition is key in rectifying the problem and preventing adverse effects.

Nerve injuries usually result from pressure and may involve the lingual nerve, hypoglossal nerve, recurrent laryngeal nerve, and internal branch of the superior laryngeal nerve. Fortunately, the vast majority are temporary and self-limited. Rare cases of transient hyposmia have been reported following nasotracheal intubation.

Cervical spine injury usually results from excessive neck manipulation and force in attempting to intubate patients with preexisting disease such as ankylosing spondylitis and rheumatoid arthritis. In patients with C-spine fractures, inadequate immobilization prior to intubation may aggravate or worsen the injury. Fiberoptic intubation is often a safer choice in these individuals.

Corneal abrasions are relatively common injuries associated with general anesthesia. They may result from a mask or other object rubbing against the eye or from the eyes being left partially open during anesthesia. Ophthalmology should be consulted for abrasions. Treatment usually consists of antibiotic ointment with an eyepatch. These injuries may be prevented by taping the lids closed and applying eyepads, particularly during head and neck surgery.

TRACHEOTOMY

Introduction (History)

The word "tracheotomy" is derived from the Greek words "tracheia arteria," meaning "rough artery," and "tome," meaning "to cut." The word "tracheostomy" comes from the Greek ending "stoma," which means "to finish with an opening or mouth." Although strictly speaking, "tracheostomy" should be used when a permanent opening is intended, nowadays the two terms are used rather loosely and interchangeably (19).

Tracheotomy has a long and colorful history. The first reference to the procedure can be found in the sacred book of Hindu medicine, the Rig Veda, dated to approximately 2000 BC. Alexander the Great is reported to have performed a tracheotomy in the fourth century BC when he "punctured the trachea of a soldier with the point of his sword when he saw a man choking from a bone lodged in his throat" (20). Antonio Musa Brasavola is credited with the first successful procedure, when he documented saving the life of a patient close to death from an "abscess of the windpipe" in 1546. The first work devoted solely to tracheotomy consisted of a 108-page book written and published in 1620 by Nicholas Habicot of Paris. In it, he described four successful tracheotomies, one of which involved a 14-year-old boy who intentionally swallowed a bag of gold coins to prevent their theft. The bag became lodged in his esophagus, producing upper airway obstruction. Habicot relieved the obstruction by performing a tracheotomy, and subsequently manipulated the bolus of coins, facilitating its esophageal descent. The boy recovered, and several days later the coins were recovered from the rectum. Despite these success stories, tracheotomy remained a marginal procedure viewed with suspicion and fear for several centuries because of very high morbidity

and mortality rates. Echoing these thoughts, Fabricius ab Aquapendente wrote: "The terrified surgeons of our times have not dared to exercise this surgery and I also have never performed it. Even the mention of this operation terrifies the surgeons; hence it is called the scandal of surgery." In 1799, when Dr. Elisha Dick recommended that a tracheotomy be performed for a patient in airway distress, two colleagues vocally opposed him, and on December 14, 1799, George Washington died of an acute upper airway obstruction.

It was not until the 19th century that prevailing attitudes toward tracheotomy began to change rather dramatically. Although the procedure had been previously described in children, first in 1766 by Caron to remove a bean lodged in the airway, and later in 1782 by Andrée, it was the description of a life-saving tracheotomy in a child in 1825 that seems to have singularly had the greatest impact. In that year, Bretonneau saved the life of a 5-year-old girl called Elisabeth de Puysergur who was suffering from diphtheria by performing a tracheotomy (19). Shortly thereafter, in 1833, Armand Trousseau recounted, "I have now performed the operation in more than 200 cases and I have the satisfaction of knowing that one-fourth of these operations were successful" (21).

Gradually, the repertoire of indications for tracheotomy cautiously expanded to include not only upper airway obstruction from croup and diphtheria, but also that resulting from trauma, tuberculosis, or syphilis. During the early 20th century, tracheotomy found a brief new indication in the administration of general anesthesia, and was touted as the only means of securing an airway. As the use of ET intubation was popularized, however, this particular use waned. During this time, subjects such as technique, complications, tube morphology, tracheostomy placement, and anesthesia were hotly debated in the medical literature, and there were almost as many views as there were surgeons.

It was to be the work of Chevalier Jackson, in 1909 (22) that would finally dispel the aura of fear and mystery that for so long had been associated with tracheotomy. Only then was the procedure firmly established as a useful tool in the surgeon's armamentarium. Jackson standardized the technique and indications for the operation, and demonstrated that with attention to a few key technical details, the morbidity and mortality from the procedure could be dramatically reduced to acceptable levels. He emphasized the importance of a long incision, avoidance of the cricoid cartilage, routine division of the thyroid isthmus, slow and careful surgery, use of a proper cannula, and meticulous postoperative care. Of the latter, Jackson wrote that "after-care in tracheotomy cases is one of good plumbing, that is, keeping the pipes, both natural and artificial, clear of obstruction. Air must be piped not merely into the trachea, but also into the lungs, and it must be the constant duty of someone to know by seeing, feeling, and hearing that it gets there." Jackson's thoughtful advice was in large part responsible for reducing the mortality of tracheotomy to less than 2% and reducing the incidence of laryngeal stenosis, particularly in children.

Indications for Tracheotomy

In most instances, ET intubation is used for short-term airway protection and/or ventilation. Over half of modern-day tracheostomies are performed on critically ill patients requiring prolonged mechanical ventilation. Other indications include pulmonary toilet, sleep apnea, chronic lung disease, primary alveolar hypoventilation syndrome (Ondine curse), and conditions requiring home mechanical ventilation (23,24). The need to establish a surgical airway may become more emergent in upper airway obstruction from trauma, neoplasms, deep neck space infections, surgery, and foreign bodies (Table 64.11).

The primary objective of a tracheotomy is to secure an artificial airway. Over the years, the indications for tracheostomy have continued to change in parallel to the evolution of medicine. Current major indications for tracheotomy include (a) relief of upper airway obstruction (both acute and chronic), (b) providing a means for assisted mechanical ventilation, and (c) enabling more efficient tracheobronchial toilet (Table 64.11). The decision to carry out a tracheotomy must be carefully considered, weighing the relative advantages and risks of tracheotomy versus alternative methods of providing an artificial airway. Factors influencing the decision include the facilities of the institution, the skills of the personnel, the particular features of the patient's airway and respiratory physiology, and the specific disorder or disease process and its likely course (25).

Whenever possible, patients with upper airway obstruction should be managed initially by ET intubation in order to stabilize the airway and the patient's general condition. Extubation is often possible as the condition improves. Examples may include the management of acute epiglottitis in children or adults, and angioneurotic edema of the larynx.

Patients with upper airway obstruction, from laryngotracheal trauma or neoplasms of the upper aerodigestive tract, may be stabilized with ET intubation initially but are likely to require conversion to a tracheotomy. In children, tracheotomy may be necessary to protect the airway in

TABLE 64.11 INDICATIONS FOR TRACHEOTOMY

- Prolonged mechanical ventilation
- Pulmonary toilet
- Upper airway obstruction, acute or chronic

conditions such as laryngeal papillomatosis and subglottic hemangioma.

Tracheotomy is often necessary in patients with chronic upper airway obstruction. Examples include patients with nasal and craniofacial anomalies, such as Crouzon's disease, large nasal encephaloceles, Treacher-Collins syndrome, subglottic stenosis, and laryngeal and subglottic webs. Premature infants with respiratory insufficiency who require artificial ventilation for long periods are at risk for developing iatrogenic laryngeal or subglottic stenosis from chronic airway management.

Patients with central nervous system disorders, stroke, drug ingestion, or respiratory failure, who are anticipated to require prolonged ventilatory assistance, should undergo early conversion from ET intubation to tracheotomy to reduce the risk of laryngeal stenosis and other laryngeal complications from prolonged ET intubation.

Tracheotomy may facilitate management of patients who require ongoing pulmonary toilet. These include individuals with chronic obstructive pulmonary disease, adult respiratory distress syndrome, and crush injuries to the chest.

Surgical Airway Techniques

Cricothyrotomy

Cricothyrotomy is particularly useful when intubation is not possible, and tracheotomy cannot be performed because there are no landmarks, the trachea is below the manubrium (e.g., kyphoscoliosis), or there is a large mass such as a goiter obscuring the trachea. Contraindications to cricothyrotomy include laryngeal trauma and transection of the airway. It should not be performed in neonates or children because of the high risk of cricoid injury and subglottic stenosis. In practice, cricothyrotomy is used primarily by emergency room physicians and others with limited airway experience because it is relatively simple and rapid, with little tissue between skin and the airway. It is only very rarely used by otolaryngologists. The primary objective is to establish an airway. Once this has been accomplished, conversion to a tracheotomy between the second and third tracheal rings should be undertaken within 48 hours or as soon as the patient is stable in order to avoid subglottic stenosis.

Equipment necessary includes a 15-blade scalpel, hemostats, a tracheal or cricoid hook, tracheal dilator, and a small cannulating device such as a no. 4 or no. 6 tracheotomy tube (Fig. 64.9). If for any reason a tracheotomy tube is unavailable, a shortened ET tube or anything that can be connected to a bag-valve mask is appropriate. Preassembled kits for cricothyrotomy are also commercially available (Fig. 64.10).

Providing the C-spine has been cleared, the patient is positioned with a shoulder roll and the head is extended on the neck. A skin preparation solution is used only if time permits. Local anesthesia is used if the patient is awake

Figure 64.9 Equipment necessary for performing a cricothyrotomy. From *left to right*: 15 blade scalpel, hemostats, a tracheal or cricoid hook, tracheal dilator, and a small cannulating device such as a no. 4 or no. 6 tracheotomy tube.

or responsive; otherwise, it may waste valuable time. Next, the larynx is grasped and stabilized between the thumb and second and third fingers of the nondominant hand. A 15 blade scalpel is used to make a 3- to 4-cm vertical skin incision that extends slightly beyond the length of the cricothyroid membrane. The incision is deepened to expose the cricothyroid membrane. If necessary, a hook placed under the thyroid cartilage with upward traction may be used to improve exposure. Once identified, the membrane is incised horizontally closer to the superior border of the cricoid in order to avoid the cricothyroid vessels and vocal folds (Fig. 64.11). A tracheal dilator is then used to enlarge the aperture and permit insertion of the tracheal cannulation device (Fig. 64.12). If a tracheal dilator is not

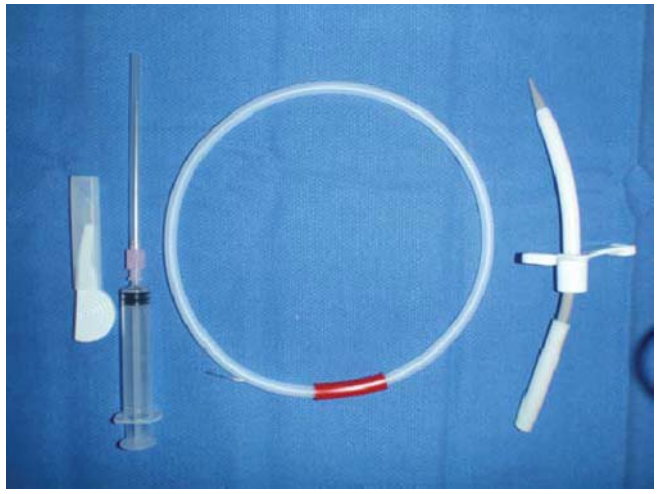

Figure 64.10 Example of preassembled commercially available kit (Cook) for cricothyrotomy: *left to right*: scalpel, syringe with 18-gauge introducer needle, J-wire, airway catheter preloaded with dilator.

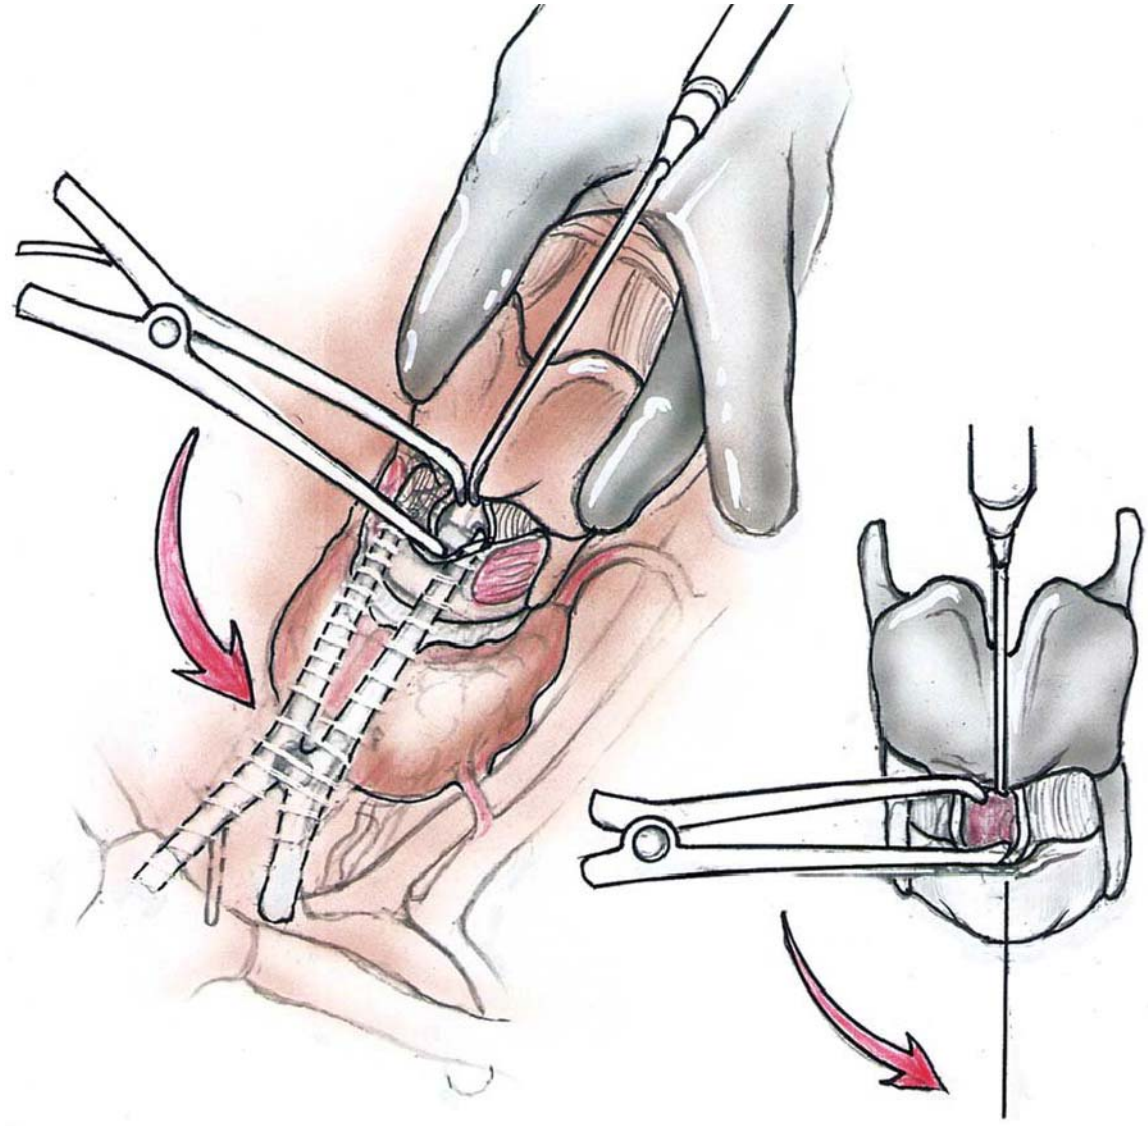
available, a Kelly clamp, hemostat, or mosquito may be used for the same purpose. Once inserted, the tracheal cannula is attached to a ventilating device, and the chest auscultated for breath sounds. The tube is secured with sutures and/or tapes as available (26).

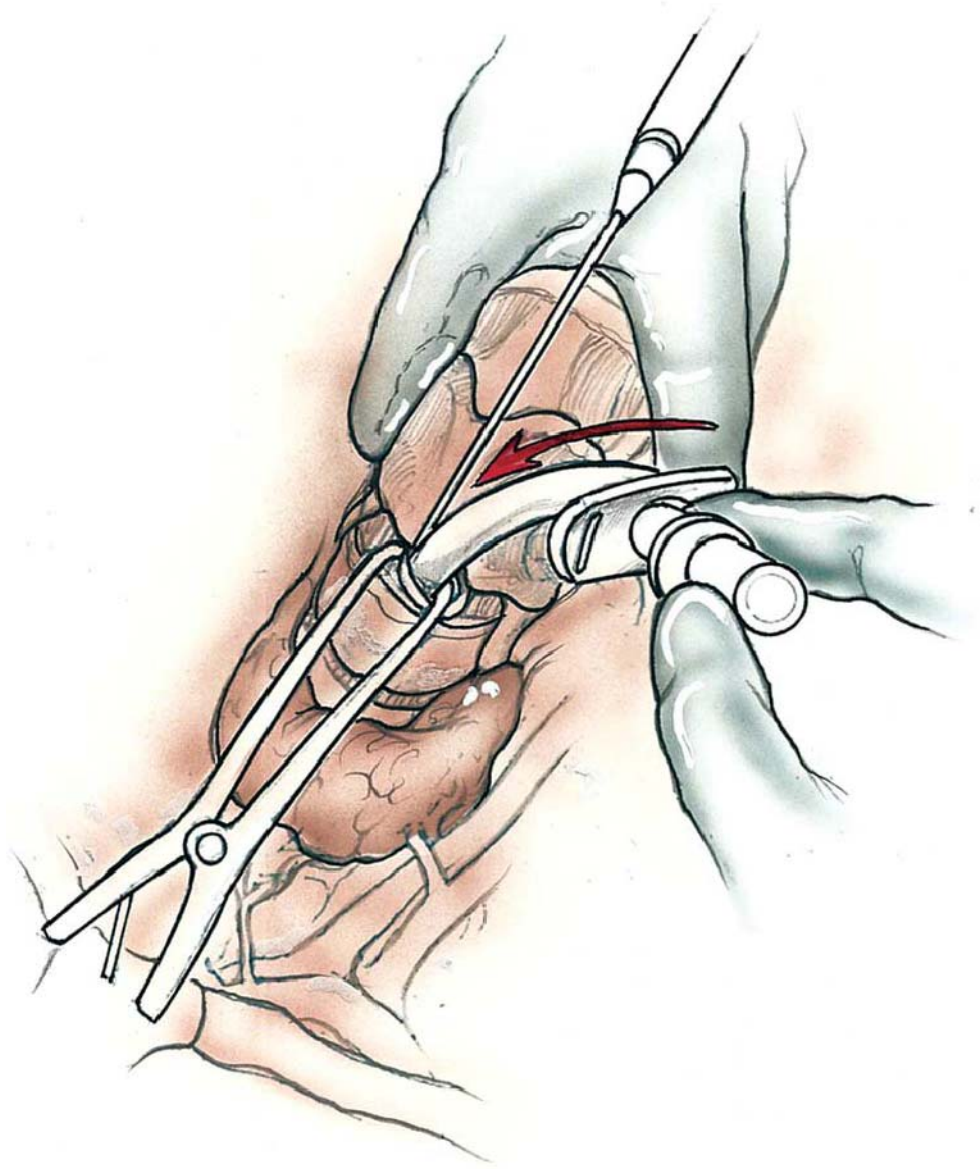
Complication rates range from 9% to 40% and vary as a function of patient anatomy and degree of technical comfort with the procedure. The most frequent complications include bleeding and tube misplacement. Bleeding is usually easily managed by direct pressure, use of a local hemostatic packing material such as Gelfoam or Surgicel, or by simply clamping and tying/suturing the offending vessel. Tube displacement/misplacement is a potentially fatal complication. Airway sounds must be verified at the time of tube insertion. Later, displacement of the tube into the pretracheal soft tissues may go unnoticed until the patient is hypoxic, suddenly requires high ventilation pressures, or develops massive subcutaneous emphysema. This is particularly likely in obese patients. Other complications include injury to the recurrent laryngeal nerve(s), vocal folds, the posterior tracheal wall, and the thyroid or cricoid cartilages. Pneumothorax and pneumomediastinum are usually the result of barotrauma from ventilation. Late complications such as dysphagia, dysphonia, infection, and subglottic stenosis occur in up to 50% of patients not converted to tracheotomy in a timely fashion (26).



Emergency Tracheotomy

Emergency bedside open tracheotomy is required in the most dire circumstances as a life-saving measure, when other options such as intubation or tracheotomy in the OR are not available or suitable. Situations involving severe facial or laryngeal trauma may make intubation an unsuitable, even dangerous choice. Indications for emergency bedside tracheotomy are rare, and include impending or actual cardiac or cardiorespiratory arrest from airway obstruction. Because death from anoxia occurs in approximately 5 minutes, an emergency tracheotomy must be performed very quickly, yet safely, in a less than ideal setting.

The surgeon should therefore be focused on establishing the airway. Other tasks such as establishing intravenous access, administering medications, and placing a mask with oxygen should be delegated.



Every emergency room should have a preassembled, easily available tray with the instruments required for a tracheotomy (Table 64.12). The tray should be placed next to the surgeon and the essential instruments laid out in a near-to-far sequence: a 15 blade scalpel, swabs on clamps, retractors (if available), a self-retaining retractor, mosquitos, cricoid hook(s), an 11 blade scalpel for opening the trachea (optional), a Trousseau or tracheal dilator, and two sizes of cuffed tracheostomy tubes (the estimated "ideal" size, and one smaller size) (Fig. 64.13). In the event that no such tray is available, the bare essentials include a blade, mosquito, and tube for the airway (tracheostomy tube, ET tube, etc.). If possible, another physician should assist; otherwise the nearest nurse or resident is recruited to help (27). No time should be wasted on a formal prep and drape or on setting up electrocautery if it is not immediately available.

Unless it is contraindicated, the patient is positioned with a makeshift shoulder roll and the head extended on the neck. The right-handed operator should be on the patient's right, and the assistant on the patient's left. If 180 degrees of the tracheal circumference is palpable, it is grasped and lifted; otherwise it is stabilized between the thumb and the index and third finger of the nonoperating hand. A midline vertical incision through the skin and platysma is made from just below the cricoid to

A

Figure 64.12 **A:** Cricothyrotomy: A tracheal hook is used to retract the thyroid cartilage superiorly, while a Trousseau dilator is inserted perpendicular to the trachea and then rotated inferiorly to enlarge the opening.

Figure 64.12 *(Continued)* **B:** A small tracheostomy tube is inserted.

TABLE 64.12 TECHNICAL TIPS FOR EMERGENCY TRACHEOTOMY

- Remain calm and focused on the task at hand
- Do not waste time on prep, cautery, or other tasks
- Minimum equipment includes a scalpel, mosquito, and airway cannula
- Stay midline
- Displace the thyroid isthmus superiorly or inferiorly, or incise it
- In difficult cases, find the airway with an 18-gauge needle on a 10-mL syringe and incise vertically above and below
- Use the tube size that will most easily fit
- Attend to hemostasis after the airway is safely established

the sternal notch. The assistant then grasps the trachea between the thumb and ring finger, leaving the index and middle finger to spread the incision (Fig. 64.14). The assistant's free hand is used to sponge or tamponade bleeding. The operator then incises through the midline raphe of the strap muscles and positions the self-retaining retractor between the strap muscles. The pretracheal space and the thyroid are now exposed. If possible, the thyroid is displaced superiorly or inferiorly to expose the trachea. Otherwise, the isthmus is divided between a mosquito placed on the contralateral side and a second mosquito placed on the ipsilateral side. If possible the ends are tied. The assistant then lifts the trachea upward with one or two hooks, and an 11 blade scalpel is used to incise the

Figure 64.13 Equipment necessary for performing an emergency tracheotomy. From *left to right*: 15 blade scalpel, swabs on clamps, retractors (if available), a self-retaining retractor, mosquitos, a cricoids hook, an 11 blade scalpel for opening the trachea (optional—not shown), a Trousseau or tracheal dilator, and two sizes of cuffed tracheostomy tubes.

membrane between the second and third rings. Tracheal retention sutures are generally not used because of time constraints. A mosquito is used to spread the opening first vertically then horizontally. The mosquito is exchanged for a tracheal dilator through which the tracheostomy tube is inserted. The tube should be held at 90 degrees to the trachea, with the tip perpendicular to the opening for insertion. With the tip of the tube in the tracheal lumen, the tube is rotated to lie parallel with the trachea as it is completely inserted (Fig. 64.15). The cuff is inflated and the tube immediately attached to an adaptor for ventilation. Bleeding is then controlled with ties, clips, or sutures as necessary. Cautery should be avoided because of the high oxygen concentration in the area and consequent risk of fire (27).

In some cases, identification of the airway may be very difficult because of preexisting conditions such as scarring, previous surgery and/or radiotherapy, a midline neck mass and kyphoscoliosis, all of which may completely obscure landmarks. In these situations, percutaneous ventilation

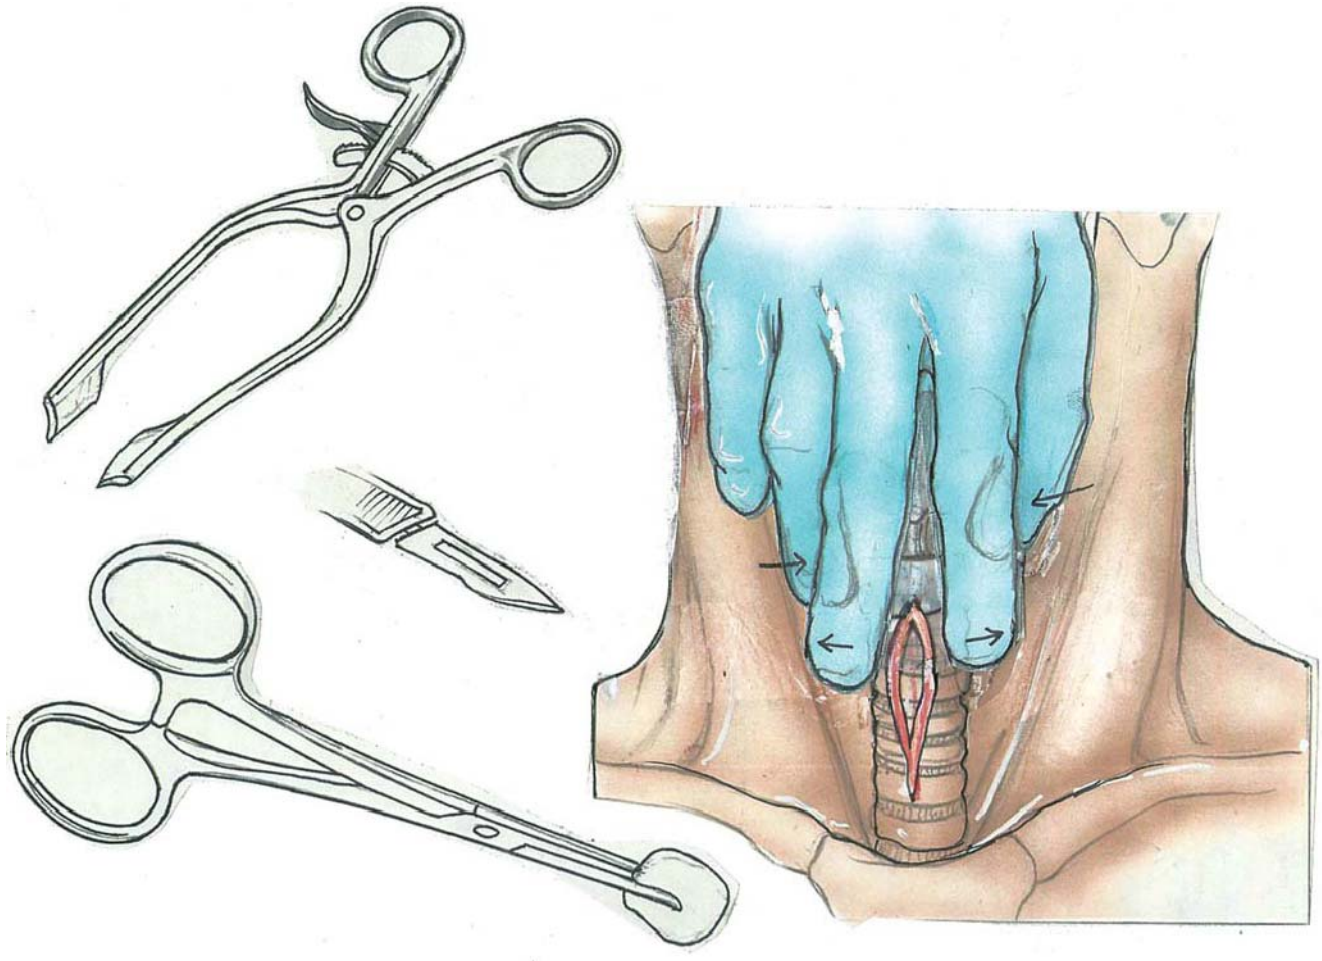

Figure 64.14 Emergency tracheotomy: position of hands during the initial dissection. The operator is on the right side and holds the scalpel with the operating hand and a self-retaining retractor with the non-operating hand. The assistant is on the left side and holds and raises the trachea with the thumb and ring fingers of the operating hand, reserving the index and middle fingers to spread the incision open; the non-operating hand is used to tamponade bleeding.

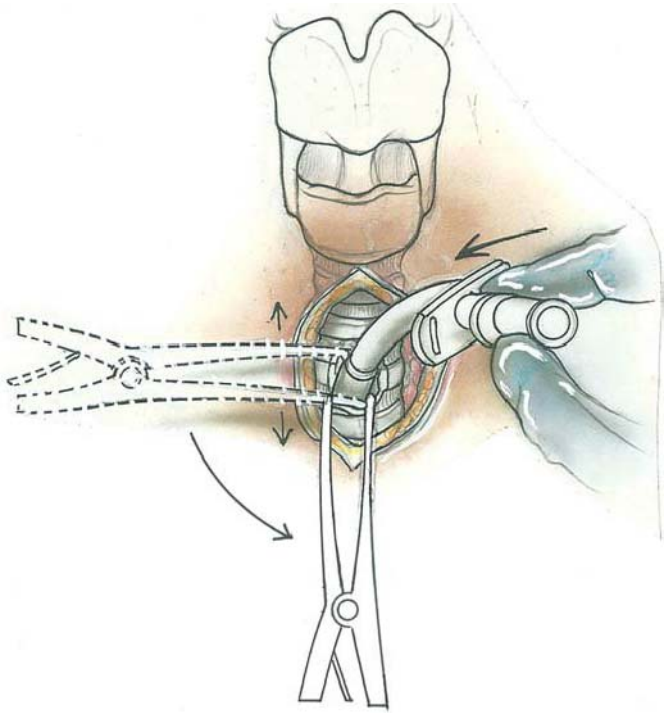

Figure 64.15 Emergency tracheotomy: The tracheostomy tube is first inserted perpendicular to the trachea; once in the trachea, it is rotated 90 degrees to the desired position.

through a transtracheal or cricothyroid puncture may buy time. If this is not possible, an 18-gauge needle attached to a syringe may be used to enter the trachea, with the position confirmed by the aspiration of air. A vertical incision made above and below the needle allows the mosquito, followed by the tracheal dilator, to sufficiently enlarge the opening for insertion of the tracheostomy tube.

The complication rate associated with emergency tracheotomies is significantly higher than that associated with "elective" tracheotomies. This being said, successfully accessing the airway is lifesaving. Adverse events may be dealt with when the patient is stable. Complications are fully discussed later in the chapter.

Open Surgical Tracheotomy

Preoperative Planning

Every effort should be made to optimize the patient's comorbidities prior to surgery. Coagulopathies should be corrected to an international normalized ratio (INR) of less than 1.5, with greater than 50,000 functioning platelets. Cessation of aspirin or other nonsteroidal anti-inflammatory drugs for 7 days preoperatively is ideal but not absolutely necessary. Clopidogrel bisulfate (Plavix) is an antiplatelet agent that should also be discontinued 7 days prior to surgery if at all possible. Use of aspirin and clopidogrel bisulfate together is very common in patients who have had cardiac stent placement, strokes, and/or myocardial infarctions. Patients on both drugs have a higher incidence of perioperative bleeding and at least one of these agents should be stopped prior to tracheotomy. Patients on warfarin should stop the drug 5 days prior to surgery or should receive infusions of fresh frozen plasma or intravenous or oral vitamin K for rapid reversal of anticoagulation. A crossmatch should be obtained if the hemoglobin is less than 100.

Traditionally, tracheotomy has been performed in the OR, which is fully equipped with adequate lighting, suction, and assistance. Admitted patients as well as those from the emergency room are best transferred to the controlled, monitored setting of the OR whenever possible. Adult, intubated patients in the intensive care unit (ICU) may undergo tracheotomy (open or percutaneous) safely either at the bedside (28–30) or in the OR (31,32) with comparable complication rates.

The anesthesia team plays an important role during the procedure monitoring the airway and vital signs and keeping the patient stable. Patients suffering from chronic respiratory insufficiency and high CO_2 levels may lose their respiratory drive or even develop pulmonary edema once the airway has been established with a tracheotomy. Support in the form of assisted ventilation and appropriate pharmacologic intervention is usually sufficient although cardiopulmonary resuscitation may be necessary in severe cases.

The choice of tracheostomy tube is important. The purpose of a tracheostomy tube is (a) to provide an airway, (b) to provide for the possibility of mechanical positive-pressure ventilation if needed, (c) to reduce the risk of aspiration by sealing the trachea, and (d) to provide a means of suctioning the tracheobronchial tree (14). Factors influencing tube selection include the shape of the tube and the neck plate. If a cuffed tube is necessary, it should be a

RMSE: 0.4 cm

low-pressure, high-volume cuff to reduce the possibility of tracheal stenosis. Tubes with an inner cannula provide an added measure of safety in that the inner cannula can be quickly removed in the event of a mucus plug, leaving the open outer cannula *in situ* and the airway protected.

Preoperative planning should also account for the need for any special type of tracheostomy tube. For instance, obese patients with thick pretracheal soft tissues are likely to require extended-length tubes to decrease the risk of accidental decannulation or tube displacement. It has been shown that pretracheal soft tissue thickness (Table 64.13) can be reliably predicted within 4 mm in obese patients as a function of neck and arm circumference (33). Using Table 64.13, it can be seen that a patient with a neck circumference of 55 cm and an arm circumference of 50 cm would have a pretracheal soft tissue thickness of 3 cm. A proximally extended tracheostomy tube would be required in this patient since "standard" tubes have a much shorter proximal length. It should be noted that tracheostomy tubes with either proximal or distal extensions are available. Tubes with adjustable flanges and those made of softer, thermolabile materials for anatomically difficult necks or tracheas are also available. Choosing the correct tracheostomy tube preoperatively is helpful in decreasing postoperative complications such as accidental decannulation, skin maceration/infection, granulation tissue, and tracheitis, all of which may be related to ill-fitting tubes.

In order to avoid surprises, it is imperative to examine the patient preoperatively with particular attention to the neck. The presence of a midline neck mass or high innominate artery may necessitate modification of the level of incision or entry into the trachea, or both. Patients who have undergone prior surgery or radiotherapy to the neck may have scarred, fibrotic, indurated tissue that precludes the ability to identify any landmarks. In these cases, slow, careful, midline dissection prevents injury to adjacent structures such as the carotid artery and allows identification of the airway. Patients with severe cervical osteoarthritis, kyphoscoliosis, or other conditions, in whom the neck cannot be hyperextended, present a formidable surgical challenge. In these situations, meticulous midline dissection with maximal upward traction on the cricoid may help pull the trachea into the accessible portion of the neck.

Surgical Technique

The patient is placed on the operating table with a rolled towel or sheet under the shoulders to extend the neck unless the patient has documented or suspected cervical spine injuries. In such cases, extension of the neck is contraindicated because of the risk of spinal cord compression. Adults with airway obstruction may not be able to tolerate the supine position, and tracheotomy may need to be performed with the patient sitting up at 45 degrees. The use of local or general anesthesia must be dictated by the circumstances. Patients with a marginal airway and respiratory distress should be managed with local anesthesia alone without sedation, for fear of suppressing the respiratory drive. In more elective situations with a protected or airway, either general anesthesia or local anesthesia with intravenous sedation may be appropriate. In children, the procedure is typically carried out under general anesthesia.

The neck, face, upper chest, and shoulders are prepared with a povidone-iodine (Betadine) or other suitable solution, and appropriately draped to allow easy access to the neck. The cricoid cartilage and sternal notch are identified and the incision site is determined. Lidocaine (Xylocaine) 1% with 1:100,000 epinephrine is injected into the skin and subcutaneous tissue at the incision site; this maneuver results in vasoconstriction and decreases cutaneous bleeding.

A transverse incision is made approximately 1 cm above the suprasternal notch or 2 cm below the cricoid cartilage. Sharp dissection is carried through the subcutaneous tissue and platysma. Exposure may be achieved with self-retaining retractors or four small rake retractors.

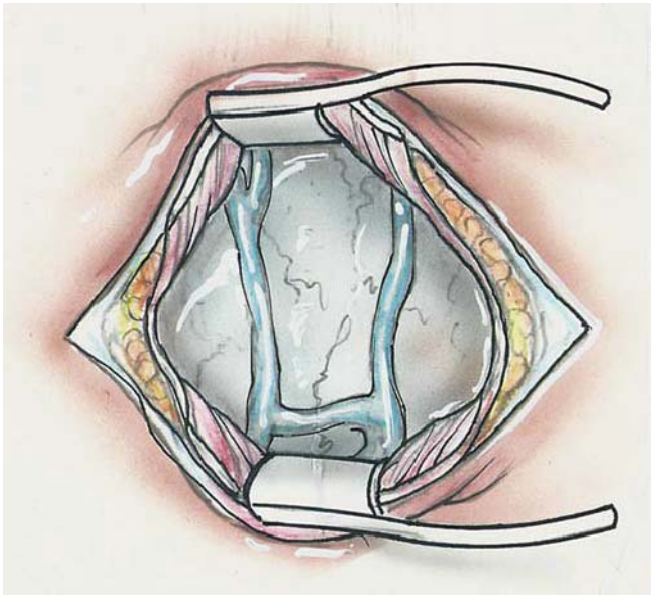

Figure 64.16 Incision extends through the platysma to expose the anterior jugular veins and the fascia overlying the strap muscles.

The anterior jugular vein(s) should be identified and retracted laterally (Fig. 64.16). It is not necessary to ligate these vessels unless they are inadvertently cut or injured, or there is a midline communicating branch. The strap muscles are divided in the midline and retracted laterally (Fig. 64.17A). The thyroid isthmus is visualized and the anterior wall of the trachea identified (Fig. 64.17B). In adults, the thyroid isthmus can often be retracted superiorly and the trachea entered (Fig. 64.17C). If the trachea cannot be exposed otherwise, the isthmus is undermined, clamped on each side with hemostats or Kelly clamps, transected, and ligated with 2-0 silk or Vicryl sutures on a cutting needle. In patients with a very thin or fatty thyroid, the isthmus may be divided with electrocautery. In patients under local anesthesia, it is important to inject additional lidocaine in the paratracheal tissues prior to opening the trachea in order to obtain effective anesthesia. Once the trachea is identified, a tracheal hook is placed under the cricoid or in the area of the second tracheal ring and secured by an assistant to immobilize the trachea in the wound. It is important to enter the trachea with a scalpel; electrocautery should be avoided because of the risk of airway fire. In infants and children, a vertical incision is made through the second and the third or the third and the fourth tracheal rings without removing any cartilage. Traction sutures are then placed just lateral to the incision (Fig. 64.18).

In adults, the anterior portion of the second, third, or fourth tracheal ring may be removed to facilitate insertion of the tracheostomy tube. In most older patients, the tracheal ring will be calcified, and heavy scissors must be used to excise a small portion of the tracheal ring after transverse cuts have been made in the area just above and below the tracheal ring. This maneuver effectively leaves a rectangular window in the trachea (Fig. 64.19). If necessary, the opening may be enlarged by removing additional cartilage with a Kerrison rongeur. Removal of the anterior aspect of the tracheal ring ensures that the cannula is placed in the trachea rather than in a false passage anterior to the trachea (24).

Traction sutures are placed to reduce the possibility of creating a false passage in the event that the tracheostomy tube becomes displaced in the immediate postoperative period before a tract has been formed. These are more easily placed in the trachea with a ligature carrier loaded with 2-0 silk (Fig. 64.20) rather than with a curved needle. While the tracheal hook retracts the trachea inferiorly, the ligature carrier is passed through the interspace just above the ring superior to the stoma and into the lumen, with care taken not to penetrate the posterior tracheal wall. A small, curved clamp is used to grasp the suture and to stabilize it while the ligature carrier is removed. A similar procedure is carried out inferiorly. Alternatively, traction sutures may also be placed in the lateral tracheal wall. The traction sutures are then tied and fixed to the skin of the chest with adhesive tape.

With the cricoid or tracheal hook still in place, the tracheostomy tube may be introduced either by pulling on the traction sutures to "exteriorize" the trachea or by inserting a Trousseau dilator into the tracheal opening. Once the tracheal opening is satisfactorily exposed, the cannula may be introduced into the stoma. This is begun with the cannula at right angles to the trachea; then, as the cannula is inserted, it is turned so that its axis is parallel to that of the trachea (Fig. 64.21A). This eliminates the difficulty encountered in trying to pass the cannula over the patient's chest. An obturator should always be utilized while the cannula is inserted. Once the cannula is properly placed in the trachea, the obturator is removed promptly and the inner cannula inserted. Once the tracheostomy tube is in place, and adequate ventilation through the tracheostomy tube is assured, the ET tube or bronchoscope utilized for stabilizing the airway may be removed.

The tracheostomy cannula is secured by suturing the neck plate to the skin and by tracheostomy tapes tied securely with a square knot with the neck flexed. Only one fingertip should be admitted between the tape and the patient's neck, and the tapes should be tied over the skin. Bulky dressings under neck tapes should be avoided as they compromise the stability of the tracheostomy tube in the early postoperative period and facilitate displacement, a potentially fatal complication. Neck tapes should be avoided completely if they lie over a regional or free flap because of the risk of compromising the blood supply. In these cases, the tube is secured only with sutures to the underlying skin (Fig. 64.21B).

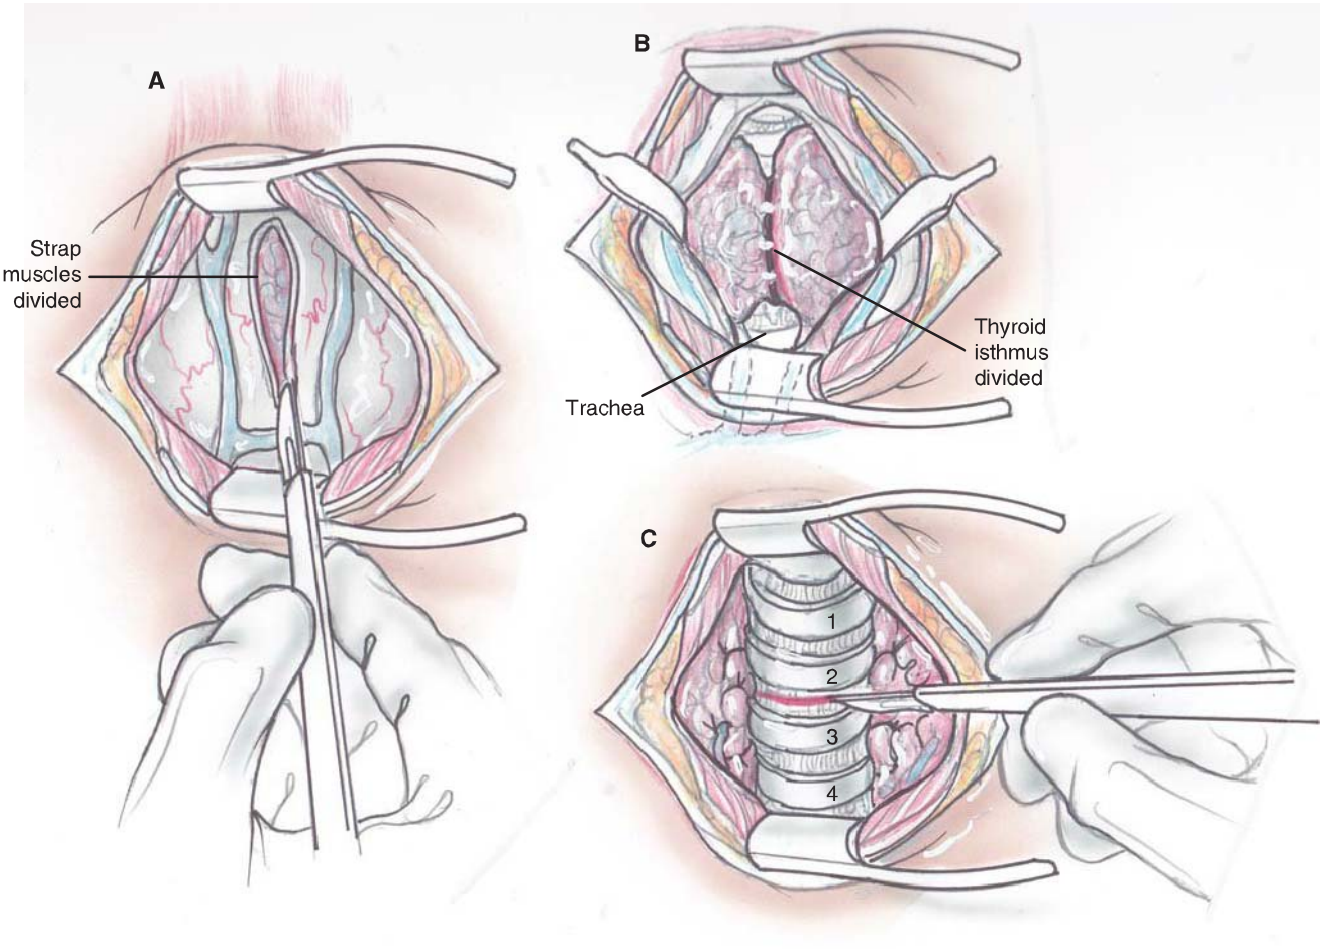

Figure 64.17 **A:** The strap muscles are divided along the midline raphe and retracted laterally. The trachea and thyroid gland are identified. **B:** The thyroid isthmus is retracted superiorly, or divided, as required. **C:** The first three or four tracheal rings are exposed. The trachea is entered between the first and second or second and third tracheal rings.

When tracheotomy is carried out under ideal circumstances, with enough time for vasoconstriction, bleeding is minimal. It is important to secure all bleeding points, with either ligatures or electrocautery, to prevent bleeding postoperatively. Caution should be exercised when using electrocautery close to the trachea because of the risk of airway fire. To reduce the possibility of this catastrophic event, the patient should be ventilated on the lowest possible oxygen concentration, and the trachea should never be entered with electrocautery.

A chest radiograph should be taken in the recovery room to rule out complications such as pneumothorax and pneumomediastinum.

Modifications of Tracheotomy

Several modifications of the "standard" tracheotomy technique have been described. The Bjork flap was originally described in 1960 as a means of facilitating tracheostomy tube reinsertion in the event of accidental decannulation in patients with difficult necks (34). This tracheal flap, which usually includes the second and third tracheal rings, is based inferiorly and is sutured to the inferior skin edge. In obese patients, the flap may not be long enough to reach the skin. In these cases, "defatting" the skin may be necessary to allow approximation of the tracheal flap to the skin. If the flap is not adequately sutured to the skin, it may be dislodged during attempted tube reinsertion and result in respiratory obstruction through a valve effect. The flap should not include more than two rings because of the subsequent risk of tracheomalacia or tracheostenosis.

The creation of a permanent stoma is more correctly referred to as a tracheostomy. It should be considered in patients in whom other options are not available or appropriate. Obstructive sleep apnea, progressive neuromuscular diseases, and severe laryngotracheal stenosis would be examples of conditions where tracheostomy is

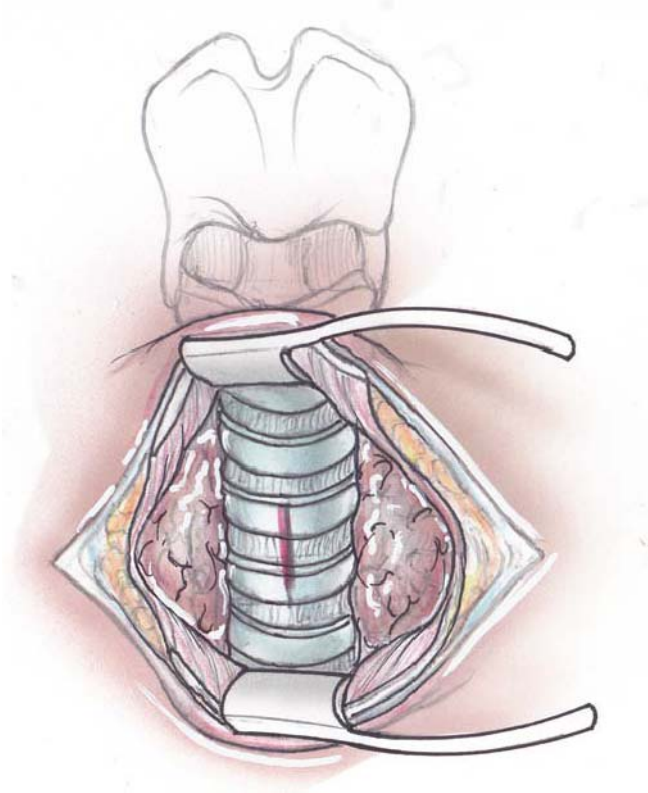

Figure 64.18 In infants and children, a vertical incision is made through the second and third or the third and fourth tracheal rings. No cartilage is removed. Traction sutures are then placed lateral to the incision.

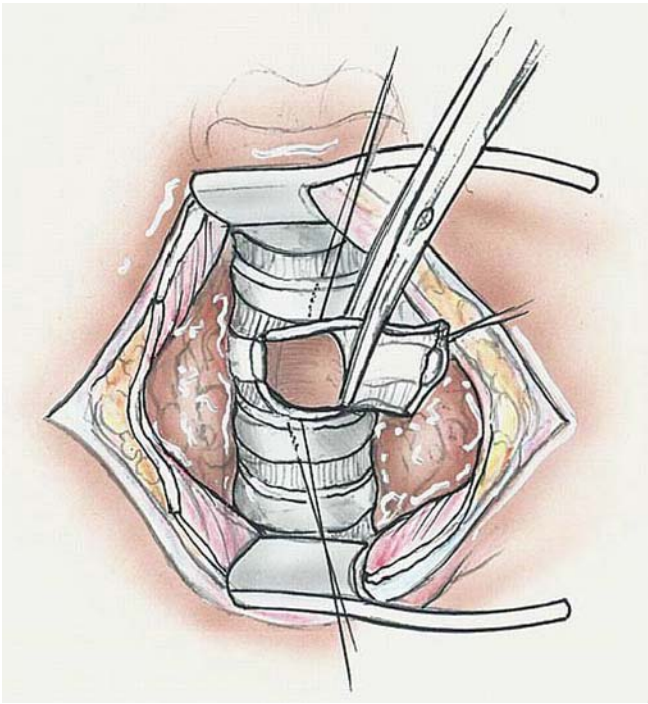

Figure 64.19 In adults, the anterior portion of the second, third, or fourth tracheal ring may be removed, leaving a rectangular window. Traction sutures may then be placed either laterally or superiorly and inferiorly.

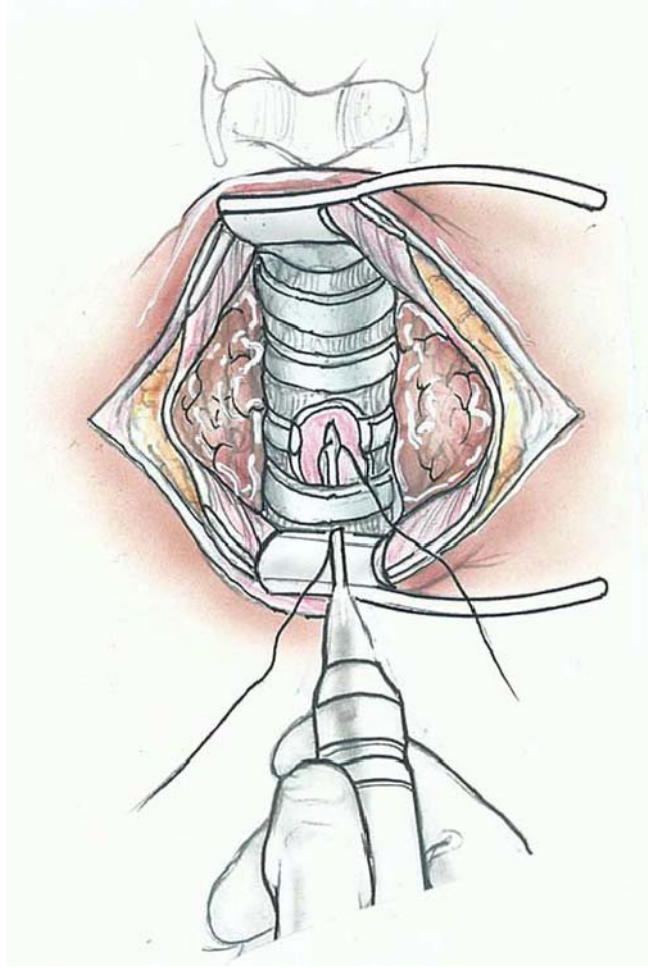

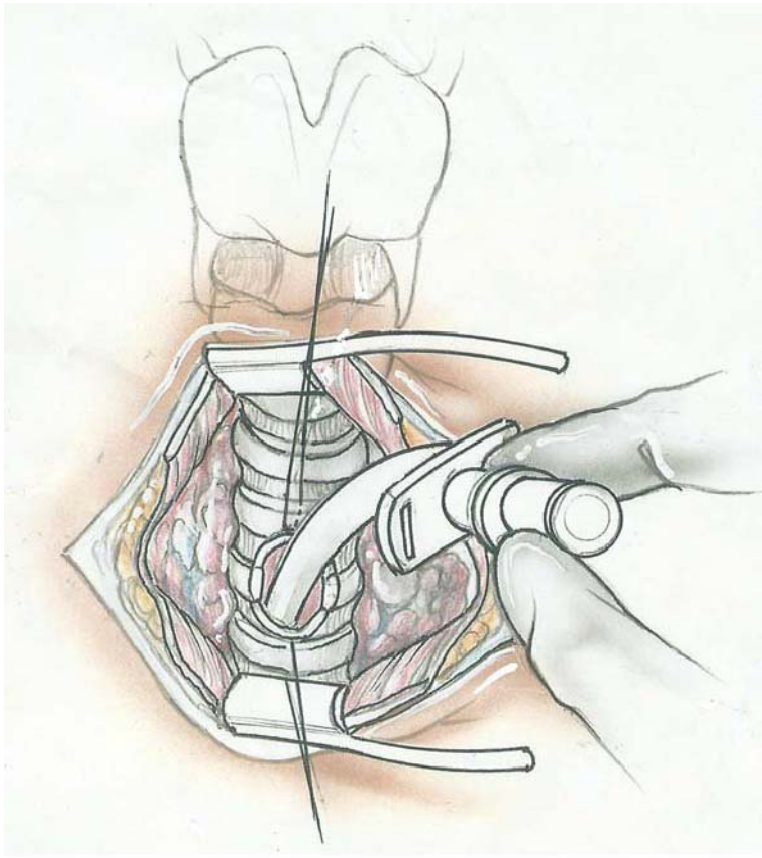

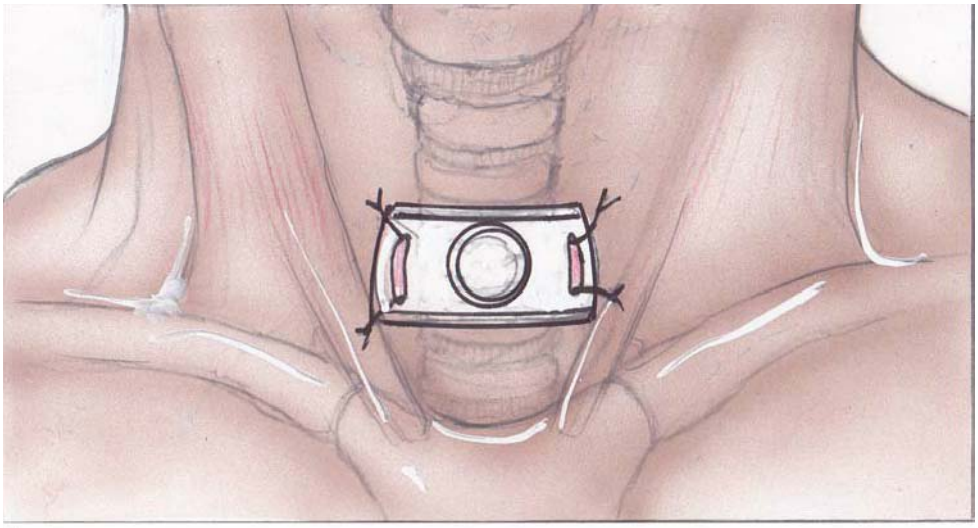

Figure 64.20 Traction sutures are placed in the trachea with a ligature carrier loaded with 2-0 silk.

likely to be needed for several years or perhaps even for life. The technique for surgically creating a permanent tracheostomy, along with additional modifications to allow for speaking, has been described by Eliachar (35). The procedure is surgically more complex than tracheotomy and involves suturing the mucosa of the trachea to skin circumferentially. An omega skin incision is made and carried down through the platysma, and subplatysmal flaps are elevated (Fig. 64.22). The strap muscles are separated along the median raphe, exposing the thyroid isthmus, which is divided and oversewn. The lobes are dissected off the anterior tracheal wall and anchored laterally to the ligament of the sternocleidomastoid muscle. With the anterior tracheal wall exposed, a superiorly based flap incorporating the second and third or third and fourth tracheal rings is created. This flap is securely sutured to an appropriately defatted superior skin edge (Fig. 64.23). The inferior skin flap must be elevated below the clavicles and then defatted to allow for a tension-free approximation to the inferior and lateral portions of the tracheal opening (Fig. 64.24). A cuffed tracheostomy tube is generally left

in position for the first 12 to 24 hours and then removed to allow healing between skin and tracheal mucosa. The more frequently reported complications include suture line dehiscence, granulation tissue, wound breakdown, and infection. Healing of the stoma is usually complete in 22 to 30 days, but can take as long as 40 days in patients who are obese or diabetic, as well as in those having received previous radiotherapy to the neck.

Postoperative Care

Postoperative care of the tracheotomy site is made considerably easier if there is the opportunity for preoperative teaching. Knowing what to expect helps both children and adults undergoing the procedure to adjust to this new way of breathing. Evidence indicates that patients undergoing tracheotomy experience a reduced quality of life (36). Appropriate teaching, family counseling, and

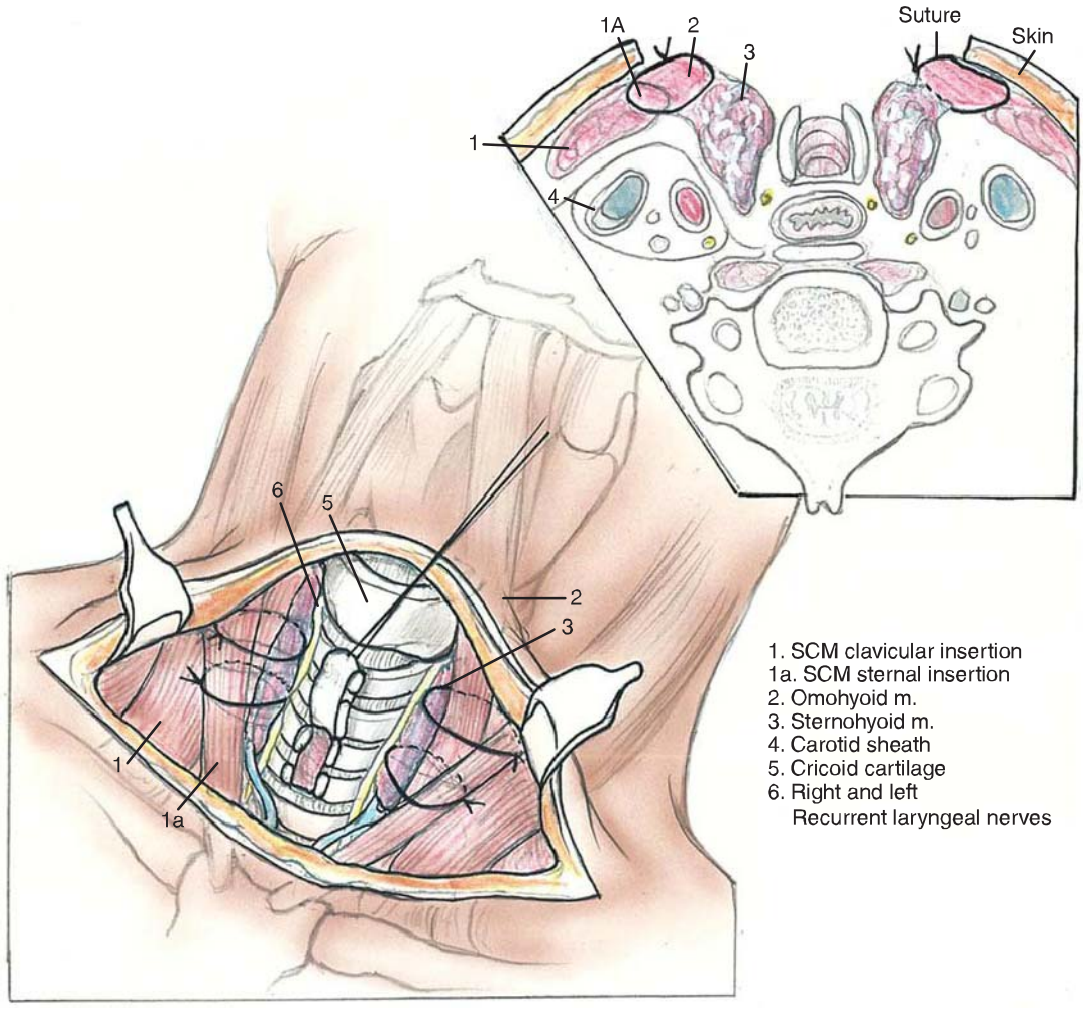

Figure 64.22 Note omega incision cresting over the cricoid cartilage. Generous subplatysmal flaps are raised superiorly and inferiorly. The anterior tracheal wall is completely exposed by suturing the thyroid lobes and strap muscles laterally to the sternal tendon of the sternocleidomastoid muscle. Customized to the patient's anatomy, a superiorly based anterior tracheal wall flap is elevated. **Inset:** Axial image of the thyroid lobes and strap muscles sutured to the tendon of the sternocleidomastoid muscle.

highly skilled nursing care are all key factors in reducing anxiety and ensuring a smooth postoperative course. Ideally, a multidisciplinary tracheotomy team involving a physician, nurse, respiratory therapist, and speech-language pathologist should be intimately involved in posttracheotomy care. Each member of the team plays a critical role in coordinating and delivering the complex care tracheotomy patients require (37). The team assists with wound care, tracheotomy tube changes, deglutition, communication, decannulation, and teaching of the patient and caregivers. The presence of a multidisciplinary tracheotomy team produces measurable results in terms of decreased postoperative morbidity: the frequency of tube obstruction decreases, the use of speaking valves increases, and patients are decannulated more rapidly (38) (Table 64.14).

In the initial postoperative period, patients are placed in a semi-Fowler position to maximize the ease of coughing and deep breathing, to facilitate suctioning, and to minimize discomfort. Vital signs require frequent monitoring because changes in blood pressure, respiratory rate, or pulse rate may indicate a new or ongoing respiratory problem, or that the tube may be plugged or have come out of the trachea. Agitation, anxiety, and restlessness may all indicate hypoxia and should not be dismissed or treated with anxiolytics.

Tracheal suctioning is performed to maintain pulmonary toilet and patency of the tracheostomy tube. Initially, this should be done as aseptically as possible and may be necessary three to four times daily. Either a portable or a wall-suction unit may provide the negative pressure needed for suctioning. Patients on mechanical ventilation are at risk for hypoxia and cardiac arrhythmias during suctioning because oxygen-rich air is suctioned and catheters may be too large. This can be prevented by ventilating the patient on 100% O_2 for at least five breaths before and after suctioning, and limiting suctioning to less than or equal to 12 seconds with a small catheter. As an alternative to this

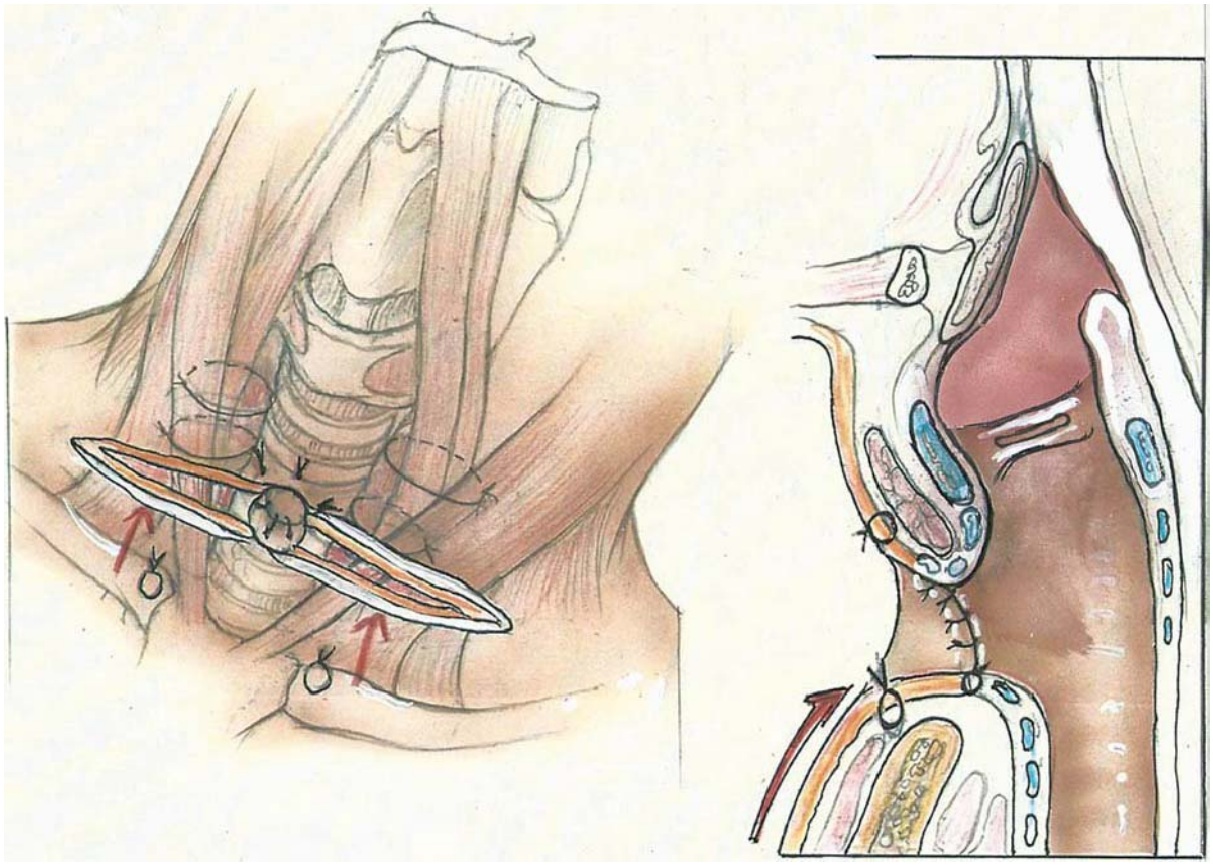

Figure 64.23 The superiorly based tracheal flap is sutured to the superior skin flap. The extensively undermined inferior flap is advanced and sutured to the lower edge of the trachea. "Suspensory" sutures may help support the flap. **Inset**: The upper and lower skin flaps are sutured to the trachea. Note the dimples from the supporting sutures on the lower flap.

open technique, a closed, multiple-use suction catheter contained within a sheath may be used (39). Similarly, in order to avoid mucus plugging of the tube, the inner cannula must be removed frequently for cleaning. Currently, inner cannulas are either disposable or reusable.

Humidification is extremely important in order to facilitate mucociliary transport of secretions and to prevent serious complications such as crusting, accumulation of secretions, and eventual obstruction of the airway. Humidification is usually carried out by a tracheal mask. The use of a T tube is avoided owing to the torque exerted on the tube, which traumatizes the tissue every time the patient moves.

Meticulous local wound care is of paramount importance. The tracheostomy site should be cleaned as necessary with normal saline or hydrogen peroxide to prevent breakdown of the skin and the progression from wound colonization to infection. Initially, this is likely to be three or four times daily. The twill tapes that hold the tracheostomy tube in place should be changed as necessary when soiled. The skin under the tracheostomy neck plate should be kept dry with a thin nonadherent dressing such as Telfa to prevent skin maceration. It takes at least 48 to 72 hours for a tract to form around the tracheotomy tube. Accordingly, the surgeon should avoid changing the tube until adhesions form between the overlying soft tissues and the trachea. Accidental decannulation in the early postoperative period can be very dangerous because the tissues collapse, sealing off the airway, and increasing the possibility of tube misplacement in a false passage when reinsertion is attempted (Fig. 64.25). Changing the tracheostomy tube requires skill and preparation, and early on it is not necessary unless the patient is to be changed from a cuffed to an uncuffed tube or if the cuff fails. Safe tube replacement in the first 48 hours requires the following (Table 64.15):

1. Optimal patient positioning
2. Assistance
3. Adequate light
4. Tracheal hook
5. Suction
6. Two tracheostomy tubes: ideal and smaller size
7. Tracheostomy tube exchanger

The use of a tracheostomy tube exchanger may be a very helpful adjunct for early tracheostomy tube changes. The exchanger is a long semiflexible tube with a central lumen through which ventilation is possible. The exchanger is inserted into the tracheostomy tube, which is then removed and replaced with the new tube. The exchanger "guides" the new tracheostomy tube into the trachea. If for any reason the new tracheostomy tube is difficult to

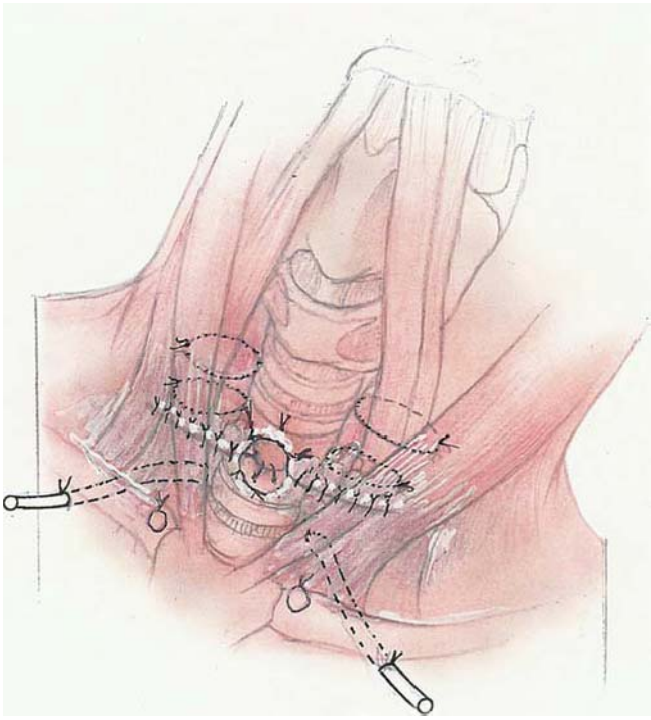

Figure 64.24 Final closure illustrating approximation of skin flaps to trachea. The laterally displaced thyroid and strap muscles are visualized through the skin. The suspension sutures supporting the lower flap can also be seen through the skin. Drains are brought out through separate stab wounds.

replace, ventilation may be temporarily continued through the exchanger.

Patients who do not require a cuffed tube may benefit from a Passy-Muir or speaking valve in the postoperative period. This one-way valve allows inspiration through the tracheostomy tube and closes on expiration, deflecting air through the vocal folds and permitting phonation. It has also been noted that these valves improve swallowing mechanics by restoring subglottic pressure, thereby facilitating deglutition. Contraindications for use of a speaking valve include (Table 64.16) a cuffed tracheostomy tube, upper airway obstruction, bilateral vocal fold paralysis, severe tracheal stenosis, copious inspissated secretions, and cognitive dysfunction.

Decannulation in adults can be safely accomplished by following a few simple steps. Indirect or flexible endoscopy should be used in both children and adults to ensure that the upper airway is adequate and the larynx is competent. Granulomas projecting into the stoma should be removed. The tube may then be downsized and plugged during waking hours. The period of plugging allows for adequate evaluation of airway adequacy. It also affords time for laryngeal adductor reflexes to be activated. The patient must be instructed to remove the plug in the event of dyspnea or shortness of breath. If the plug is not tolerated further, the nature of the obstruction must be investigated before further attempts at decannulation. If the patient tolerates the plug for 24 hours, the cannula can be removed and the stoma covered with a light dressing and occlusive tape,

which is changed as necessary. In the vast majority of cases, the stoma will close by secondary intention within a few days. The resultant scar from a transverse incision is cosmetically superior to that from a vertical incision.

Complications

Complications of tracheotomy may be divided into intraoperative, immediate postoperative, and late postoperative complications. The majority of complications are preventable and occur in the postoperative period. For admitted patients or airway emergencies, the surgery is best done in the controlled setting of the OR if possible. For those patients in respiratory distress, the airway should be secured whenever possible by insertion of an ET tube prior to proceeding to the OR. For adult intubated ICU patients, the procedure may also be safely performed at the bedside, provided adequate light, suction, and assistance are available.

Intraoperative Complications

Hemorrhage

Hemorrhage may be related to the patient ingesting anticoagulants, aspirin, or other nonsteroidal anti-inflammatory agents. These may contribute to excessive bleeding during the procedure and in the immediate postoperative period. Patients with coagulation disorders, such as hemophilia, leukemia, and liver disease, may also have excessive bleeding. Every effort should be made to correct these problems preoperatively unless the situation is emergent, in which case correction may be undertaken during the procedure and the surgeon must be absolutely meticulous in controlling the bleeding (Table 64.17).

Bleeding during tracheotomy may be minimized by careful attention to detail. When using local anesthesia, the procedure should not be begun until adequate vasoconstriction has been achieved. Bleeding is usually minimized by staying in the midline with the dissection, being cautious to dissect layer by layer, and maintaining adequate light and assistance with retraction of the soft tissues. This is particularly important in the pediatric age group, where the great vessels are vulnerable because of their proximity to the surgical site. Bleeding from transection of the anterior jugular vein, or the thyroid isthmus, are possible and should be dealt with appropriately by identifying, ligating, or cauterizing the offending vessel. Careful preoperative examination allows identification of a high innominate artery possible and injury preventable. In the unlikely event of injury to the innominate artery, repair requires the expertise of a vascular surgeon. Introduction of the tracheal cannula may cause a paroxysm of coughing, and bleeding may occur at that time. Retraction, suction, and lighting will facilitate identification and ligation of the involved vessel. Packing should be avoided because extravasation of air through the packing during coughing may predispose to subcutaneous emphysema.

Intraoperative Tracheoesophageal Fistula

Intraoperative tracheoesophageal fistula is unusual, but has been reported when the tracheal wall has been injured inadvertently, usually during an "urgent" tracheotomy with overpenetration of the trachea itself. If this is recognized at the time, it may be necessary to open the neck once the airway has been established and individually close the wounds in the trachea and the esophagus.

Pneumothorax

Pneumothorax is most likely to occur in a patient suffering from air hunger. It may also be due to direct puncturing of the pleura by the surgeon. This latter situation is most common in children, in whom the apex of the lung protrudes into the lower neck and is more vulnerable to injury. Pneumothorax may also occur when the tracheostomy tube is inserted between the anterior wall of the trachea and the soft tissues of the anterior mediastinum, creating a "false passage". This condition is much less likely to occur if the cannula is inserted with adequate exposure, retraction, and the use of traction sutures.

Pneumomediastinum

Pneumomediastinum occurs more commonly in children and is usually noted on routine postoperative chest radiographs. Predisposing factors include excessive dissection of the paratracheal soft tissues, breathing against an obstructed airway, and excessive coughing that forces air from the open tracheostomy into the deeper planes of the neck. Patients with pneumomediastinum are generally asymptomatic, and no therapy is required.

Postobstructive Pulmonary Edema

Cardiopulmonary arrest may occur in patients who have had chronic air hunger and elevated CO_2 levels. Sudden

TABLE 64.17 INTRAOPERATIVE COMPLICATIONS

- Postobstructive pulmonary edema

relief of chronic upper airway obstruction may also result in congestive heart failure and pulmonary edema. This occurs from extravasation of fluid into alveoli from the sudden reduction of obstruction-induced PEEP. This possibility should be discussed with anesthesia in the event that cardiopulmonary resuscitation is necessary.

Fire

Fire during tracheostomy is a rare but catastrophic event. External burns may result from the use of electrocautery shortly after prepping the skin with alcohol-containing solutions. This is of particular concern in hirsute patients, in whom body hair interferes with the drying of the solution. Therefore, every effort should be made to ensure that the operative field is completely dry prior to electrocautery use, or the solutions should be avoided when possible.

Fire may also occur when using electrocautery in the presence of high concentrations of oxygen, whether delivered by mask (as in local procedures) or via the ET tube under general anesthesia. Oxygen concentrations should be kept at a minimum safe concentration for the patient, and cautery should never be used to enter the airway. In the unfortunate instance of an airway fire, the immediate response includes turning off the oxygen, changing the ET tube, and the use of water in the field, followed by bronchoscopy to assess the extent of injury. Medical treatment consists of antibiotics, steroids, and observation in the ICU. The best treatment consists of instituting all measures necessary to prevent such events.

Immediate Postoperative Complications

Tube Obstruction

Tube obstruction, a potentially fatal complication, may be caused by thick mucus or blood clots. This problem is largely preventable with attentive nursing care, proper humidification, and frequent suctioning. Routine use of a tracheostomy tube with an inner cannula allows regular inspection, cleansing, and suctioning. If for some reason the obstructed tube cannot be cleared, it should be removed and replaced (Table 64.18).

Displaced Tracheostomy Tube

Displacement of the tracheostomy tube may occur at any time and is potentially fatal (Fig. 64.25). This complication is most dangerous in the immediate postoperative period before a tract has formed in the soft tissues around the tracheostomy tube. Obese patients are particularly vulnerable to tube displacement because of the inadequate length of standard tracheostomy tubes. Insertion of an extended length tracheostomy tube at the time of surgery largely prevents this problem. Other patient factors that may predispose to displacement of the tube include excessive coughing and agitation. Additional factors include incorrect placement of the opening into the trachea, creating a false passage, loosening of the neck tapes as a result of resolution of subcutaneous emphysema, poorly tied tracheotomy tapes, failure to suture the neck plate to the skin, and use of bulky dressings.

Displacement of the tracheostomy tube should be suspected when a patient with a fresh tracheotomy develops respiratory distress or is suddenly able to speak. Tube displacement may be managed by one of two ways. (a) Reinserting the tracheostomy tube: pulling on the previously placed traction sutures and then returning the sutures to a position parallel to the patient's neck. This effectively retracts the skin and helps bring the stoma into the wound. A tracheal hook, if available, may further improve visualization of the tracheal opening. The tracheostomy tube is then inserted and adequate ventilation verified. (b) If reinserting the tube fails, is deemed too difficult, or if a patient is known to have difficult anatomy, it may be best to secure the airway by reintubating the patient and later identifying and opening the tracheostomy tract.

TABLE 64.18 EARLY POSTOPERATIVE COMPLICATIONS

- Tube obstruction
- Displaced tracheostomy tube
- Postoperative hemorrhage
- Wound infection
- Subcutaneous emphysema

Postoperative Hemorrhage

Postoperative bleeding may occur when the vasoconstriction from the epinephrine wears off or if vessels that were injured during surgery were not ligated and/or cauterized. Treatment requires identification and ligation of vessels. For "oozing," use of a hemostatic packing such as Surgicel may be helpful. Coagulopathies should be identified and corrected. If there is significant bleeding, and visualization at the bedside is difficult, the patient should be returned to the OR, the wound explored, and hemostasis secured.

Wound Infection

The tracheal wound is colonized within 24 to 48 hours by many species of organisms, including *Pseudomonas* and *Escherichia coli*, as well as Gram-positive cocci (40,41). It is not possible to prevent colonization. Tracheostomy tubes are also colonized by bacteria such as *Staphylococcus epidermidis*, which are imbedded in biofilm. The longer the tube is in place, the heavier the load of biofilm. This biofilm functions as a "coat of armor" of sorts, effectively protecting bacteria from local and/or systemic antibiotics. A true infection of the tracheal stoma is uncommon. Antibiotics simply select for colonization by a resistant organism and should not be used. Regular tracheostomy tube changes every 2 weeks for admitted patients may decrease the incidence of granulation tissue and biofilm formation (40).

The fundamental principles of tracheotomy wound care consist of meticulous hygiene with suctioning, cleansing,

dressing and tie changes, and tube changes when necessary to remove crusts and necrotic debris, thereby reducing bacterial load. Traction sutures should be removed when the tract has formed (3 to 4 days). True infection with surrounding cellulitis is unusual and should be treated with organism-specific antibiotics as well as aggressive local wound care with debridement.

Tracheobronchitis may be due to underlying disease or aspiration, or both. Treatment is with suctioning, vigorous pulmonary exercise (blow bottles, cupping and clapping, ambulation), and judicious administration of antibiotics.

Rarely, necrotizing stomal infections may occur, with substantial loss of soft tissue down to and including the tracheal wall. Further progression of the process may result in carotid artery exposure, with its attendant risks. Management includes aggressive wound debridement and cleaning with antiseptic dressings as well as culture-guided antibiotics. Rarely, local flaps may be necessary to provide soft tissue coverage to vital structures.

Subcutaneous Emphysema

Air may be forced into the subcutaneous tissues during or shortly after tracheotomy. Factors predisposing to this complication include excessive coughing, use of an uncuffed tracheostomy tube, tight suturing of the wound around the tracheostomy tube, and packing of the wound. Emphysema is usually mild and may be diagnosed by palpating crepitus in the tissues of the neck, chest, or face. Subcutaneous emphysema is generally prevented by using a cuffed tracheostomy tube and not packing the wound. If the condition is severe, the wound should be opened and any packing removed. Otherwise, no treatment is necessary because the air is slowly absorbed from the tissues.

Late Postoperative Complications

Granulation Tissue

Granulation tissue is considered to be a late complication or sequela of tracheostomy, variably reported as occurring in 3% to 80% of cases (40). It is commonly seen in children, especially those in whom a fenestrated tube has been used. The clinical importance of granulation tissue lies in its ability to bleed, complicate tracheostomy tube changes, delay attempts at decannulation, and completely obstruct the tracheostomy tube with potentially catastrophic results. Factors thought to favor formation of granulation tissue include bacterial infection, gastroesophageal reflux, suture material, and powder from surgical gloves. Although a number of topical treatments such as steroid creams, antibiotic ointments and silver nitrate have been suggested, larger amounts of granulation tissue, particularly when obstructive, may require surgical excision, with or without the use of laser (Table 64.19).

The prolonged presence of the same tracheostomy tube, which is a foreign body, elicits an inflammatory tissue response favoring the growth of granulation tissue, increased secretions, and bacterial colonization with biofilm production (16). Regular tube changes on a schedule of every 2 to 3 weeks have been shown to dramatically reduce the incidence of this problem (40).

TABLE 64.19 LATE POSTOPERATIVE COMPLICATIONS

- Granulation tissue
- Tracheoesophageal fistula
- Tracheoinnominate artery rupture
- Tracheal stenosis and tracheomalacia
- Tracheocutaneous fistula
- Depressed scar

Tracheoesophageal Fistula

Late tracheoesophageal fistula is rare and may result from an overinflated or improperly fitted cuff. A malpositioned tracheostomy tube pushed to the posterior wall of the trachea against an indwelling nasogastric tube may also result in the formation of a fistula. Penetration of the posterior tracheal wall during surgery along with local infection may cause a tracheoesophageal fistula. Treatment consists of open repair with individual closure of the tracheal and esophageal defects, and interposition of soft tissue, such as muscle in the defect. Although the passage of food through the tracheostomy may be an indication of a tracheoesophageal fistula, it is more often a manifestation of aspiration. This can be confirmed on modified barium swallow.

Tracheoinnominate Artery Rupture

Rupture of the innominate artery usually occurs within the first 3 weeks after tracheotomy and may be fatal. This complication may occur in patients of any age and may be related to several factors: (a) placing the tracheostoma too low, below the third tracheal ring where the inferior concave surface of the cannula may erode the artery; (b) an aberrant or abnormally high innominate artery; (c) use of an excessively long or curved tube, with erosion of the tip through the trachea and into the vessel wall; (d) prolonged pressure on the tracheal wall by an inflated cuff; and (e) tracheal infection (42,43).

Rupture of the innominate artery is usually heralded by a "sentinel bleed," which may stop and be followed a few days later by a catastrophic hemorrhage. The patient coughs up bright red blood from the tracheostomy tube. If this sign is recognized, the cuff of the tracheostomy tube should immediately be overinflated and suprasternal pressure applied in an attempt to control the hemorrhage. If the inflated tracheostomy cuff does not prevent blood from entering the lungs, it can be changed for an ET tube that can be advanced to the desired level and the cuff inflated to control bleeding and prevent aspiration of blood. These maneuvers generally control the bleeding at least temporarily. The patient should be crossmatched and transported to the OR immediately, keeping continuous pressure

between the anterior trachea and sternum. Sternotomy and ligation of the innominate artery is a lifesaving maneuver.

Tracheal Stenosis and Tracheomalacia

Tracheal stenosis and tracheomalacia are late complications. Steps toward decreasing the occurrence of these sequelae include (a) proper placement of the tracheostomy tube between the first and third tracheal rings, (b) use of the smallest possible tube size, (c) minimizing cuff inflation pressures (less than 25 mm Hg), and (d) minimizing cuff inflation times.

Tracheocutaneous Fistula

Tracheocutaneous fistula is a persistent opening between the trachea and skin following decannulation. It occurs when there is inward growth of the skin to meet the trachea. It is more likely to occur in long-standing tracheotomies. Another less frequent cause is partial upper airway obstruction, in which case the fistula compensates for the compromised airway. This can be easily verified with an endoscopic exam prior to undertaking any repair of the fistula.

A persistent tracheocutaneous fistula results in the following problems: difficulty speaking or coughing without digital occlusion of the fistula, moist, macerated skin from mucus, and social embarrassment. Although the simplest repair consists of excising the skin within the fistula and allowing the wound to close by secondary intention, a depressed scar is likely to result. A better method entails removing a small ellipse of skin that includes the fistula. The skin is then dissected off the scar and widely undermined laterally. The strap muscles, which are scarred, are released from the trachea and reapproximated in the midline with absorbable sutures. This maneuver fills in the depressed area and separates the skin from the trachea. The skin is then closed and a light pressure dressing is applied to prevent air from escaping from the wound. Patients should be instructed to apply pressure to the area if they need to cough. The procedure requires general anesthesia in children but can be carried out under local anesthesia in the outpatient setting in adults.

Depressed Scar

A depressed scar is visible when the skin is adherent to the underlying trachea. Such scars are unsightly and draw attention because the skin moves with the trachea every time the patient swallows. They can be repaired under local anesthesia by excising the involved skin, widely undermining the edges of skin, freeing and reapproximating the intervening layer of scarred strap muscles, and closing the skin without tension.

Percutaneous Dilatational Tracheotomy in the Intensive Care Unit

Critically ill patients represent a special subset of the population by virtue of their multisystem disease and the complexity of the care they require. Tracheotomy is a frequently performed procedure in intubated ICU patients, and, not surprisingly, is associated with a higher risk (23). As such, special consideration is required in terms of indications, technique, and care. Moving these critically ill patients to the operating room with their monitors requires additional personnel and carries a number of different risks, including accidental extubation and vital sign changes requiring pharmacologic intervention (44,45).

Standard surgical tracheostomy (ST) at the bedside in the ICU is a reasonable option, with complication rates comparable to ST in the OR. This approach may be inconvenient, however, because of the need for special instrument trays, adequate suction, extra lighting, and electrocautery, which must be transported from the OR to the ICU. The lack of trained OR nurses and assistants as well as difficult visualization may compound the problem. Since most intubated, ventilated patients require an FiO_2 of greater than or equal to 30%, spontaneous ignition with the use of electrocautery is a real concern. Endoscopic percutaneous dilatational tracheotomy is an attractive alternative for patients in the ICU needing a tracheotomy because it is safe, simple, and can be performed at the bedside, reducing the need for OR time.

Seldinger's description in 1953 of catheter replacement of the needle in percutaneous anteriography over a guidewire served as a basis for the development of several percutaneous tracheotomy techniques. While many of these early procedures were quickly abandoned because of high complication rates, interest in this area persisted, and in 1985, when Ciaglia described a bedside percutaneous dilatational tracheotomy (18) technique, the procedure was rapidly adopted in many ICUs, principally by critical care physicians and anesthesiologists. The technique is based on progressive dilatation of an initial tracheal puncture. There were early concerns over safety because the procedure, as originally described, was blind. The addition of endoscopic guidance, first reported in 1990 in 61 patients by Marelli et al. (46), addressed the "blind aspect" of the procedure. Kost's series of 500 cases published in 2005 demonstrated that, with bronchoscopic visualization and attention to technical detail, endoscopic percutaneous dilatational tracheostomy (PDT) is a safe, cost-effective alternative to ST in the OR, with complication rates comparable to or lower than those of ST (47).

Cost analyses of PDT compared to ST in the OR almost uniformly agree that PDT is significantly less expensive (48). The results are more controversial when PDT is compared to ST at the bedside. Not all analyses include the cost of cleaning/sterilizing instruments, as well as the cost of the disposables associated with electrocautery (cautery tip, grounding pads). PDT is often said to be more costly because the kits are disposable and because of the added cost of bronchoscopy. While this may be correct for specific sets, several different kits are available, and the prices between them differ significantly.

Procedure time for PDT is reduced by up to 50% when compared to ST at the bedside. Although this should by no

means be the deciding factor in which technique to use, expediency when establishing an airway is advantageous.

PDT has been the subject of intense controversy, particularly in the Otolaryngology–Head and Neck Surgery community, for over a decade. The majority of published articles on the subject are from the specialties of critical care, anesthesia, and general surgery. Results from a recent survey of American residency training programs indicated that PDT was performed regularly in only 29% of Otolaryngology–Head and Neck Surgery programs. In the other 71%, program directors indicated their residents did not have the opportunity to learn PDT while on the Otolaryngology–Head and Neck Surgery service.

Patient Selection

It must be stressed that PDT is suitable only in adult intubated patients. This patient population accounts for almost two-thirds of all tracheostomies performed today (Tables 64.20 and 64.21).

Anatomical and medical suitability for this procedure must be determined preoperatively with a careful examination with the patient's neck extended (47,49). Contraindications to PDT (Table 64.21) include the inability to palpate the cricoid cartilage above the sternal notch, the presence of a midline neck mass or large thyroid gland, and a high innominate artery. Patients with these conditions should undergo ST in the OR. Coagulopathies are common in ICU patients and should be corrected as much as is medically safe preoperatively. Ideally, the number of functioning platelets should be greater than or equal to 50,000 and the INR should be corrected to less than or equal to 1.5. Patients requiring a PEEP of greater than or equal to 15 cm H_2O are at high risk for complications such as subcutaneous emphysema and pneumothorax and should undergo ST in the OR.

Nonintubated patients with acute airway compromise constitute an absolute contraindication to PDT. The procedure requires a secure airway for bronchoscopic visualization through an ET tube or LMA. PDT should never be attempted in children. The different airway dimensions and anatomy in the pediatric population as well as the technical difficulties of maintaining adequate ventilation with a bronchoscope within a small ET tube renders the procedure completely unsuitable in this age group (49). Patients having had a previous tracheostomy may undergo PDT safely if they have no other contraindications (47). Obese patients may also undergo PDT provided a proximally extended tracheostomy tube is used to reduce the risk of accidental decannulation.

TABLE 64.20 INDICATIONS FOR PERCUTANEOUS TRACHEOTOMY

- Adult intubated ICU patients

TABLE 64.21 CONTRAINDICATIONS FOR PERCUTANEOUS TRACHEOTOMY

- Unprotected airway
- Airway emergency
- Inability to palpate the cricoid cartilage
- Midline neck mass
- High innominate artery
- Children
- PEEP > 15 cm H_2O

Preoperative Planning

Preoperative testing is minimal and includes a recent chest radiograph as well as serum determination of hemoglobin, prothrombin time, partial thromboplastin time, INR, and platelets. Cross-matching is not necessary even in the presence of low hemoglobin levels. A fully equipped intubation cart should be available nearby in the event of accidental extubation during the procedure. Special consideration should be given to obese patients or those with a short thick neck. It must be emphasized that the presence of thick subcutaneous tissues in this group places them at particular risk for accidental decannulation. This potential problem may be circumvented by using a tracheostomy tube with a proximal extension (47).

As with all other minimally invasive techniques, there is a learning curve for endoscopic PDT. Familiarity with open surgical tracheotomy does not confer expertise to PDT, and appropriate training should be obtained prior to using the technique. Careful selection of patients with anatomically favorable necks for the first 30 to 40 patients allows the surgeon to gain experience and reduces the likelihood of complications.

Personnel

In addition to the attending staff surgeon, a resident or critical care colleague is required to perform the bronchoscopy, and a respiratory technician to assist in suctioning, adjust ventilator settings, and hold the ET tube firmly in position. A nurse is needed to administer medication, monitor vital signs, and help in obtaining necessary materials and instruments. The right-handed surgeon and necessary instruments are positioned to the patient's right, the respiratory technician and bronchoscope cart are to the patient's left, and the bronchoscopist is at the head of the bed.

Instruments

Currently, there are a number of commercially available kits that are similar in that they all create an initial tracheal puncture that is dilated to a size large enough to admit the preselected tracheostomy tube. Over the last decade, both the technique and instruments have been refined, and the process is continuing to evolve. The original kits contained a series of graduated dilators for progressive

dilatation. In the last several years, these graduated dilators have been replaced by a single sharply tapered dilator that simplifies the procedure. More recently, a new kit has been introduced in which the initial tracheal puncture is dilated with a pressure-controlled inflatable balloon. The purported advantage is that the balloon produces constant radial pressure on the trachea and does not cause depression of the anterosuperior wall. Although early data suggest the technique is safe, there are currently no studies to indicate it is superior. As such, selection of any particular kit is largely a question of preference.

The simplest and most thoroughly evaluated kit in North America is the Ciaglia Blue Rhino Percutaneous Introducer Kit (Cook Critical Care Inc., Bloomington, Indiana). The basic kit contains the following: a 15 blade scalpel, a 5-mL syringe, an introducer needle, a J-wire guide, an introducer dilator, a white guiding catheter, a sharply tapered single blue dilator with a hydrophilic coating, as well as 24-French, 26-French, and 28-French loading dilators (Fig. 64.26).

Other required instruments include a scalpel, curved hemostat, straight scissors, a needle driver, nonresorbable sutures, water-based lubricant, sterile saline to activate the hydrophilic coating of the single dilator, two 10-mL syringes, and an appropriately sized tracheostomy tube. The instruments should be placed on an instrument stand over the patient's bed and in the order in which they are to be used (Fig. 64.27). The preselected tracheostomy tube is fitted over the loading dilator: a no. 6 Shiley tracheostomy tube is fitted over the 26-French loading dilator while a no. 8 Shiley tracheostomy tube is fitted over the 28-French loading dilator. A no. 4 tracheostomy tube may be fitted over the 24-French loading dilator but is infrequently used. Shiley "Per-Fit" tracheostomy tubes are commercially available and have been specially designed and tapered to permit for easier insertion. The white guiding catheter is inserted into the single dilator such that the tip of the dilator rests on the ridge of the guiding catheter. An appropriately sized bronchoscope with a suction port must be chosen to fit within the ET tube while still allowing adequate ventilation. A pediatric bronchoscope may be required for ET tubes less than 7.5 mm. Almost any bronchoscope may be used in patients ventilated through an LMA. If available, a video monitor may be connected to the bronchoscope, allowing full visualization of the intratracheal portion of the procedure by the operating surgeon and assistant staff.

Anesthesia

Any procedure involving manipulation of the trachea is highly stimulating to the patient and requires adequate local anesthesia supplemented by intravenous sedation. Local anesthesia, consisting of 1% or 2% lidocaine with 1:100,000 epinephrine is used for generous infiltration of the incision site and pretracheal soft tissue. Topical anesthesia in the form of 2 mL of 2% to 4% lidocaine injected through the bronchoscope is useful in decreasing the cough reflex. Intravenous sedation is also required with the particular drug combination dependent on the needs of the individual patient and the institution. Frequently used

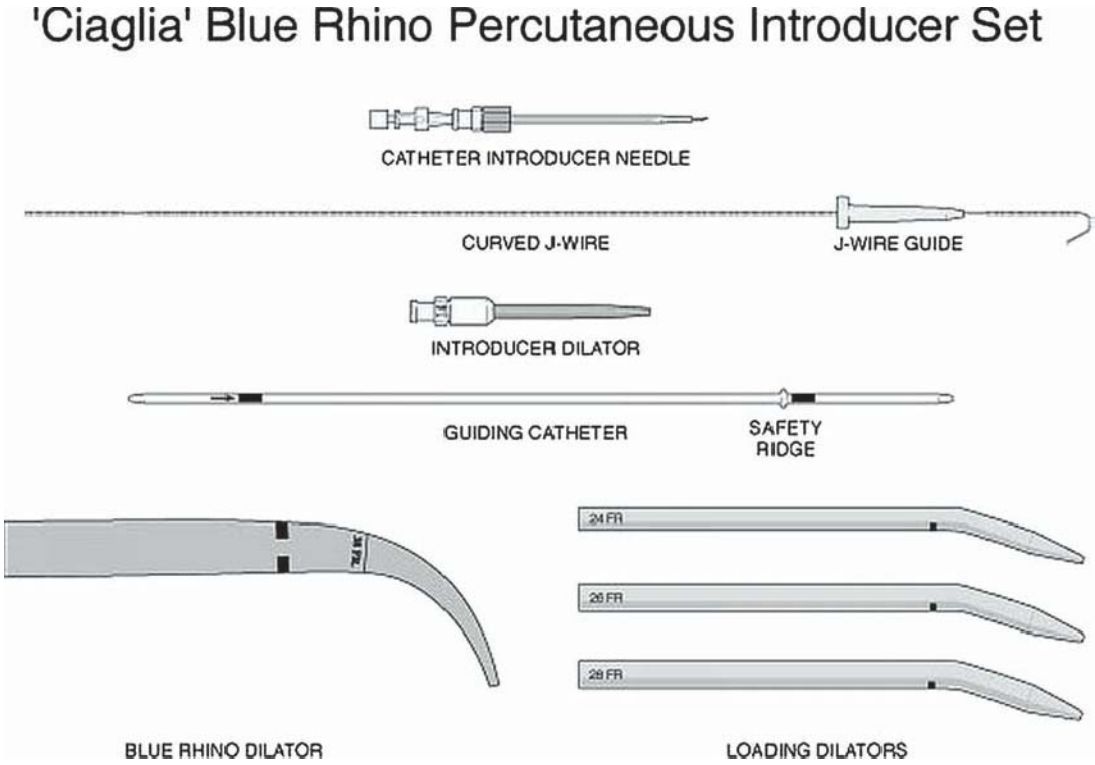

Figure 64.26 Ciaglia Blue Rhino Introducer Kit.

medications include midazolam, given a few minutes prior to commencing the procedure, followed by propofol, administered as a continuous infusion or in boluses, and sublimaze (Fentanyl). Muscle relaxants such as pancuronium bromide may be used as an adjunct in cases where agitation is a problem. The presence of an anesthetist is optional and may depend on hospital policy. Care should be exercised in administering these medications particularly in the elderly patient since large fluctuations in blood pressure and heart rate may occur even with small doses (47).

Technique

Following the administration of appropriate sedation, the patient is thoroughly suctioned and ventilator settings are adjusted to deliver 100% O_2. Vital signs including heart rate, blood pressure, and oxygen saturation are monitored continuously throughout the procedure. The instruments for the Ciaglia Blue Rhino Introducer Set are illustrated in Figure 64.26. Instruments are laid out on a Mayo stand in the anticipated order of use (Fig. 64.27). The patient is positioned as for conventional tracheostomy with the neck extended provided that there is no contraindication (e.g., cervical spine fracture). Important anatomical landmarks including the thyroid and cricoid cartilages and sternal notch are palpated. The patient's neck and upper chest are then prepped and draped in a standard fashion, and the incision site is infiltrated with 2% lidocaine with 1:100,000 epinephrine.

A 1.5- to 2-cm skin incision, just long enough to allow for the circumference of a tracheostomy tube, is made at the level of the first and second tracheal rings. This corresponds to approximately one fingerbreadth above the sternal notch or two fingerbreadths below the cricoid cartilage. The subcutaneous tissues are gently separated horizontally with a curved hemostat to allow accurate palpation of the cricoid cartilage and tracheal rings. No attempt is made to divide or otherwise manipulate the isthmus of the thyroid gland.

At this point, 1 to 2 mL of 4% lidocaine may be instilled into the ET tube in order to decrease coughing. Any tapes or ties are loosened to allow manipulation of the ET tube. From this point on, the ET tube must be held securely by the bronchoscopist or respiratory technician to prevent accidental extubation. An appropriately sized flexible bronchoscope with a suction port is lubricated at the tip and inserted through an adapter into the ET tube and advanced until the tip of the bronchoscope lies flush with the ET tube. During this step, the bronchoscope light will be seen through the incision as it is advanced into the ET tube. The ET tube (with the cuff momentarily deflated) and bronchoscope are slowly withdrawn as a unit until the incision is transilluminated and/or digital depression of the trachea is clearly visualized endoscopically. All ensuing steps are visualized through the bronchoscope. It should be noted that the ET tube cuff position will lie at, or just below, the true vocal folds and must be carefully held at all times. With the ET tube and bronchoscope properly positioned, the tracheal rings are palpated and a no. 14 or no. 16 Teflon catheter introducer needle is used to lightly depress the anterior tracheal wall between the first and second or second and third tracheal rings. The location of the needle is verified endoscopically and modified until an intercartilaginous position between 11 and 1 o'clock is achieved. At this point, the needle is inserted into the tracheal lumen taking care not to puncture the posterior tracheal wall (Fig. 64.28). The needle is removed, and

Figure 64.27 The instruments are placed on an instrument stand over the patient's bed in the order in which they are to be used. Above, from *left* to *right*: Skin preparation solution, gauze, suture scissors, forceps, needle driver and 2-0 silk for suturing the tracheostomy tube to the skin, sterile saline for activating the hydrophilic coating on the single dilator. Below, from *left* to *right*: Gauze for skin preparation, 10-mL syringe with 2% lidocaine with 1:100,000 epinephrine, 15 blade scalpel, mosquito, 5-mL syringe with sheathed introducer needle, J-wire, introducer dilator in center, single dilator pre-assembled over guiding catheter with ridge, no. 6 tracheostomy tube with pre-fitted 26-French Obturator dilator.

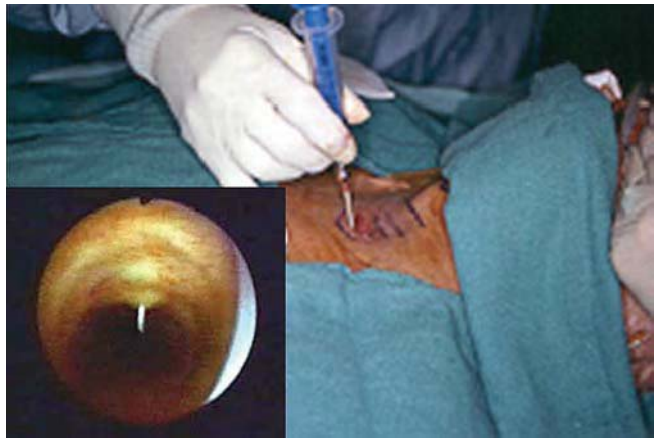

Figure 64.28 With the ET tube and bronchoscope properly positioned, the tracheal rings are palpated and a Teflon catheter introducer needle is used to depress the anterior tracheal wall between the first and second or second and third tracheal rings. The location of the needle is verified endoscopically and modified until an intercartilaginous position between 11 and 1 o'clock is achieved. At this point, the needle is inserted into the tracheal lumen taking care not to puncture the posterior tracheal wall. **Inset:** Endoscopic view of needle insertion.

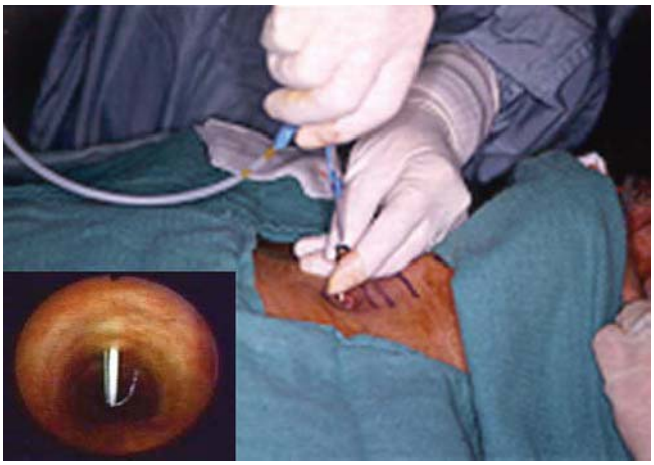

Figure 64.29 The needle is removed, and a J-tipped guidewire is threaded through the remaining catheter into the trachea. **Inset:** Endoscopic view of J-wire advanced through the catheter.

a J-tipped guidewire is threaded through the remaining catheter into the trachea (Fig. 64.29). This catheter sheath is replaced by a 14-French introducer dilator (Fig. 64.30A & B). Removal of the introducer dilator allows for passage of the

Figure 64.31 The introducer dilator is removed to allow insertion of the previously assembled guiding catheter/single which is dipped in saline to activate the hydrophilic coating. The guiding catheter/single dilator unit is held like a pen, introduced over the guidewire between the markings, and advanced in an arc conforming to the tract undergoing dilatation until the black mark of the single dilator is seen through the bronchoscope. **Inset:** Endoscopic view of single dilator/guiding catheter assembly entering the trachea.

previously assembled guiding catheter/single dilator unit, which is dipped in saline to activate the hydrophilic coating. The guiding catheter/single dilator unit is held like a pen, introduced over the guidewire between the markings, and advanced in an arc conforming to the tract undergoing dilatation until the black mark of the single dilator is seen through the bronchoscope (Fig. 64.31). Some depression of the anterior tracheal wall may occur during dilatation. Slight overdilatation and leaving the single dilator *in situ* for 10 to 15 seconds facilitate placement of the tracheostomy tube. The single dilator is removed, leaving the guidewire/guiding catheter *in situ*. The guidewire/guiding catheter unit serves as a scaffolding over which the tracheostomy tube, prefitted with the appropriately sized loading dilator, is advanced into the trachea. Two points of resistance are typically encountered during this maneuver: the interface between the loading dilator and tracheostomy tube, and upon insertion of the balloon (Fig. 64.32).

At this point, the loading dilator, guiding catheter, and guidewire are removed and replaced with the inner cannula (Fig. 64.33). The cuff is inflated, and ventilation is continued through the tracheostomy tube. The tracheostomy tube is secured with four corner sutures and tape ties (Fig. 64.34). Blood and/or secretions are suctioned from the trachea. Only when adequate ventilation is established should the ET tube be removed. The vocal cords may be inspected upon removal of the bronchoscope and ET tube.

Tracheostomy tube size is chosen based on the clinical needs and gender of the patient. Whenever possible, smaller no. 6 I.D. tubes should be used in females to reduce the likelihood of tracheal stenosis or tracheomalacia. In a patient with a short, thick neck, a proximally-extended

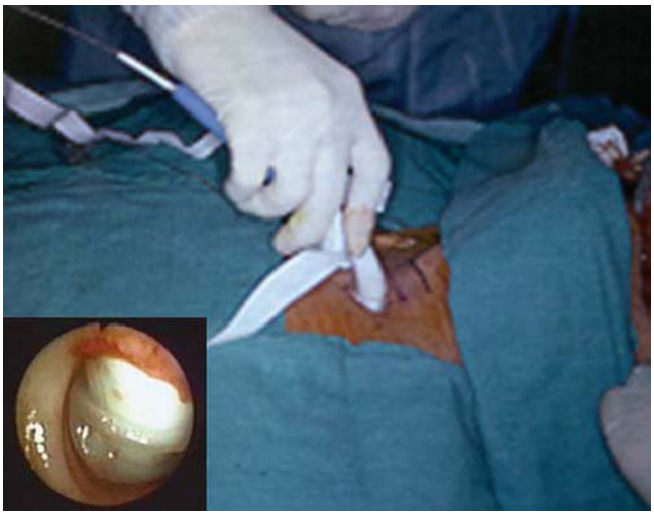

Figure 64.32 The single dilator is removed, leaving the guidewire/guiding catheter unit as a scaffold over which the tracheostomy tube, prefitted with the appropriately sized loading dilator, is advanced into the trachea. Two points of resistance are typically encountered during this maneuver: the interface between the loading dilator and tracheostomy tube, and upon insertion of the balloon. **Inset:** Endoscopic view of the tracheostomy tube and balloon entering the trachea.

tracheostomy tube should be used to prevent accidental displacement of the tube into the pretracheal soft tissue.

Depending on the degree of calcification of the tracheal cartilages, fracture of the ring immediately adjacent to the dilator may occur during dilatation. This is akin to intentionally incising one or more rings during an open ST. There is no evidence to suggest that this occurrence increases the incidence of tracheomalacia and tracheal stenosis (47).

Postoperative Considerations

Continuous vital sign monitoring should continue in the postoperative period. With the termination of the intense stimulation produced by the procedure, the effects of the sedation may become more pronounced, resulting in hypotension, tachycardia, or O_2 desaturation. All these changes may require correction with pharmacologic intervention. Suctioning may be necessary to clear secretions or blood, thus preventing a drop in O_2 saturation. A postoperative chest radiograph is required to ensure the absence of pneumothorax and pneumomediastinum.

Figure 64.33 The loading dilator, guding catheter, and guidewire are removed and replaced with the inner cannula. **Inset:** Endoscopic view of the tracheostomy tube in place.

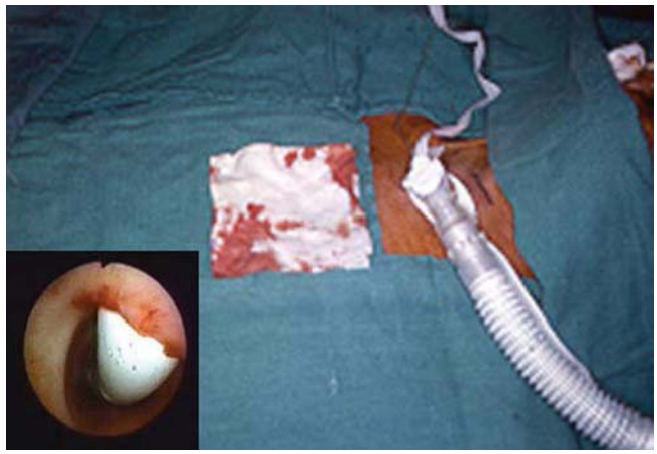

Figure 64.34 Ventilation is continued through the tracheostomy tube. The tracheostomy tube is secured with four corner sutures and tape ties. **Inset:** Endoscopic view of tracheostomy tube in place.

Many of these patients have copious secretions from the tracheostomy site from their associated pulmonary condition. A tracheostomy tube with an inner cannula facilitates care and hygiene and ensures added safety by allowing rapid removal should obstruction from secretions occur. The PDT technique is primarily dilatational with minimal tissue dissection resulting in a tighter tract and a very snug fit of the tracheostomy tube. The technique does not allow for easy placement of traction sutures at the level of the trachea. Because of these factors, the patient should be reintubated orally in the event of accidental decannulation within the first 5 to 7 days of the procedure while the tract is still relatively immature. Because of the tight tract, attempts at forcefully replacing the tracheostomy tube in an emergent situation could result in bleeding, the creation of a false passage, pneumomediastinum, hypoxia, and even death.

Complications

Potential intraoperative and postoperative complications are similar to those reported for surgical tracheotomy. Notable differences in terms of frequency are discussed below. Interpreting available data for both techniques can be difficult for several reasons: (a) Uneven reporting of complications. Examples include desaturation, subcutaneous emphysema, and infection, which frequently go unmentioned. (b) Uneven threshold for reporting of complications. In some series, even minor bleeding is reported while in others it is only mentioned if the loss is in excess of a "significant" amount (e.g., 200 mL). (c) Inhomogeneity of techniques, patient subsets, and surgeons is observed in

many studies (48,50). Fundamentally different PDT techniques are frequently considered together and compared to ST, leading to biased results (48,50). The patient subsets for PDT and ST are different and yet results from both groups are often compared. PDT patients are relatively homogeneous and consist only of adult intubated ICU patients, identified as having a higher risk of complications because of their multiple co-morbidities. Most patients undergoing ST are neither intubated, nor from the ICU. In the majority of reported PDT studies, the procedure is performed by nonsurgeons, while in virtually all ST studies the procedure is performed by surgeons. This fact can also bias results. Many or all of these inhomogeneities exist together in many reports, including meta-analyses, thus further complicating data analysis.

With the above information in mind, some general statements can be made. The overall complication rate for endoscopic PDT in the literature is approximately 9% (47). This compares favorably to that of ICU patients undergoing open surgical tracheotomy in the OR, where complication rates of 14% to 66% have been reported (47), or at the bedside where complication rates of 4% to 41% have been reported (47). Procedure-related mortality is very low for both PDT (0.5%) and ST (less than 2%). Comparative data on individual complications (e.g., bleeding, infection) for surgical and percutaneous tracheotomies vary widely, but overall PDT compares favorably to ST. Although the use of continuous endoscopic visualization has been debated in the literature, several series have shown that it is crucial to the safety of the procedure and in reducing complications (47,49).

Obese patients with a body mass index greater than or equal to 30 are at higher risk for complications. This risk is further increased in obese patients who are "more ill" as assessed by the ASA classification. The most common complication in this group is accidental decannulation owing to the thickness of the subcutaneous tissues. Use of a proximally extended cannula largely circumvents this problem. There is no data available on the risk of complications in obese patients undergoing open ST, and therefore no evidence that the risk for this subset of patients is reduced in ST (47). Early mortality in morbidly obese patients undergoing ST may be higher than in nonobese patients (51). There is no data on early mortality in obese patients undergoing PDT. There is a learning curve for endoscopic PDT, and careful selection of patients with anatomically favorable necks is advisable before proceeding to patients with thick or less favorable necks.

Desaturation

The real risk of this complication is unknown since it is infrequently reported in both the "open" and percutaneous tracheotomy literature. Brief episodes of mild oxygen desaturation may occur at the time of tracheostomy tube insertion, particularly in patients with compromised pulmonary function requiring high FiO_2 concentrations (47). The risk of such an occurrence may be minimized by thorough pre-/intraoperative suctioning of secretions and by ventilating all patients on 100% O_2 for the duration of the procedure.

Bleeding

The reported incidence of bleeding varies widely in the literature from 0% to 37% for open surgical tracheotomy compared to 1% to 19% for percutaneous tracheotomy. Overall, the incidence of bleeding complications in larger series is lower in PDT than in ST. This can be explained by the blunt nature of the technique as well as the tamponade effect of the tracheostomy tube against the tight tract that is created (47,49). Occasionally, there is bleeding from a thyroid vein at the time of initial tracheal puncture. This can be addressed by removing the needle, applying pressure for 5 minutes, and creating a new puncture. Alternatively, the procedure may be continued at the original puncture site, since the bleeding will stop with the tamponade effect of the tracheostomy tube. Minor oozing from wound edges can be controlled with simple pressure. Occasionally, a small hemostatic packing may be helpful. Although there are isolated reports of life-threatening hemorrhage for both "open" and percutaneous techniques, this rare complication usually results from an unanticipated anatomical anomaly, from violating a major vessel, or, later, from erosion into the innominate artery.

Infection

Reported infection rates vary widely from 0% to 10% for PDT compared to 0% to 31% for ST. In the largest series, the infection rate is less than 1%. The lower risk of infection in PDT can be explained by the small wound and tight tract, which reduces the surface area available for bacterial colonization compared to the more extensive soft tissue dissection in ST (47,49). Treatment principles for infection following PDT are the same as those for ST.

Accidental Extubation

The true incidence of accidental extubation for either PDT or open surgical tracheotomy is unknown because it is so infrequently mentioned in the literature. It has, however, been reported to occur with both techniques. The risk of this potentially serious complication may be reduced through the following steps: the ETT should be held and manipulated only by a physician or a respiratory therapist and such manipulation should occur only after the bronchoscope has been positioned within the ET tube and while the patient is ventilated on 100% oxygen.

Posterior Wall Injury

Occasional overzealous initial needle insertion may puncture the posterior wall, but this is clinically insignificant and is easily corrected by simply withdrawing the needle to the appropriate position. Serious posterior wall injury can be avoided by attention to technical detail (proper positioning of the guidewire, guiding catheter, and dilator)

and, most importantly, constant endoscopic visualization of the posterior wall during the procedure (47).

Technical Misadventures

Loss of the puncture site and accidental removal of the J-wire include some of the possible technical mishaps. In these instances the procedure must be continued from the previous step or started anew as dictated by the circumstances. Occasionally, dilatation may be difficult because resistance is encountered. If this is the case, the size of the incision and soft tissue "tunnel" should be verified. As a rule, the surgeon's index finger should fit comfortably in the incision and soft tissue tunnel. If not, additional spreading of the soft tissue should correct the problem. If the initial needle insertion is through a tracheal ring, dilatation will be difficult and the needle should be repositioned between rings. If the tracheostomy tube is difficult to insert, the tract should be "redilated." The use of excessive force during any step of the procedure always indicates a problem and should never be used as it is likely to lead to complications and/or damage of the instruments. Technical problems may prolong the procedure but rarely directly impact patient safety or outcome (47).

False Passage, Pneumothorax, Pneumomediastinum, and Subcutaneous Emphysema

These potentially fatal complications can be almost completely avoided by continuous bronchoscopic visualization of every step of the procedure (47). Excessive force should never be used during dilatation or tracheostomy tube insertion, and always indicates a technical problem. Subcutaneous emphysema in association with PDT is rarely reported and probably occurs in patients requiring a PEEP greater than 15 cm H_2O. For this reason, such patients should undergo ST.

Accidental Decannulation

Accidental decannulation is unusual because of the tight tract. Most at risk are obese patients or those with short thick necks in whom subcutaneous adipose tissue effectively shortens the intratracheal length of the tracheostomy tube. This potential problem may be circumvented by using proximally extended length tracheostomy tubes (47).

SUMMARY

Expertise in airway management requires a thorough understanding of airway anatomy and available management options. Intubation and tracheotomy are the most frequently used means of securing the airway. Knowing when to use one over the other must be dictated by the clinical context, as well as the skills of the anesthetist and surgeon. Communication between all involved medical personnel is essential in developing an appropriate management plan for any given patient.

HIGHLIGHTS

- Intubation allows for controlled mechanical ventilation with operative and nonoperative indications.
- A detailed airway history and examination prior to intubation are critical in planning and executing the appropriate intubation technique and in avoiding complications.
- The decision to intubate or perform a tracheotomy is predicated on the anticipated duration of mechanical ventilation, the clinical condition of the patient, and the skill of the anesthetist and surgeon, respectively.
- A number of intubating aids and devices are available for managing the difficult airway.
- Fiber optic orotracheal or nasotracheal intubation is the cornerstones in management of the difficult airway.
- The Hunsaker Mon-Jet tube is an attractive option for microlaryngeal surgery because it is laser-safe, offers superior laryngeal visualization, and is associated with few complications.
- The LMA is a supraglottic airway device that is less invasive than ET intubation, easy to insert, can be used blindly, and is associated with few complications.
- Most complications related to intubation are preventable with careful planning, selection of the appropriate technique, and attention to technical detail.
- When cricothyrotomy is necessary, it should be converted to a tracheotomy within 48 hours in order to avoid subglottic stenosis.
- Emergency bedside open tracheotomy is a life-saving measure, which must be performed very quickly because death from anoxia occurs in 5 minutes.
- Preoperative planning prior to tracheotomy decreases the likelihood of complications and includes a thorough head and neck exam, optimizing comorbidities, and proper tube selection.
- Postoperative tracheotomy care includes careful vital sign monitoring, frequent suctioning, cleaning/changing of the inner cannula, humidification, and meticulous local wound care.
- A multidisciplinary tracheotomy team produces measurable results in terms of decreased postoperative morbidity: the frequency of tube obstruction decreases, the use of speaking valves increases, and patients are decannulated more rapidly.
- Percutaneous dilatational tracheotomy can be performed safely with appropriate training, careful patient selection, and attention to technical detail, especially continuous endoscopic visualization.
- Overall, complications rates for endoscopic percutaneous dilatational tracheotomy are comparable to those for open surgical tracheotomy in the operating room.

Voice: Anatomy, Physiology, and Clinical Evaluation

65

Lucian Sulica

The Larynx is a biologic valve located at the junction of the respiratory and the digestive tracts. Its evolutionary origins lie in the need to protect the lungs of amphibious organisms from water, and airway protection remains its most important biologic task. The development of the larynx into a phonatory organ arose because its position atop the tracheobronchial tree and its valving function gave it a unique ability to regulate expiratory airflow. Human voicing is the result of complex interactions among all of the elements of the upper aerodigestive tract, but it depends on precise and finely modulated glottic closure for sound.

The human larynx has a number of features that are specially adapted to its role as a sound source, including unique tissues capable of sustained high-speed oscillation and neuromotor specializations for fine control of vocal fold movement. As laryngology grows increasingly sophisticated and ambitious, especially with regard to restoration and even enhancement of voice quality, these details of anatomy and physiology have taken on a new clinical relevance. Increased insight into these has developed hand in hand with a better appreciation of factors leading to dysphonia. To be most effective, the otolaryngologist must understand all of these elements—anatomy, physiology, and clinical evaluation as a reflection of both—as an integrated whole that forms the foundation of any effort to treat the patient with a voice disorder.

ANATOMY

The Laryngeal Framework

The supporting framework of the larynx consists of one bone, the hyoid, and four cartilages: the cricoid, thyroid, and paired arytenoids (Fig. 65.1). The external framework is formed by the hyoid, the thyroid, and the cricoid, linked together by the thyrohyoid and cricothyroid membranes. All of these elements are suspended from the skull base and mandible by means of soft tissue attachments. The mylohyoid, the geniohyoid, the hyoglossus, and the stylohyoid muscles; the stylohyoid ligament; and the sling of the digastric insert into the superior aspect of the hyoid and exert cephalad traction. This is counterbalanced by the caudad pull of the omohyoid, sternohyoid, thyrohyoid, and sternothyroid muscles, all except the last inserting into the hyoid as well. The larynx thus moves vertically as a unit, dependent from the hyoid, its most superior element. This displacement is important not only in protecting the airway during swallowing but also in modifying the shape of the supraglottal resonating tract in voice production.

The cricoid cartilage may be considered the base of the larynx. As the only complete ring in the entire airway, it is particularly important in maintaining airway patency. However, the rigidity of this segment appears to predispose it to mucosal injury from endoluminal pressure, such as that from an endotracheal tube cuff and consequent stenosis. The thyroid cartilage rests atop the cricoid. Its inferior horns articulate with the outer surface of the cricoid posteriorly, and its V-shaped body envelops the soft tissue of the glottis. The angle at which the two halves of the thyroid cartilage join at the anterior midline is more acute in men than in women, and this accounts for its increased prominence in the male neck.

The paired arytenoids rest on the cephalic rim of the posterior cricoid and are the anchors for the mobile ends of the vocal folds, each one stretching from an anterior projection known as the vocal process to the anterior midline of the thyroid cartilage, just below the root of the epiglottis. Functionally, the arytenoid serves to translate the vectors of force of all of the individual intrinsic laryngeal muscles (but for the cricothyroid) into adductory and abductory vocal fold motion. Its eccentric shape is well suited to the task. A posterolateral projection from its body constitutes its muscular process, receiving insertions from both the lateral cricoarytenoid and the posterior

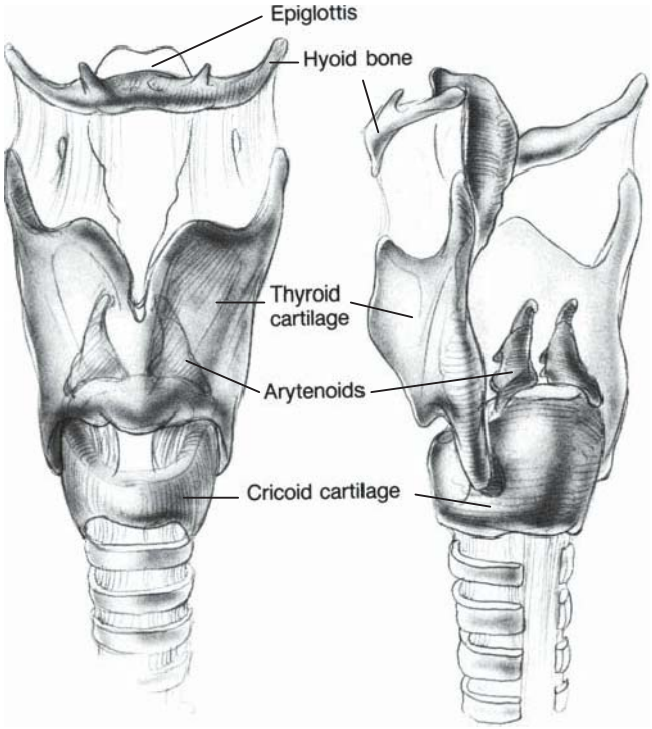

Figure 65.1 Laryngeal framework.

cricoarytenoid muscle and acting as a lever to amplify their actions. Its anterolateral face offers a broad attachment for the thyroarytenoid muscle, which functions to adduct and shorten the vocal fold. Scalloped facets face one another on the posteromedial surfaces of the arytenoids and house the attachments of the adductory interarytenoid muscle. The anteriorly projecting vocal process finally converts the action of laryngeal muscles into vocal fold motion.

The epiglottis, an elastic cartilage that has no structural role in the adult, is secured to the supporting elements of the larynx by means of the thyroepiglottic and hyoepiglottic ligaments. It is passively deflected to hood the laryngeal introitus during swallowing and serves as an accessory barrier to laryngeal entry. Finally, small cartilages of indeterminate and probably inconsequential function are found about the superior rim of the larynx. The corniculate cartilages (of Santorini) rest atop the arytenoid apices, and cuneiform cartilages (of Wrisberg) are contained within the superior rim of the aryepiglottic fold just anterolateral to the arytenoid mound. Whatever height and rigidity these may add to the aryepiglottic rim is probably not functionally significant in humans. Triticeal cartilages are sometimes found at the posterior border of the thyrohyoid membrane and are significant only because they may be mistaken for a foreign body on radiography.

In addition to bony and cartilaginous elements, two fibroblastic membranes are structurally important in the larynx (Figs. 65.2 and 65.3). The conus elasticus originates on the upper border to the cricoid cartilage and rises to the glottic aperture. Superiorly, its thickened free edges form

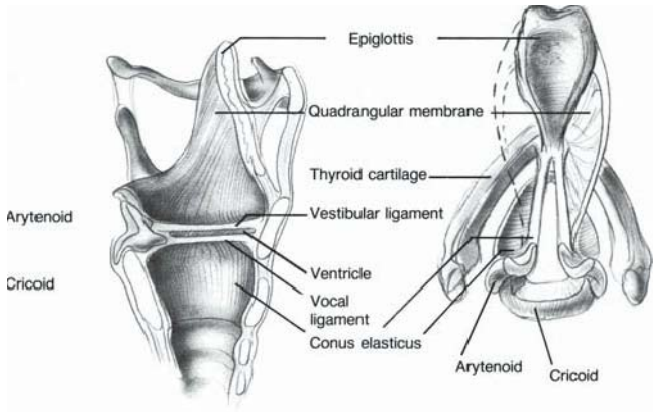

Figure 65.2 Fibroelastic membranes.

the vocal ligaments. The conus elasticus defines the convergent shape of the subglottis, which is of considerable physiologic importance in phonation. The supraglottic quadrangular membrane extends inferiorly from the aryepiglottic fold to the leading edge of the ventricular folds, similar to an inverted conus elasticus in shape, although not in functional importance. Both the conus and the quadrangular membrane, in addition to supporting the shape of the vocal fold and the ventricular fold, respectively, are barriers that may influence the spread of malignant disease.

Covered on the outside only by strap muscles and skin, the external bony and cartilaginous elements of the larynx are usually easily palpable. The most prominent points are the anterior arch of the cricoid and the superior notch of the thyroid in the anterior midline, and laterally,

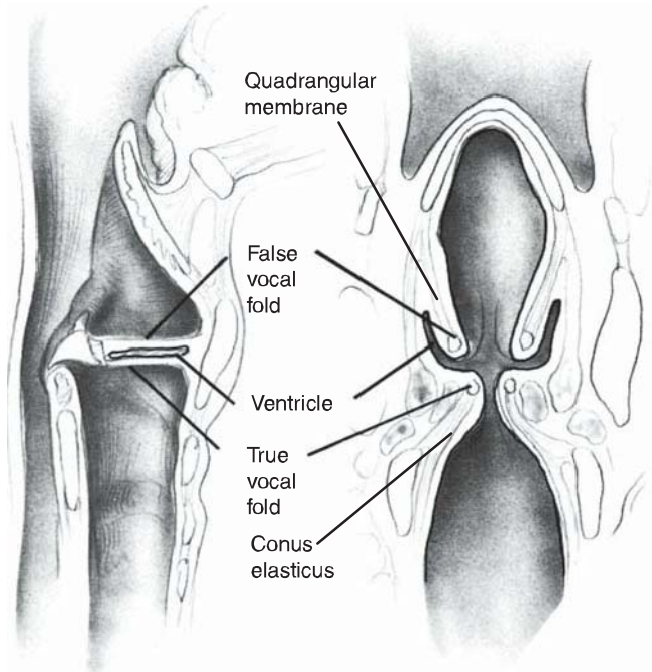

Figure 65.3 Vertical section through the larynx.

the superior horns of the thyroid and greater horns of the hyoid. From these landmarks, the location of most of the structures of the larynx can be extrapolated for purposes of manipulation, placement of surgical incisions, electromyography, injection, or other intervention. Tethered above and below by the strap muscles, the normal larynx may usually be rotated or displaced from side to side without difficulty or much discomfort. The latter motion normally produces a crepitus that is felt by the examiner's hand and the patient rather than heard and that results from the cartilaginous structures of the larynx sliding over the bony elements of the cervical spine.

The nature of the articulations of the laryngeal cartilages determines the range and trajectory of motion of the vocal folds and are thus worth some attention. Each cricothyroid joint consists of a shallow articulatory facet that seats the tuberculum of the inferior horn of the thyroid cartilage. These paired structures permit a rotatory motion between the thyroid and the cricoid cartilage, resulting in a visorlike approximation of their anterior portions on cricothyroid muscle contraction. As the anterior arch of the cricoid rises, the posterior plate drops, carrying with it the arytenoids. In consequence, the vocal folds lengthen and thin, which is a principal method of increasing phonatory pitch. The ligaments of the cricothyroid joint also seem to permit a ventrodorsal sliding motion, particularly when the articular facet on the cricoid cartilage is poorly defined or absent, as may be the case in as many as 70% of larynges (1). This sliding might account for as much as 40% of the increase of vocal fold length on cricothyroid contraction.

The cricoarytenoid joint is the principal articulation for vocal fold adduction and abduction. Arytenoid cartilage motion is sometimes presented as simple rotation around a vertical or helical axis, although it has long been known to be more complex. This oversimplification is likely the result of two factors. First, available means of clinical examination of the larynx, which renders vertical height differences between the vocal folds notoriously difficult to assess, create the impression of vocal fold motion in a single plane. Second, this misperception was of little or no practical consequence prior to relatively recent advances in laryngeal framework surgery.

Accounts also generally break down arytenoid motion into three axes, but this creates an artificially fragmented notion of the movement, which according to all evidence is smooth across its entire trajectory.

The arytenoid rests atop a convex articular surface on the cephalic edge of the cricoid. The joint surface faces more laterally at its posterior end and rotates superiorly as it extends anteriorly (2). It functions as a slipway for motion of the arytenoid body. The arytenoid body thus shifts anteromedially as it is pulled closed but posterolaterally when pulled open. The first motion depresses the vocal process, so that its adduction is not only medial but also inferior. Conversely, its abduction is lateral and superior, so that the vocal fold does not move into the body of the thyroarytenoid muscle but upward toward the ventricle. Vertical vocal process displacements, measured in cadavers, range up to 2.4 mm. The cricoarytenoid joint facets and consequently the paths of motion of the vocal process are often not symmetric, which should warn us against ascribing pathologic significance to small asymmetries of vocal fold motion. Wang (2) has noted correctly that symmetry is of functional importance only when the vocal folds are in adduction.

Understanding the three-dimensional nature of vocal fold motion is important to clinical evaluation and rehabilitation of glottic insufficiency because a denervated vocal fold may rest at any point along its normal sweep (3,4). (The classic terms for the position of an immobile vocal fold—median, paramedian, cadaveric, etc.—are purely descriptive; they have no physiologic or topognostic significance, contrary to time-honored belief.) In fact, with muscle traction diminished or even absent, it may even lie outside of this trajectory, as in the case of a so-called prolapsed arytenoid, when the vocal process may lie below the inferiormost extent of normal motion. Laryngoscopy may not readily reveal the height difference, and simple medialization, like that achieved by a thyroplasty implant alone, may not approximate the vocal folds at the same level.

The cricoarytenoid joint is remarkably stable for a structure that permits so many degrees of freedom in arytenoid motion. Dissection has revealed a layered network of articulatory ligaments that provide substantial stability in most directions. Multiple muscular and ligamentous attachments must be severed to produce subluxation (2). In cadaver experiments, even without active muscular support, the joint is extremely resistant to dislocation, both by endotracheal tube and direct manual manipulation (5,6). Available evidence suggests that cricoarytenoid joint dislocation is a very rare clinical condition.

Muscles and Nerves

The intrinsic muscles of the larynx—those that originate and insert on the laryngeal cartilages—are responsible for vocal fold motion (Fig. 65.4). The sole abductor of the vocal fold is the posterior cricoarytenoid muscle, which reaches from the posterior surface of the cricoid superolaterally to the muscular process of the arytenoid. Its principal antagonist is the thyroarytenoid muscle, which stretches from the inner surface of the thyroid to the arytenoid body. Together with the lateral cricoarytenoid muscle, it forms the principal adductory muscle complex of the vocal fold. It is aided in adduction by the interarytenoid, which is the only nonpaired laryngeal muscle. The thyroarytenoid also shortens the vocal folds by means of anterior traction on the arytenoid. The cricothyroid muscle, stretching from the external anterior surface of the cricoid to attach broadly on the caudal rim of the thyroid, functions as an antagonist to the thyroarytenoid in this respect. It elongates the vocal folds by effecting torsion at the cricothyroid joint, as

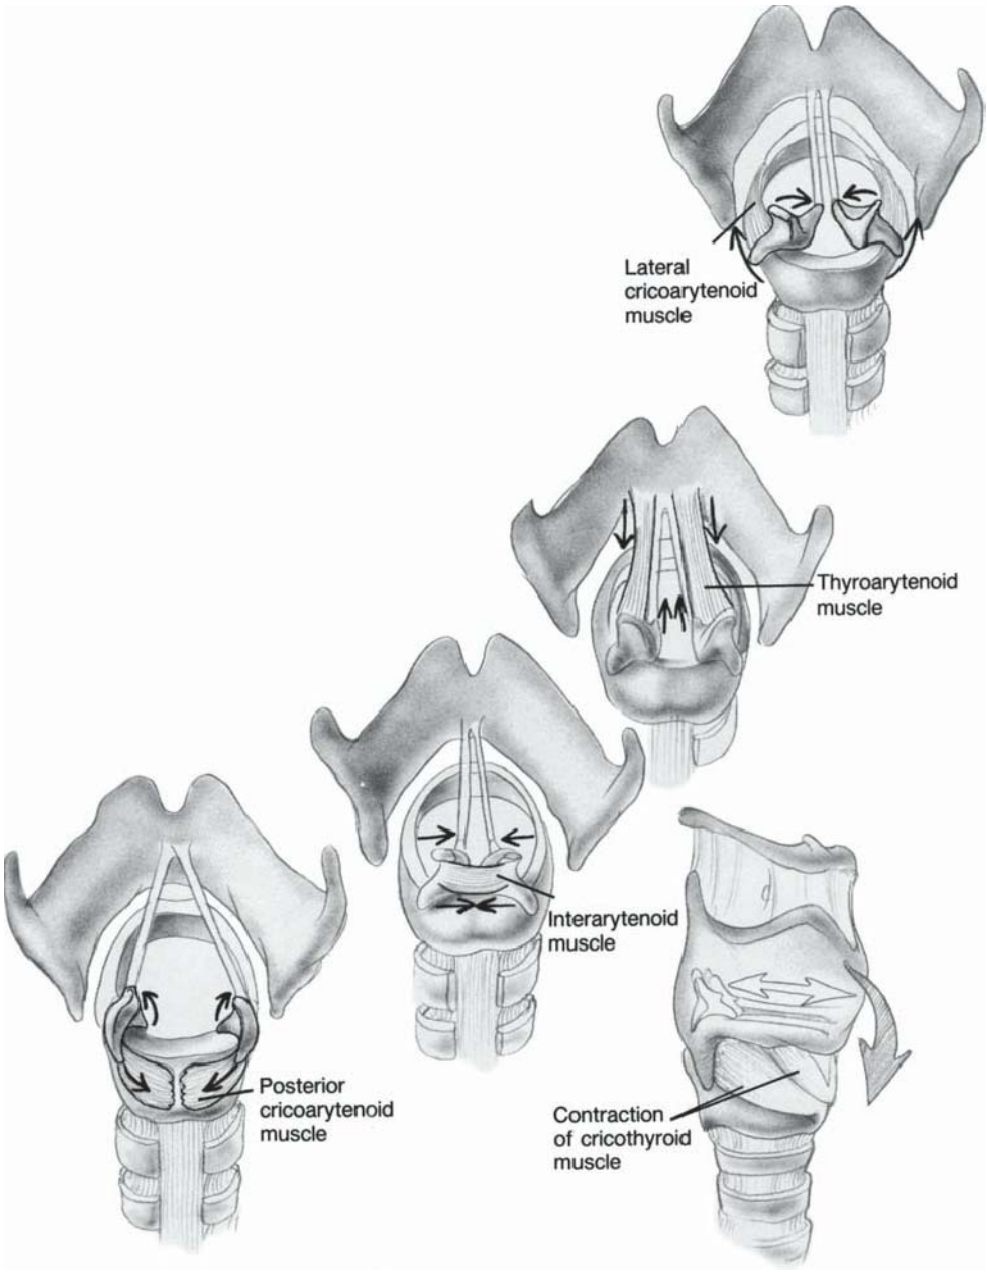

Figure 65.4 Intrinsic laryngeal muscles.

we have already seen. Minor aryepiglottic muscles, as well as a cephalad projection of the thyroarytenoid, serve to constrict the ventricular folds and supraglottic structures, which are accessory means of glottic valving that usually come into play during voicing only under pathologic circumstances.

There is considerable evidence that the thyroarytenoid–lateral cricoarytenoid muscle complex, the posterior cricoarytenoid muscles, and the cricothyroid muscles are divided into functionally separate compartments distinguished by fascial barriers and corresponding arborization patterns of laryngeal nerves (7–10). This impression is reinforced by differences in the concentration of muscle fiber types and specialized proprioceptors among these compartments (11). For instance, the medial division of the thyroarytenoid, known as the vocalis, contains fatigue-resistant slow-twitch fibers (12). These imply that it is especially suited to activity that requires fine-tuned tonic contraction, such as phonation. In contrast, the lateral compartment has a high concentration of fast-twitch fibers, better suited to rapid movement, such as that demanded by reflexive glottic closure for airway protection. A similar difference exists between the horizontal and the vertical compartments of the posterior cricoarytenoid. No muscle fiber distinctions seem to exist among the two compartments of the cricothyroid, but each exerts a different vector of force on the cricothyroid joint by virtue of differences in fiber origin, insertion, and direction (10,13).

Each hemilarynx receives its innervation from ipsilateral branches of the vagus. The superior laryngeal nerve arises from the bottom half of the nodose ganglion, about 36 mm below the jugular foramen (14). It travels medial to both the internal and external carotid arteries and splits into two branches after some 15 to 20 mm. The internal branch pierces the thyrohyoid membrane in company with the superior thyroid artery and ramifies to the mucosa of the ipsilateral laryngeal mucosa by means of a variable number of branches. The external branch runs lateral to the inferior constrictor muscle until it curves anteriorly at approximately the level of the inferior edge of the thyroid lamina to reach the cricothyroid muscle. Its path in relation to the apex of the thyroid lobe and its blood supply is of obvious clinical significance. Most nerves cross the superior thyroid artery well away from the superior pole of the thyroid. However, up to 30% cross that vessel within 1 cm of the gland, and up to 20% actually pass under the gland itself, representing the situation of considerable risk during thyroidectomy (15,16).

On the right side, the recurrent nerve arises from the main trunk of the vagus as it passes anterior to the subclavian artery and loops underneath that structure to travel toward the larynx. For purposes of investigation of right-sided vocal fold paralysis, it is important to understand that the course of the nerve can thus extend into the superior mediastinum; diagnostic imaging studies should not be restricted strictly to the neck. The left-sided nerve follows a similar path but loops around the aorta instead of the subclavian artery, as the result of differences in embryologic vascular development from one side to the other (17). These pathways in large part determine the vulnerability of each nerve to injury, be it from surgical manipulation, tumor compression, or other disease.

Classic descriptions hold that the recurrent nerve supplies motor input to all of the intrinsic muscles but for the cricothyroid, which receives its innervation from the external branch of the superior laryngeal nerve. Sensory information from the level of the glottis and above travels to the central nervous system via the internal branch of the superior laryngeal nerve and from below the glottis via the recurrent laryngeal nerve. This view, although essentially correct, may not capture the full complexity of the neuromuscular system of the larynx. Historically, the ansa of Galen, an extension of a branch of the internal branch of the superior laryngeal nerve running underneath the mucosa of the medial wall of the piriform sinus, has been regarded as the only anastomosis between the superior and recurrent laryngeal nerves. By means of neurospecific stains, inconsistent but relatively common connections have been found between the external branch of the superior nerve and the recurrent nerve within the thyroarytenoid muscle (7,18,19). Some investigators have asserted that the bilaterally innervated interarytenoid muscle contains anastomosis between the contralateral nerve populations, which may include contributions from the internal branch of the superior nerve (20,21).

The precise physiologic significance of such insights into nerve and muscle anatomy remains to be determined, but traditional concepts of laryngeal anatomy are being revised by an increased appreciation for fine muscular specialization and for the possibility of a more complex scheme of innervation, featuring more anastomotic pathways than previously suspected, interdigitating nerve branches, and terminal plexuses. This evolving picture may help to explain not only the robust tendency for reinnervation in the human larynx but also why such innervation is so often dysfunctional and why dynamic surgical reinnervation remains such a challenging clinical problem.

The Membranous Vocal Fold

The paired shelves of tissue formed by the thyroarytenoid muscles and their soft tissue cover, which extend from the vocal process of the arytenoids to the anterior midline of the thyroid cartilage, are known as the vocal folds. These form the principal valve for glottic closure and, of special interest to us, for glottic resistance necessary for phonation. This latter function is dependent on the unique and delicate microarchitecture of the leading edge of the vocal fold (Fig. 65.5).

The vocal fold is covered by a thin layer of stratified squamous epithelium, in contrast to the respiratory epithelium of other surfaces of the larynx and trachea. Below this lies the lamina propria, a pliable layer of fibrous proteins, including elastin, collagen, and other extracellular elements, which together account for its unique biomechanical properties. A sparse cell population composed principally of fibroblasts, thought to be responsible for the production and regulation of the components of the lamina propria, is also present (22,23). The superficial lamina propria lies immediately underneath the basement

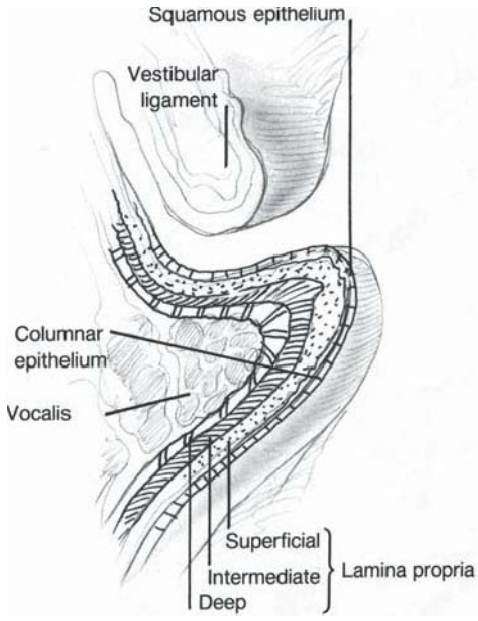

Figure 65.5 The vocal fold.

membrane of the epithelium and contains the lowest concentration of fibrous proteins. The superficial lamina propria has often been described, incorrectly, as a potential space. In reality, it has its own thickness and mass—about 0.5 mm at the middle of the adult vocal fold (24)—and is a distinct anatomic structure, not at all like the true potential space between the pulmonary pleura and the chest wall. It is true that it offers little resistance to injection of fluid, for instance, but this is a function of its loose structure rather than any anatomic separation. The time-honored eponym of "Reinke's space" is thus misleading and should probably be modified to "Reinke's layer" or not used at all. That the superficial lamina propria has depth and substance is a key point to grasp for anyone who would operate on lesions of the vocal fold.

Beneath the superficial layer of the lamina propria lie the intermediate and deep layers. These are not crisply distinct from one another; instead they represent a gradient along which elastin fiber concentration decreases and collagen fiber concentration increases as it sinks deeper. Stiffness increases in proportion to collagen fiber concentration. Taken together, these form the vocal ligament and are contiguous with the walls of the conus elasticus rising from below. Combined with the superficial lamina propria and the epithelium, these comprise the mucosa of the vocal fold (25). Deep to this mucosa lies the thyroarytenoid muscle, which likely consists of functionally distinct superficial and deep compartments, as we have seen.

For reasons that will become apparent in the discussion of phonatory physiology, the layers of the vocal fold structure have been divided into a "cover" and "body," each with fundamentally different physical properties that come into play during phonation. The cover of the vocal fold includes the epithelium and the superficial lamina propria. The ligament represents a transition zone, variably assigned by authors to either the body or the cover, and the body includes the thyroarytenoid muscle (25).

The anatomy of glottic closure is of considerable physiologic significance. Examined in cross-section, vocal folds do not taper to a sharp apex medially; they have a flattened, fairly blunt contour. As a result, the area of vocal fold contact in adduction has a vertical dimension (under most phonatory conditions), and the mucosa of one vocal fold approximates the other across a larger area than in a single plane. This is not entirely intuitive because laryngoscopy under continuous light (as opposed to stroboscopic light) tends to create the impression that vocal fold closure is a two-dimensional phenomenon, just as it distorts adduction and abduction in the same way. The contour of the vocal fold can be modified by the action of the muscles of the larynx, with consequences to the sound produced.

Laryngeal Changes with Age

At birth, the larynx rests considerably higher in the pharynx than it does in the adult (Fig. 65.6). In this position, the superior portion of the epiglottis overlaps with the

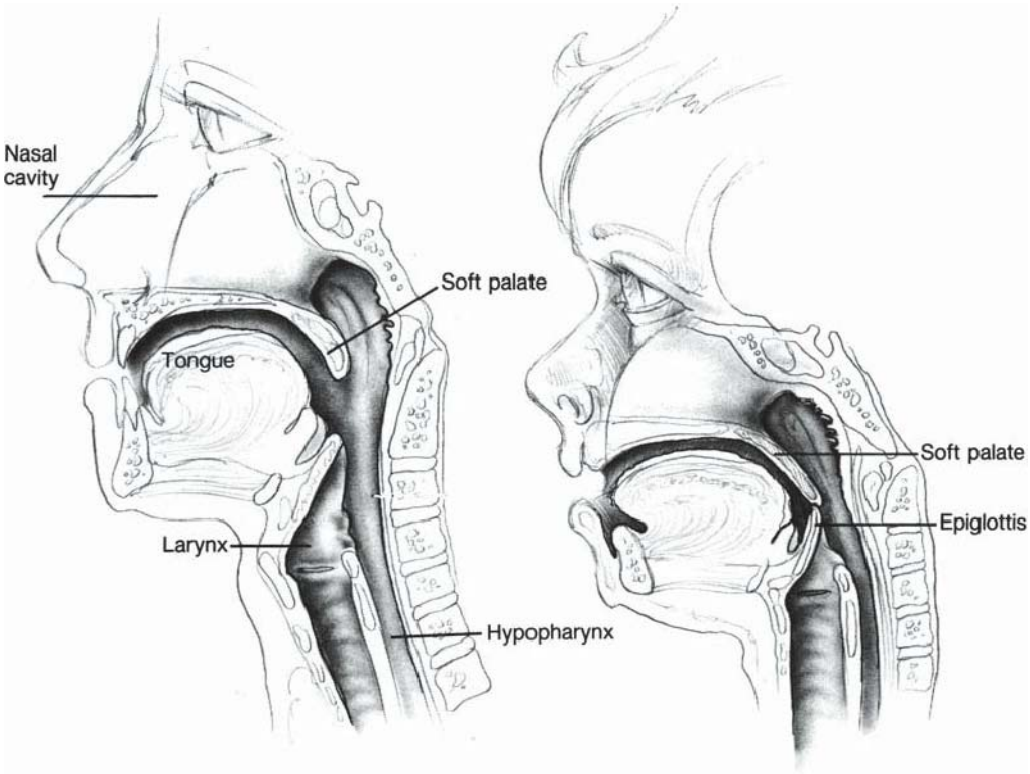

Figure 65.6 Laryngeal position in the adult and in the child.

caudal edge of the soft palate, effectively separating the respiratory from the alimentary tract. This is probably a necessary adaptation to breastfeeding, during which the infant must be able to breathe and suckle simultaneously. At the same time that it increases swallowing safety, this laryngeal position renders the newborn an obligate nosebreather until maturational laryngeal descent begins. The lower position of the larynx in the adult offers the capability of increased range and complexity of phonation by engaging the mouth and tongue in modification of sound, at the cost of an increased risk of choking and aspiration. That evolution has obviously favored such an arrangement hints at the biologic advantages of complex phonation.

The layered structure of the vocal fold is not present at birth; it develops throughout childhood from a homogenous and hypercellular mucosa (25,26). Lamina propria layering appears as early as 2 months, but the process is not complete until approximately 13 years of age, when the vocal fold assumes an essentially adult histologic configuration. This approximately coincides with the beginning of laryngeal framework growth at puberty. This growth is especially pronounced in males, in whom it is accompanied by an increase in vocal fold length and thickness, which largely accounts for characteristics of the adult male voice (27).

Assessing laryngeal changes purely as a result of aging is complicated by the difficulty in separating them from comorbidities such as neurologic disease and pulmonary parenchymal disease. Evidence suggests that much age-related change is not neurologic or even muscular in nature—it has to do with alterations in the lamina propria. In general, fibroblasts that produce superficial lamina propria elements become less metabolically active (28–30). In consequence, apparently, the lamina propria thins, principally as a result of a loss of elastin fibers (31). Its stiffness increases in large part because of the relative increase in the amount of collagen (32). Such changes are more typical in men. In women, edema of the lamina propria is a more salient feature for unclear reasons (29). In addition to gender differences, significant variation from individual to individual is present in the aging larynx (33). Much remains to be discovered in this domain, but it seems clear from available evidence that the bowing that has been accepted as the laryngoscopic correlate of laryngeal aging is not just a loss of muscular bulk, easily remediable by medialization, but also a change in the vibratory characteristics of the vocal fold cover.

PHYSIOLOGY

Airway Protection

The most important biologic function of the larynx is airway protection, achieved most simply by glottic closure. Comparative anatomy reveals that the crudest laryngeal structures are simple sphincters to protect the lungs from the entry of water (22) and suggests that the evolutionary origin of the larynx thus lies in the emergence of amphibious life. The human larynx is, of course, a much more sophisticated structure, but the redundancy of its mechanisms for closure—vocal folds, ventricular folds, and epiglottis—and apparent specializations in the lateral compartment of the thyroarytenoid muscle hint at the continued primary importance of this action. It is also no surprise to find that laryngeal sensory receptors are a varied population that responds to a wide number of different kinds of stimuli, both mechanical and chemical. There is evidence for specific sensitivity to pH, chloride ions, and ion salts, with stimulation resulting from detected deviations from physiologic norms (23). These trigger laryngeal closure via a reflex arc made up of the superior laryngeal nerve and the recurrent nerve. The automaticity of laryngeal closure has been adapted by investigators as a clinical test of the integrity of laryngeal sensation (24).

The phenomenon of laryngospasm likely represents an exaggeration or perpetuation of reflex laryngeal closure as a result of factors that are not yet completely described. Laryngeal receptors may also serve as triggers for extralaryngeal responses such as apnea, bronchoconstriction, bradycardia, and changes in peripheral vascular resistance, all of which may be mediated by generalization of the efferent response to the entire vagus, including sympathetics (23). There has been speculation that such a response, unchecked by an immature neural system and possibly in reaction to laryngopharyngeal reflux, may underlie sudden infant death syndrome (34,35).

Cough and throat clearing represent the addition and integration of a respiratory component into the basic mechanism for airway protection and may be voluntary. Glottic closure following inspiration permits the individual to raise subglottic air pressure and use high-pressure forceful exhalation to clear an irritant or obstruction.

Respiration

The larynx participates actively in respiration as a regulator of airway dimension. Respiratory activity in the larynx is focused in the posterior cricoarytenoid muscles (principally the horizontal belly), the sole abductors of the vocal folds, which generally activate to counteract and even slightly anticipate the negative intraluminal pressure generated by diaphragm contraction (inspiration) (36,37). The posterior cricoarytenoid muscles are not merely entrained with respiratory muscles to mirror phasic activity during the respiratory cycle, however. They appear to have the ability to respond independently to receptors monitoring air pressure, temperature, humidity, and CO_2 concentration (37,38).

There is disagreement on whether vocal fold adduction during expiration represents active adduction or merely passive relaxation of the posterior cricoarytenoid. It seems

clear that in some situations, adduction is indeed active and that the size of the glottic aperture is a major determinant of respiratory rate, by means of control of the duration of exhalation (39).

The Valsalva Maneuver

Relatively high-pressure glottic closure is needed for effective thoracic fixation in the Valsalva maneuver. A wide variety of effortful physical activity depends on or is enhanced by the integrity of the thoracic fixation maneuver, including lifting, pushing, rising from a sitting position, and climbing. This range of activities only grows with impairment of the physical condition of the individual. Clinically, compromise of the Valsalva maneuver may be one of the most misunderstood symptoms in conditions of glottic insufficiency such as vocal fold paralysis. It is often mistaken for shortness of breath related to obstruction and may thus steer the physician directly away from measures necessary to restore glottic competence.

Voice

In voicing, the larynx functions only as an integrated part of the larger respiratory system. The larynx rests atop the tracheobronchial tree and lungs, which are at the same time its evolutionary reason for being and its principal source of energy for phonation, air. Distal to the larynx are the resonating and articulatory structures of the pharyngeal, oral, and nasal cavities, which, although not strictly essential for phonation, modify laryngeal output to such a degree that it would not be recognizable to the listener were they not there. Phonation represents a complex interaction among all of these elements, the details of which are well beyond what can be covered in this text. Voicing, as discussed below, focuses on laryngeal function during sustained phonation in modal register as representative of the most typical clinical situation. Numerous important aspects are therefore not covered, and the interested reader is strongly urged to explore the topic further in works by Titze (27) and others (40,41).

Phonation results from a cyclic interaction between exhaled air and the unique biophysical properties of the vocal folds, as explained originally by the *myoelastic-aerodynamic theory of phonation* (42). The glottal cycle begins with the accumulation of air pressure against the convergent walls of the subglottis, the result of exhalation of air against closed or, ideally, nearly closed vocal folds. At a certain pressure threshold, the air column begins to push the bottom of the vocal folds apart. As discussed earlier, vocal fold closure has a vertical dimension, and the rising air column parts the vocal folds from inferior to superior in a progressive way (Fig. 65.7). As air passes through the constriction formed by the vocal folds, it accelerates until it reaches the widened supraglottic lumen, where it slows again. Total energy must remain constant, however, so this

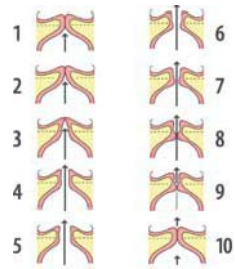

Figure 65.7 The phonatory glottic cycle. Courtesy of Voiceproblem.com.

increased velocity results in a drop in pressure in the area of constriction, according to the relationships set forth in the Bernoulli equation. This lower pressure (relative to the pressure immediately above the glottis) across the area of constriction is an important factor in glottic closure.

The glottal air column compresses the tissues of the vocal folds laterally as it passes through. These have an inherent elasticity, and their progressive deformation results in an equally progressive increase in the tissue forces favoring return to the midline. These forces combine with the decreased intraluminal pressure to begin the closure of the lower glottal edge, even as the upper edge is opened by the air column. This vertical phase difference is important in perpetuating the glottal cycle and corresponds to the mucosal wave seen on stroboscopic or high-speed photographic examination. Once the glottis is restored to its original configuration, the cycle repeats. The characteristics of the glottal cycle depend on inherent tissue properties, including the elasticity and viscosity of the vocal fold cover and the activity of the intrinsic laryngeal muscles, and the energy imparted by exhaled air.

The vocal fold oscillation of the glottic cycle changes an air column of constant pressure into one in which pressure varies regularly, and which is the physical correlate of what we perceive as sound. Like any periodic phenomenon, sound can be described in terms of the physical properties of its pressure waveform—amplitude, frequency, wave morphology, and periodicity. Each of these has a principal perceptual correlate—loudness, pitch, and voice quality, respectively. These may be altered by changes in either the aerodynamic contribution to the glottic cycle (air pressure) or the myoelastic contribution (tissue anatomy and stiffness), or, most commonly, both.

The amplitude of the pressure wave is perceived as loudness or sound intensity. The simplest means of increasing loudness is to raise the subglottic air pressure by using forced or active exhalation. However, tissue changes must occur to compensate for the raised pressure, or it will compromise the glottal cycle by overwhelming the elasticity of the vocal fold. This phenomenon is commonly seen in an individual with a denervated vocal fold. Because it is impossible to increase the stiffness of the paralyzed fold, the elevated pressure simply pushes it laterally, and a breathy break in the voice takes the place of the intended

shout. Under normal circumstances, increased tension of the vocal fold by means of appropriate muscle contraction (principally the thyroarytenoid but also the cricothyroid) increases the glottal resistance, restoring the balance of forces needed to maintain the glottal cycle.

The fundamental frequency, the rate of oscillation of the vocal folds, is mainly responsible for perceived pitch. This rate is a function of vocal fold tension on the one hand and mass on the other. The mechanism for controlling pitch involves an interaction between the cricoarytenoid, the thyroarytenoid muscle, and air pressure. Contraction of the cricothyroid muscle lengthens the vocal folds, increasing tension, decreasing mass per unit length, and thereby increasing frequency. Conversely, contraction of the thyroarytenoid shortens the vocal folds, decreasing tension, increasing mass per unit length, and thereby decreasing frequency. This relation is not true at all vocal intensities; however, because in louder phonation at lower frequencies, not only the mucosa but also the vocalis muscle is involved in vibration. As a result, its contraction increases tension and thus frequency.

It is principally in pitch control that the body and the cover of the vocal fold mentioned earlier in the discussion of anatomy play an important role. The body is a muscle with contractile properties that result in relatively large changes in mass and stiffness. The cover is a pliable, viscous, nonmuscular structure, the stiffness of which depends principally on its extracellular elements and extrinsic factors and varies a good deal less than that of the body. These two regions are decoupled—that is, they act as essentially separate oscillatory masses during phonation. Together, they act to preserve glottal elasticity, and thus the integrity of the glottal cycle, across a wider variety of vocal fold lengths and tensions than would otherwise be possible.

In reality, pitch and loudness are not separate phenomena; they are linked by aerodynamic and myoelastic phenomena. Greater air pressures tend to increase stretch of the vocal fold, which decreases mass and increases tension, resulting in higher frequency. Experimental work has shown that frequency rises together with sound intensity unless deliberate compensation takes place.

In general terms, hoarseness is the perceptual correlate of perturbations in the regularity of the glottal cycle and breathiness resulting from glottic insufficiency. A mental review of the clinical spectrum of voice disorders reveals the variety of ways in which this may occur. Edema, scars, and age-related changes alter the stiffness of the vocal fold cover, and if substantial enough, edema may alter mass as well. Mass lesions interfere with glottic closure and affect the elasticity and pliability of the vocal fold cover. Denervation impairs the ability to alter mass and stiffness of the vocal fold body, even when there is glottic closure at adduction. If the vocal folds cannot approximate, phonatory threshold pressure increases, sometimes beyond the capacity of the individual to sustain.

EVALUATION

History

Voice disorders have long resisted straightforward objective clinical characterization, despite the array of instrumental measures of acoustics and aerodynamics available. In most cases, important personal and subjective considerations influence not only the voice complaint but also the patient's treatment expectations. In consequence, medical evaluation of voice disorders requires attention to several factors not encompassed by the usual history solicited from patients with head and neck complaints. These include careful characterization of the complaint, both with respect to its nature and its severity, and an assessment of the patient's voice demands and habits. This approach emphasizes the functional limitations caused by the patient's voice problems.

Through the history, the otolaryngologist must first understand for what aspects of impaired voice production the patient seeks help. Patient perceptions of voice problems tend to be very individual and directly connected to the amount and type of vocal demands: for example, a school teacher's notion of "hoarseness" is likely to differ substantially from a singer's or a construction foreman's. "Hoarseness" is used broadly to describe a variety of phenomena and can refer to altered voice quality, phonatory fatigue, insufficient loudness, restricted pitch range, increased phonatory effort, breathlessness, impaired singing quality, or other features. It is not always the feature most obvious to the clinician that the patient finds troublesome.

The perception of the severity of these complaints is also subject to personal interpretation. Individuals have expectations and requirements of their voices that are not always a direct reflection of their occupational demands or other easily assessed factor and are often different from what the otolaryngologist might assume. Many people with dysphonia never seek medical attention, unaware that any problem exists. Others simply want to be reassured that their dysphonia is not caused by a malignancy. Still others complain of phonatory disturbances that are not apparent to the casual listener, and can even consider these crippling to professional or social activity. In part to help characterize the severity of an individual's voice problem, several standardized and statistically validated questionnaires have been developed. Among them, the Voice Handicap Index (VHI) (43) and the Voice Related Quality of Life (44) are the most widely used. The VHI-10 (45) is an abridgment of the former that makes it even easier to use without loss of statistical validity. Such inventories are useful to understand patient motivation and make appropriate treatment recommendations. Applied both before and after treatment, these can also form an important means of assessing outcome, which allows comparison among interventions, techniques, and studies.

We have seen that phonation depends on the integrity of the glottal cycle. Under typical circumstances, the glottal cycle repeats at approximately 100 cycles per second in men and 220 cycles per second in women. The physical stress on the tissues of the vocal fold cover is only beginning to be characterized by investigators, but it is considerable. This stress, known as *phonotrauma*, has the potential to cause changes to the oscillatory properties of the vocal folds and even to cause local tissue injury. When an individual uses the voice extensively or in adverse circumstances, phonotrauma and the potential for damage to the vocal apparatus grows. Because phonotrauma may be the single most important factor underlying most benign vocal fold lesions, assessing the particulars of voice use is an essential task of the voice history.

Independent of medical factors, phonotrauma is related to amount and intensity of voice use (which in turn may be the product of vocal demand, which usually results from an individual's professional requirements) and inappropriate or excessive voicing, usually resulting from an inherently talkative and extroverted personality. Teachers, for example, are notoriously overrepresented among voice patients, largely as a result of the relentless vocal demand of their work rather than any intrinsic behavioral factors. Distinguishing between demand and personal inclination is obviously important to making appropriate treatment recommendations. Otolaryngologists traditionally receive little or no training in the behavioral aspects of phonation. Probably as a result, "vocal abuse," like "hoarseness," is a term that has been used broadly and somewhat indiscriminately in otolaryngology as a synonym for phonotrauma. However, it is not always correct, and almost never helpful, simply to blame the patient for his or her vocal predicament.

A speech-language pathologist who is skilled and experienced in the management of voice problems may add considerable depth to the voice evaluation, especially with respect to its behavioral aspects. The speech-language pathologist is able to focus on factors of the history and individual voicing techniques that contribute to phonotrauma and may also experiment with therapeutic techniques during the initial visit. Not only can this help to determine how best to address behavioral factors, but it can also help to distinguish malingering or psychogenic disorders from organic ones and may facilitate the laryngeal examination itself by addressing compensatory behaviors such as ventricular fold hyperfunction in cases of glottic insufficiency.

Examination

The voice examination too has specialized elements, not least among them the use of the ear as a diagnostic instrument. It begins with a qualitative assessment of the voice prior to any attempt at laryngoscopy. Gross abnormalities will be readily apparent as the patient describes the complaint; more subtle ones require specific maneuvers and phonatory tasks to search for breakdowns of phonatory physiology. Low-intensity, high-pitched phonation, which results in voice breaks, irregularities, and delays in voice onset, suggests a small mucosal lesion. Reduced maximum phonation time (normally greater than 20 seconds) and limitations in volume point to poor glottic closure. It may require a sustained vowel to clearly reveal a tremor or other instability. The clinician should develop a diagnostic impression based on the contents of the history and the voice assessment prior to any visualization of the larynx. Discrepancy between the preliminary diagnostic and laryngoscopic findings should serve as a warning that the evaluation is not complete. A flexible fiberoptic examination that reveals no mucosal pathology when voice qualities suggest that it must be present is not a rare clinical situation. Rather than settling on a vague and nonspecific diagnosis—"chronic laryngitis" and "reflux" are the current favorites—the physician should pursue more specialized diagnostic techniques, including rigid or flexible distal-chip endoscopy and stroboscopy, or consider referral to a laryngologist if these are not available.

The well-known Grade, Roughness, Breathiness, Asthenia, and Strain scale (46) and, more recently, the Consensus Auditory-Perceptual Evaluation of Voice (47) represent efforts to systematize qualitative voice assessment and standardize the terminology used. These serve a principally descriptive purpose rather than a diagnostic one. Although not essential for routine clinical practice, they are useful to focus the assessment and for inquiry into clinical outcomes and efficacy.

The larynx may be directly examined in a number of ways. The venerable laryngeal mirror has the advantage of crisp optical resolution and color fidelity, but in practice, these do not offset the inability to record the examination and the occasional technical difficulty of the examination. The flexible fiberoptic laryngoscope is readily available in nearly every otolaryngologist's office and offers the surest means of visualizing the vocal folds. Only the very rare patient will find the examination intolerable. Flexible fiberoptic laryngoscopy also disturbs normal laryngeal dynamics least, permitting laryngeal visualization during connected speech, a feature that makes the flexible laryngoscope the instrument of choice for the evaluation of most neurologic disorders (see Chapter 70). The typical findings of spasmodic dysphonia, tremor, and other diseases may change or disappear when the tongue is pulled forward for peroral laryngoscopy. Similarly, glottic dynamics in cases of vocal fold paralysis or paresis may be more reliably evaluated without tongue traction. However, because of dependence of optic fibers, the flexible fiberoptic scope is optically inferior to every other means of examining the larynx, including the mirror, and will not reliably reveal small mucosal lesions. New designs that convert the optical signal to digital information at the tip of the endoscope (so-called "chip tip" devices) do away with

fibers and improve the picture. The rigid endoscope, which transmits the image to the eyepiece via a glass rod, offers high-resolution optical qualities at the price of increased technical skill, similar to that required to handle a laryngeal mirror. As a result, it is a superior means of evaluating mass lesions and other anatomic, as opposed to dynamic, abnormalities.

The limited depth perception offered by all commonly used techniques of office examination tends to obscure the three-dimensional nature of laryngeal function, as we have seen with gross vocal fold motion and glottic closure. Efforts to extrapolate this from careful examination have not always proved reliable and may lead to significant diagnostic confusion. The endoscopist should always keep this limitation in mind.

Stroboscopy uses a pulsed light source to create an illusion of continuous, slow-motion mucosal oscillation. The light pulses at a frequency just slightly different from that of the glottal cycle, generating a series of still images of the vocal fold at slightly different points across several glottal cycles, which are fused into an apparently fluid and continuous sequence by the examiner's eye. The stroboscopic effect depends on appropriate timing of the light pulses in relation to phonatory frequency and so is most reliable when vocal fold oscillation is periodic. Yet we have seen that aperiodicity is an important component of dysphonia. If severe, it tends to compromise stroboscopic light timing and thus the quality of the examination. Despite this limitation, stroboscopy is the only practical way of imaging mucosal oscillation routinely in the clinic and the optimal—occasionally the only—way of identifying abnormalities in mucosal pliability. It is likely the single strongest diagnostic instrument in most cases of dysphonia, especially for those disorders related to disturbances of mucosal vibration (e.g., scar and sulcus).

Stroboscopy is often considered synonymous with the rigid endoscope and video recording. Indeed, by virtue of the excellence of its optics, a rigid endoscope is an ideal vehicle for the stroboscopic examination. Although it is possible to perform stroboscopy via the flexible laryngoscope, the quality of the image will usually be inferior to that obtained with a rigid peroral endoscope. In all office laryngoscopy, but especially in stroboscopy, video recording is important for documentation and to enhance the diagnostic power of the examination. Review, both at normal and reduced speeds, can reveal aspects of pathology not seen in the initial examination, even if it is meticulous and unhurried. Video recording is essential for comparison across time and accurate and revealing assessment of the results of clinical interventions.

This text has reviewed only the most common among the tools available to assess laryngeal functions. Many more are available to complement the core evaluation, consisting of the history and perceptual and laryngoscopic assessment. Among these are additional means of vocal fold imaging such as high-speed photography; videokymography; and, more recently, three-dimensional computed tomography. Electroglottography and photoglottography allow assessment of glottic closure and opening, respectively, and a host of acoustic and aerodynamic measures provides further insight into phonatory dynamics and efficiency. The reader searching for more breadth and depth regarding instrumental laryngeal evaluation is referred to several standard works (48,49).

CONCLUSION

An understanding of anatomic features and physiologic processes involved in phonation is inextricably linked with the practice of laryngology. Most clinical advances in the last few decades have been based on corresponding advances in these areas, and this same body of knowledge now forms the basis of an effective clinical approach to voice disorders. Tools for routine evaluation of the anatomic and physiologic elements most important to voice production are commonly available, and the otolaryngologist must use these to reveal the problem and plan an appropriate clinical intervention. Modern laryngology, and particularly laryngeal surgery, has become a functional endeavor. The aim of treatment is no longer simply to excise pathology—it is to restore the normal physiology of phonation. For this to succeed, it is necessary that the clinician understand the laryngeal basic sciences thoroughly and strive to transform each new development and insight in those fields into an ever-higher standard of voice rehabilitation.

HIGHLIGHTS

- The laryngeal framework consists of four principal cartilages. The thyroid envelops the soft tissues of the larynx. The cricoid is the base of the larynx and is an important structural airway element. The arytenoids serve to translate the vectors of force of all intrinsic laryngeal muscles except the cricothyroid into vocal fold motion.
- The thyroarytenoid, lateral cricoarytenoid, and interarytenoid muscles are the principle adductors of the vocal folds. The posterior cricoarytenoid muscles are the sole abductors. The cricothyroid muscles elongate the vocal folds by effecting torsion at the cricothyroid joint.
- The arytenoid body shifts anteromedially as it is pulled closed and posterolaterally on being pulled open. Vocal fold adduction and abduction is thus a three-dimensional motion: adduction is medial and inferior, and abduction is lateral and superior.
- The recurrent laryngeal nerves are the principal sources of motor innervation to all of the intrinsic

laryngeal muscles except the cricothyroid and sensory innervation below the glottis. The superior laryngeal nerves are the principal sources of motor innervation to the cricothyroid muscle and sensory innervation above the glottis.

- The medial margin of the vocal fold consists of epithelium covering a layered matrix of fibrous proteins, known as the lamina propria, with unique biophysical properties essential for high-speed vocal fold oscillation necessary for phonation.
- The superficial lamina propria of the vocal fold is a distinct anatomic layer, rather than a potential space as the name "Reinke's space" implies. It is usually intimately related to mucosal pathology of the vocal fold, and its disruption leads to postoperative dysphonia.
- The larynx descends during human development so that the airway and swallowing passage are no longer separate. The capability for complex phonation thus comes at the price of an increased potential for choking and aspiration.
- The larynx functions as the sound source for voicing. Oscillation of vocal fold structures induced by exhaled air creates cyclic changes in air pressure perceived as sound.
- Loudness or sound intensity is the main perceptual correlate of the amplitude of the air pressure wave, generated principally by changes in exhaled air pressure. Pitch is the main perceptual correlate of the frequency of the pressure wave, generated principally by changes in mass and tension of the vocal folds.
- Evaluation of voice disorders consists of the history, including a characterization of individual vocal demand and behavioral elements contributing to the voice disorder, the perceptual assessment of the voice, and laryngoscopy.
- Stroboscopy is the only technique that allows routine clinical imaging of vocal fold oscillation, and as a result it is likely the single strongest diagnostic instrument in most cases of dysphonia.
- Dysphonia results from disruptions of phonatory physiology. To be most effective, treatment of dysphonia must focus on the restoration of normal physiology rather than excision of a specific lesion or alteration of laryngeal anatomy.

66 Laryngopharyngeal Reflux

Joel H. Blumin *Nikki Johnston*

Reflux of gastric contents into the esophagus, gastroesophageal reflux (GER), is a normal physiologic phenomenon that occurs in most people, particularly after meals. Brief and infrequent exposure of the esophagus to gastric contents does not result in injury and disease, implying that there are intrinsic defense mechanisms that act to maintain mucosal integrity. In fact, based upon pH monitoring studies, up to 50 reflux episodes a day (below pH 4) are considered normal (1). It is thought that esophageal symptoms and complications arise when reflux is prolonged and/or there is a breakdown in the defense mechanisms. This is termed gastroesophageal reflux disease (GERD). GERD is accepted as possibly the most common chronic disease of adults in the United States affecting more than 30% of Western society (2).

When gastric reflux travels more proximal into the laryngopharynx, it is termed laryngopharyngeal reflux (LPR) (3). Other terms, such as gastropharyngeal reflux and esophagopharyngeal reflux (EPR), have been used synonymously. These are all considered as part of extraesophageal reflux (EER), reflux involving structures other than, or in addition to, the esophagus. LPR contributes to several otolaryngologic symptoms, inflammatory disorders, and perhaps also neoplastic diseases of the laryngopharynx (3–9) and appears to be as common in children and infants as adults (10). It is estimated that 10% of patients visiting otolaryngology clinic have reflux-attributed disease, and up to 55% of patients with hoarseness have reflux into their laryngopharynx (3,7). LPR is actually one of the most common factors associated with inflammation in the upper airways and is a common source of chronic laryngitis (3,4). Compared to the esophagus, where up to 50 reflux episodes (below pH 4) a day are considered normal or physiologic, the laryngopharynx appears to be more sensitive to injury by gastric refluxate. It has been shown experimentally that three reflux episodes per week or less into the laryngopharynx results in severe damage of the laryngeal epithelium (3). Recently published normative data utilizing impedance monitoring statistically demonstrated that one or more reflux events per 24-hour period are significant for diagnosis of LPR and that LPR events are indeed rare in an asymptomatic population (11).

Symptoms of LPR include dysphonia, throat clearing, postnasal drip, chronic cough, dysphagia, globus pharyngeus, excessive phlegm, heartburn, dyspnea, laryngospasm, and wheezing (12). Signs of LPR include those of laryngeal inflammation such as erythema and edema of the larynx, especially in the postcricoid and hypopharyngeal areas. Additional signs associated with LPR include vocal fold edema, diffuse laryngeal erythema and edema, pseudosulcus vocalis, obliteration of the laryngeal ventricles, thickened laryngopharyngeal mucus, and granulomata (12). One should consider that many of these signs are not specific to LPR and can be associated with other forms of laryngopharyngeal inflammation.

REVIEW OF GASTRIC REFLUX CONTENTS AND PHYSIOLOGY

Gastric Acid

Gastric acid is produced by parietal cells in the stomach. Parietal cells contain an extensive secretory network, called canaliculi, from which gastric acid is secreted into the lumen of the stomach. These cells are part of the fundic glands in the gastric mucosa. Gastric acid is approximately pH 2 in the human stomach lumen, the acidity being maintained by the proton pump H^+/K^+ ATPase. The resulting highly acidic environment in the stomach lumen causes proteins from food to denature, thus exposing the protein's peptide bonds. The chief cells of the stomach secrete inactive enzymes pepsinogen and renin for protein breakdown. Gastric acid then activates pepsinogen into pepsin—this enzyme then helps digestion by breaking the

bonds linking amino acids, a process known as proteolysis. In addition, the acidic environment of the stomach inhibits growth of many microorganisms; the gut's bacterial load is controlled and this helps prevent infection.

Secretion of Gastric Acid

Gastric acid secretion happens in several steps. Chloride and hydrogen ions are secreted separately from the cytoplasm of parietal cells and mixed in the canaliculi ultimately forming hydrochloric acid (HCl). This acid is then secreted into the lumen of the oxyntic gland and gradually reaches the stomach lumen. Chloride and sodium ions are secreted actively from the cytoplasm of the parietal cell into the lumen of the canaliculus. This creates a negative potential of −40 to −70 mV across the parietal cell membrane that causes potassium and sodium ions to diffuse from the cytoplasm into the parietal cell canaliculi. The enzyme carbonic anhydrase catalyzes the reaction between carbon dioxide and water to form carbonic acid. This acid immediately dissociates into hydrogen and bicarbonate ions. The hydrogen ions leave the cell through H^+/K^+ ATPase antiporter pumps. At the same time, sodium ions are actively reabsorbed. The majority of secreted potassium and sodium ions therefore return to the cytoplasm. The highest concentration that gastric acid reaches in the stomach is 160 mM in the canaliculi. This is about 3 million times that of arterial blood, but is isotonic with other bodily fluids. The lowest pH of the secreted acid is 0.8, but as the acid is diluted in the stomach lumen with other secretions, the intragastric pH will range between 1 and 3.

There are three phases in the secretion of gastric acid:

The cephalic phase: 30% of the total gastric acid produced is stimulated by anticipation of eating and the smell or taste of food.

The gastric phase: 60% of acid secreted is stimulated by the distension of the stomach with food. Digestion also produces proteins, resulting in even more gastrin production.

The intestinal phase: the remaining 10% of acid is secreted when chyme enters the small intestine, and is stimulated by small intestine distension.

Regulation of Secretion

Gastric acid production is regulated by both the autonomic nervous system and several hormones. The parasympathetic nervous system, via the vagus nerve, and the hormone gastrin stimulate the parietal cell to produce gastric acid, both directly acting on parietal cells and indirectly by stimulating secretion of the hormone histamine from enterochromaffin-like (ECL) cells. Vasoactive intestinal peptide, cholecystokinin, and secretin all inhibit production. The production of gastric acid in the stomach is tightly regulated by positive regulators and negative feedback mechanisms. Four types of cells are involved in this process: parietal cells, G cells, D cells, and ECL cells. In addition, the endings of the vagus nerve (CN X) and the intramural nervous plexus in the digestive tract also significantly influence secretion. Nerve endings in the stomach secrete two stimulatory neurotransmitters: acetylcholine and gastrin-releasing peptide. Their action is both direct on parietal cells and mediated through the secretion of gastrin from G cells and histamine from ECL. Gastrin acts on parietal cells directly and indirectly too, by stimulating the release of histamine. The release of histamine is the most important positive regulation mechanism of the secretion of gastric acid in the stomach. Its release is stimulated by gastrin and acetylcholine, and inhibited by somatostatin.

Neutralization of Acid

In the duodenum, gastric acid is neutralized by sodium bicarbonate. This also blocks gastric enzymes that have their pH optima in the acid range. The secretion of sodium bicarbonate from the pancreas is stimulated by secretin. This polypeptide hormone gets activated and secreted from S cells in the mucosa of the duodenum and jejunum when the pH in duodenum falls below 4.5 to 5.

This neutralization is described by the equation:

$$HCl + NaHCO_3 \rightarrow NaCl + H_2CO_3$$

The carbonic acid instantly decomposes into carbon dioxide and water, and is eliminated through the kidneys in urine.

Role of Gastric Acid in Disease

In hypochlorhydria and achlorhydria, there is low or no gastric acid in the stomach, potentially leading to problems as the disinfectant properties of the gastric lumen are decreased. In such conditions, there is greater risk of infections of the digestive tract (such as infection with *Helicobacter* bacteria). In Zollinger-Ellison syndrome and hypercalcemia, there are increased gastrin levels, leading to excess gastric acid production, which can cause gastric ulcers. Reflux of gastric acid into the esophagus and more proximally into the laryngopharynx and other extra-esophageal sites also cause significant injury and disease—to be discussed in more detail later in this chapter.

Pharmacology

The H^+/K^+ pump enzyme is the target of proton pump inhibitors (PPIs), used to increase gastric pH in diseases that feature excess acid. Histamine H_2 antagonists indirectly decrease gastric acid production. Antacids have high pH and neutralize existing acid.

Pepsin

Pepsin is expressed as a pro-form zymogen, pepsinogen, whose primary structure has an additional 44 amino

acids. In the stomach, chief cells release pepsinogen. The acid present in the stomach activates this zymogen. The hormone gastrin and the vagus nerve trigger the release of both pepsinogen and HCl when food is ingested. HCl creates the acidic environment that allows pepsinogen to unfold and cleave itself in an autocatalytic fashion, thereby generating pepsin, the active form of the enzyme. Pepsin then cleaves the 44 amino acids from pepsinogen creating more pepsin. Pepsin will digest up to 20% of ingested protein's amide bonds by cleaving preferentially after the N-terminal of aromatic amino acids such as phenylalanine, tryptophan, and tyrosine. Pepsin exhibits preferential cleavage for hydrophobic, preferably aromatic, residues in P1 and P1′ positions. Increased susceptibility to hydrolysis occurs if there is a sulfur-containing amino acid close to the peptide bond, which has an aromatic amino acid. Pepsin cleaves Phe–Val, Gln–His, Glu–Ala, Ala–Leu, Leu–Tyr, Tyr–Leu, Gly–Phe, Phe–Phe and Phe–Tyr bonds in the B chain of insulin. Peptides may be further digested by other proteases in the duodenum and eventually absorbed in the intestine. Pepsin is stored as pepsinogen; so it will only be released when needed and does not digest the body's own proteins in the stomach's lining.

Pepsin is maximally active at pH 2, but has activity up to pH 6.5. While inactive at pH 6.5 and above, it remains stable to pH 8. The enzyme is not irreversibly inactivated (denatured) until pH 8. While the stomach is designed to resist damage by pepsin, reflux of pepsin into the esophagus and laryngopharynx causes damage even above pH 4. Pepsin is considered an important etiologic factor in reflux disease of the aerodigestive tract and a biomarker for reflux, whose levels and acidity can be related to the severity of damage.

Bile

Bile is produced by hepatocytes in the liver, draining through the many bile ducts that penetrate the liver. During this process, the epithelial cells add a watery solution that is rich in bicarbonates that dilutes and increases alkalinity of the solution. Bile then flows into the common hepatic duct, which joins with the cystic duct from the gallbladder to form the common bile duct. The common bile duct in turn joins with the pancreatic duct to empty into the duodenum. If the sphincter of Oddi is closed, bile is prevented from draining into the intestine and instead flows into the gallbladder, where it is stored and concentrated up to five times its original potency between meals. This concentration occurs through the absorption of water and small electrolytes, while retaining all the original organic molecules. Cholesterol is also released with the bile, dissolved in the acids and fats found in the concentrated solution. When food is released by the stomach into the duodenum in the form of chyme, the duodenum releases cholecystokinin, which causes the gallbladder to release the concentrated bile to complete digestion.

The human liver can produce close to one litre of bile per day. About 95% of the salts secreted in bile are reabsorbed in the terminal ileum and reused. Blood from the ileum flows directly to the hepatic portal vein and returns to the liver where the hepatocytes reabsorb the salts and return them to the bile ducts to be reused, sometimes two to three times with each meal.

Action of Bile Salts in Digestion

Bile acts to some extent as a surfactant, helping to emulsify the fats in food. Bile salt anions have both a hydrophilic and hydrophobic side, and therefore tend to aggregate around droplets of fat (triglycerides and phospholipids) to form micelles, with the hydrophobic sides toward the fat and hydrophilic to the outside. The hydrophilic sides are positively charged due to the lecithin and other phospholipids that compose bile, and this charge prevents fat droplets coated with bile from reaggregating into larger fat particles. Ordinarily, the micelles in the duodenum have a diameter of around 14 to 33 μm.

The dispersion of food fat into micelles thus provides an increased surface area for the action of the enzyme pancreatic lipase, which digests the triglycerides, and is able to reach the fatty core through gaps between the bile salts. A triglyceride is broken down into two fatty acids and a monoglyceride, which are absorbed by the villi on the intestine walls. After being transferred across the intestinal membrane, fatty acids are reformed into triglycerides, then absorbed into the lymphatic system through lacteals. Without bile salts, most of the lipids in the food would be passed out in feces, undigested.

Since bile increases the absorption of fats, it is an important part of the absorption of the fat-soluble substances, such as the vitamins D, E, K, and A. Besides its digestive function, bile serves also as the route of excretion for bilirubin, a by-product of red blood cells recycled by the liver.

The alkaline bile also has the function of neutralizing any excess stomach acid before it enters the ileum, the final section of the small intestine. Bile salts also act as bactericides, destroying many of the microbes that may be present in the food.

Role of Bile in Reflux Disease

Reflux of bile is known to cause esophagitis and is likely to play a role in reflux-attributed laryngeal injury and disease (13). The mechanism of bile-induced mucosal injury is thought to be related to "intramucosal trapping" of bile acids that results in mucosal damage primarily by disorganizing membrane structure or interfering with cellular metabolism. Taurocholic acid does this at pH 2 and chenodeoxycholic acid at pH 7. Some bile acids cause damage at high pH due to their lipophilic properties at the pH at or near the pK_a value. For example, taurocholic acid (which is a conjugated bile acid with a $pK_a \sim 2$) and

chenodeoxycholic acid (which is an unconjugated acid with pK_a ~ 7) are unionized and therefore can enter the cell at an acidic and neutral pH, respectively. Once inside the cell, bile acids are trapped by ionization and subsequently cause mucosal damage.

Trypsin

Trypsin is secreted into the duodenum, where it acts to hydrolyze peptides into their smaller building blocks—amino acids (these peptides are the result of the enzyme pepsin breaking down the proteins in the stomach). This enables the uptake of protein in the food because peptides (though smaller than proteins) are too big to be absorbed through the lining of the ileum. Trypsin catalyzes the hydrolysis of peptide bonds.

Trypsin is produced in the pancreas in the form of inactive zymogen, trypsinogen. When the pancreas is stimulated by cholecystokinin, it is then secreted into the small intestine. Once in the small intestine, the enzyme enteropeptidase activates it into trypsin by proteolytic cleavage. The resulting trypsins themselves activate more trypsinogens (autocatalysis), so only a small amount of enteropeptidase is necessary to start the reaction. This activation mechanism is common for most serine proteases, and serves to prevent autodigestion of the pancreas.

Involvement of Trypsin in Reflux Disease

Studies have shown that trypsin can stimulate the production of inflammatory mediators. Chemokines and prostaglandins are increased in human esophageal epithelial cells when exposed to trypsin *in vitro* (14). Trypsin has also been shown to induce chronic esophageal inflammation in rats (15).

PATHOPHYSIOLOGY OF LPR

Gastric refluxate, containing acid, pepsin, bile, and trypsin, obviously passes through the esophagus (as in GER) and enters the laryngopharynx (as in LPR), yet patients with laryngeal symptoms and injury do not often have esophageal symptoms or injury. It is thought that LPR patients have intact esophageal defense mechanisms that prevent esophageal injury by the refluxate. For example, in the esophagus, peristaltic motility helps clear the refluxate, salivary bicarbonate neutralizes the refluxate, and mucus secretions prevent the refluxate from penetrating the epithelium. In addition, the upper esophageal sphincter (UES) closes to prevent refluxate from entering the laryngopharynx. It is thought that UES function is defective in many patients with reflux-attributed laryngeal symptoms and endoscopic findings. The larynx lacks many of the intrinsic defense mechanisms present in their esophageal counterparts, perhaps explaining its increased sensitivity to gastric refluxate compared to the esophagus.

Reflux is thought to cause laryngeal symptoms and induce extraesophageal pathology by several different mechanisms. First, by direct contact of acid and pepsin with the epithelium—the microaspiration theory (4). Second, the trauma theory suggests that exposure of the laryngeal epithelium to gastric refluxate alone is not sufficient to cause injury and that an additional factor, such as vocal abuse or concomitant viral infection, is necessary to induce mucosal lesions (3,16). Finally, the esophageal–bronchial reflex theory suggests that acid in the distal esophagus stimulates vagally mediated reflexes that cause chronic cough, which in turn causes laryngeal symptoms and lesions (17).

Differences between LPR and GERD

Ossakow et al. (18) compared symptoms of patients with reflux esophagitis with those of patients with laryngitis. They found that hoarseness was the most prevalent symptom of patients with LPR (100%), although none of the patients with GERD reported experiencing hoarseness. Heartburn was present in the majority of patients with GERD (89%), but only a small percentage of LPR patients (6%). Wiener et al. (19) demonstrated abnormal pH studies in 78% of patients with hoarseness, all of whom had normal esophageal manometry, and of these, 72% had normal endoscopy with biopsy. This supports the theory that the majority of LPR patients have normal acid clearance mechanisms (20). Although both esophagitis and laryngitis are likely to be caused by the damaging effects of the corrosive refluxate, significantly more damage occurs in the larynx compared to the esophagus following exposure to acid and pepsin. This may be because the esophagus has better defense mechanisms to counteract such damage, for example, peristalsis, saliva, and bicarbonate production (3,21). Therefore, although there may not be sufficient reflux to cause esophagitis, it may be enough to develop symptomatic LPR.

The pattern and mechanism of LPR and GERD are different. LPR patients typically have upright (daytime) reflux with good esophageal motor function and no esophagitis, whereas GERD patients have supine (nocturnal) reflux and esophageal dysmotility (3,22,23). GERD patients often have a dysfunction of the lower esophageal sphincter (LES), while the UES is a primary defect in LPR patients (24). The different pattern and mechanism of reflux may explain the different clinical manifestations observed in LPR and GERD.

Role of Nonacid and Weakly Acid Reflux in Laryngeal Inflammation and Disease

Studies using combined multichannel intraluminal impedance with pH monitoring (multichannel intraluminal impedance-pH [MII-pH]; discussed later in this chapter) reveal a positive symptom association with nonacidic

reflux and a significant association between nonacidic and weakly acidic reflux and persistent symptoms on PPI therapy (25–27). Using MII-pH monitoring, Tamhankar et al. (25) showed that PPI therapy decreases the H^+ ion concentration in the refluxed fluid, but does not significantly affect the frequency or duration of reflux events. Kawamura et al. (28) reported on a comparison of GER patterns in 10 healthy volunteers and 10 patients suspected of having reflux-attributed laryngitis. Using a bifurcated MII-pH reflux catheter, the investigators found that gastric reflux with weak acidity (above pH 4), is more common in patients with reflux-attributed laryngitis compared to healthy controls. Oelschlager et al. (29) demonstrated that the majority of reflux episodes into the pharynx are in fact nonacidic. Sharma et al. (27) reported that 70/200 (35%) patients on at least twice daily PPI had a positive symptom index for nonacidic reflux. Finally, Tutuian et al. (26) also recently reported that reflux episodes extending proximally are significantly associated with symptoms irrespective of the pH of the refluxate. Patients with signs and symptoms associated with nonacidic and weakly acidic reflux would likely have a negative pH test and would not benefit from PPI therapy. Diagnosis and treatment has focused on the acidity of the refluxate because it was thought that the other components of the refluxate would not be injurious at higher pH. However, it is now known that certain bile acids are injurious at higher pH (30,31), and recent data supports a role for pepsin in reflux-attributed laryngeal injury and disease, independent of the pH of the refluxate (32,33). Given these data, it seems that a treatment regimen based on acid suppression alone would be bound to fail. Much of the controversy that has revolved around LPR management can easily be explained by this inflammation caused by weakly or nonacidic agents.

Antireflux surgery, such as fundoplication, is one of the few options for patients with persistent reflux-attributed symptoms and endoscopic findings. Unlike medical therapy, which does not stop reflux from occurring but only increases the pH of the refluxate, surgical therapy restores the physiologic separation between the abdomen and thorax and strengthens the LES, preventing refluxate from coming up the esophagus. Iqbal et al. (34) recently reported a study in which 85% of patients who had a fundoplication for extraesophageal symptoms of reflux had a positive outcome. The majority of these patients had refractory symptoms on maximal acid suppression therapy. These data additionally question the role of acid alone in the development of reflux-related pathology and highlight a potential role for the other components of the refluxate.

A role for pepsin in nonacid reflux has been postulated in the recent literature. As already stated, this enzyme is maximally active at pH 2, but can cause tissue damage above this pH, with complete inactivation not occurring until pH 6.5 (33,35,36). While pepsin is inactive at pH 6.5, it remains stable until pH 8 and thus can be reactivated when the pH is reduced. Pepsin is not irreversibly inactivated until pH 8 (33,36). Thus, even if the pepsin, which has been detected in, for example, laryngeal epithelia, is inactive (37,38) (mean pH of the laryngopharynx is 6.8), it would be stable and thus could sit inactive/dormant in the laryngopharynx and have the potential to become reactivated by a decrease in pH, either by a subsequent acid reflux event or perhaps once taken up by laryngeal epithelial cells and transported through intracellular compartment of lower pH (33,39–41).

Johnston et al. described how pepsin causes laryngeal epithelial cell damage at pH 7, and thus in nonacidic refluxate. These data may help explain why some patients have refractory symptoms on maximal PPI therapy, and help explain the reported symptom association with nonacidic reflux events. The authors report mitochondrial and Golgi damage in laryngeal epithelial cells exposed to pepsin at pH 7 (40). Cell toxicity was also demonstrated using the MTT cytotoxicity assay. Pepsin at pH 7 was also found to significantly alter the expression levels of multiple genes implicated in stress and toxicity. Of most clinical significance, they report that pepsin (0.1 mg/mL, pH 7) induces a proinflammatory cytokine gene expression profile in hypopharyngeal FaDu epithelial cells *in vitro* similar to that which contributes to disease in GER patients (42). Collectively, these data suggest a mechanistic link between exposure to pepsin, even in nonacidic refluxate, and cellular changes that lead to laryngopharyngeal inflammatory disease. In this context, the unexpected finding that pepsin is taken up by human laryngeal epithelial cells by receptor-mediated endocytosis is highly relevant. Pepsin has been previously assumed to cause damage by its proteolytic activity alone, but the discovery that pepsin is taken up by laryngeal epithelial cells by receptor-mediated endocytosis opens the door to a new mechanism for cell damage. It is possible that inactive, but stable, pepsin at pH 7 taken up by laryngeal epithelial cells becomes reactivated once inside the cell in compartments of lower pH such as late endosomes and the trans-reticular golgi where pepsin presence has been confirmed (32). The therapeutic potential of receptor antagonists and irreversible inhibitors of peptic activity to prevent pepsin uptake and/or reactivation are currently being studied.

OTHER CLINICAL MANIFESTATIONS OF EER

EER has been implicated as a source or cofactor of inflammatory disease of the mucosa of the entire head and neck. Subsites affected by reflux include mucosa of the nose, paranasal sinuses, eustachian tube and middle ear, nasopharynx, oropharynx, hypopharynx, larynx, subglottis, trachea, and lower airway. Connection of EER to specific disease states has been demonstrated in an ever expanding list of conditions of the aerodigestive tract including otitis media (OM), sinusitis, cough, sleep disordered breathing,

laryngitis, laryngospasm, airway stenosis, and lower airway problems such as asthma, chronic obstructive pulmonary disease, interstitial pulmonary fibrosis, and chronic lung transplant rejection. Evidence for these has been based largely on clinical findings that correlate to pH probe studies confirming EER or detection of elements of refluxate in the subsite in question. Animal and basic science studies have been used to propose or confirm a mechanism, but in most cases, direct cause and effect in the human condition has yet to be confirmed. Mechanism for disease is typically explained as occurring either by direct contact of refluxate and resulting inflammation of the mucosa or via a vagally mediated neurogenic process as previously discussed.

Extraesophageal Reflux and the Middle Ear

It has been proposed that refluxate that reaches to the nasopharynx can induce an inflammatory cascade that leads to middle ear dysfunction and OM. This can occur from direct inflammation and obstruction of the eustachian tube or by flow through the eustachian tube into the middle ear (43,44). Ambulatory pH probe studies of children with OM show a high rate of acid reflux (45). The presence of pepsin within the middle ear has also been shown in children with OM (46,47). The relatively neutral pH environment of the middle ear has led to criticism of the role of reflux in OM. Data showing presence of bile acids in effusions (48) as well as the recent expansion of our understanding of pepsin-induced mucosal injury at weakly or nonacidic pH provides another possible explanation (49). There have been limited evaluations of the effects of acid suppressive treatment in OM. In two small studies (50,51), there were significant clearing of effusions with antireflux therapy alone.

Extraesophageal Reflux and the Nose and Paranasal Sinuses

Although an association between sinonasal disease and gastric hypersecretion was first documented in 1950, only more recently has the awareness of this association been more fully investigated. In the late 1990s, several studies revealed a high association between EER and sinonasal disease. DiBaise et al. (52) performed pH probe studies on a group of patients with chronic rhinosinusitis (CRS) and noted 78% of patients had evidence of reflux. A larger epidemiologic study by El-Serag et al. (53) demonstrated that adults with GER were more likely to also have a history of sinusitis. In another study, patients with sinusitis were evaluated for reflux and those with objective findings of reflux were treated with acid suppression with a PPI. The majority of patients in this small noncontrolled study demonstrated improvement in their sinonasal symptoms following treatment for reflux. More recent studies of acid detection by pharyngeal probe have demonstrated its presence in the nasopharynx and multiple studies have demonstrated a high prevalence of GER with sinusitis in the pediatric population; however, cause and effect have yet to be proved (54).

The mechanism for disease is similar to other sites of the head and neck and can be explained by direct mucosal contact of refluxate or via a vagally mediated neurogenic process. With respect to the neurogenic mechanism, abnormalities of the autonomic system have been demonstrated in those with sinusitis and reflux. These abnormalities have been proposed to affect sinonasal mucosal edema and ostial function (55).

As with OM, there have been attempts to evaluate the effect of acid suppression and CRS (56). Results have been positive, but study design has been questioned. Bothwell noted that children with medically refractive CRS experienced relief of symptoms and avoided operation after acid suppressive therapy (57). Patients with CRS and a positive pH probe study tend to respond better to acid suppressive therapy then their cohorts without positive pH studies (52,58).

Extraesophageal Reflux and Stenotic Lesions of the Larynx and Airway

Stenotic lesions of the larynx and trachea continue to be a challenge to the otolaryngologist and patient. Although many of these lesions are posttraumatic or related to collagen-vascular disease, a subset remains idiopathic. Reflux has long been suggested to have a significant role in development of and worsening of laryngotracheal stenosis (LTS).

Bogdasarian and Olson (59) first suggested that reflux of gastric acid might play a significant role in the cause of posterior glottic stenosis. Later, Bain et al. (60) reported a case of subglottic stenosis (SGS) in a 57-year-old woman without a history of operation, trauma, or intubation. Her preoperative airway was described as being the size of a pencil eraser and then 5 months after a Nissen fundoplication and endoscopic airway management, her airway returned to a normal caliber. Little et al. (61) reported a case of a 12-year-old girl with recalcitrant SGS who continued to produce exuberant granulation tissue. During an endoscopic procedure, she was noted to have gastric contents in her larynx and hypopharynx. This patient was then treated with H_2-receptor blockers and antireflux behavioral management; she was subsequently decannulated and there was no further formation of granulation tissue.

In Koufman's widely cited manuscript on the description of EER, 225 patients with a variety of laryngeal disorders were systematically evaluated for reflux (3). Ambulatory 24-hour pH monitoring was preformed in 182 patients of whom 32 had LTS. Over three-quarters of those with LTS had abnormal pH studies. This group also had the highest rate of acid reflux identified of the seven categories of EER that were evaluated. In 1997, Little et al. (10) evaluated 222 children with a 24-hour dual probe pH monitoring.

About one-quarter of these patients had laryngeal findings and those with laryngomalacia or laryngeal stenosis had the highest number of pharyngeal reflux events. Maronian et al. (62) studied nineteen patients with SGS and was able to test fourteen with a three or four port pH probe monitor. Only two patients did not demonstrate pharyngeal reflux events. About one-half of the studied patients had idiopathic SGS and they concluded that reflux was the probable cause. The remaining group had concomitant disease states including sarcoidosis, Wegener's granulomatosis, laryngeal trauma, and intubation. Reflux was involved in all tested patients and it was concluded that it acts as a synergistic factor that stimulates granulomatous disease to react and subsequently result in the development of stenosis.

Clinical evaluations of acid suppression and management of LTS have been overwhelmingly positive. In most studies, patients taking H_2 blockers or PPIs show enhancement of surgical outcomes (63). Antireflux operation in the form of Nissen fundoplication is commonly recommended for those with LTS and confirmed EER as demonstrated from pH probe or MII-pH studies.

DIAGNOSIS

The diagnosis of LPR is based on a constellation of patient symptoms, clinical evaluation with visualization of the laryngopharynx, and specific invasive testing procedures (16). Many paradigms for diagnosis and treatment exist. The best diagnosis is based on a specific testing procedure, but many patients forego this and elect to undergo empiric therapy with acid suppression (such as a PPI, available now in the United States over the counter) as it is safe and effective. Response to treatment has been questioned as placebo effect (64). Given long-term treatment costs and potential risks, an objective test should be recommended for those undergoing long-term therapy (65). At the time of this writing, dual-probe ambulatory 24-hour pH monitoring is considered by many as the gold-standard evaluation, however, this accolade is not without debate, and indeed may soon be superseded by MII-pH monitoring (29,66).

Quality of Life Instrument

The most widely used quality of life (QOL) instrument related to LPR in the otolaryngologic literature is the *reflux symptom index* (RSI) developed by Belafsky et al. (67) This instrument (Table 66.1) consists of nine questions related to symptoms of irritation of the aerodigestive tract and was validated with ambulatory pH probe monitoring and appropriately controlled. A total score greater than 13 suggests the presence of LPR.

Laryngopharyngoscopy

When evaluating disorders of the upper aerodigestive tract, visualization of the organ of interest is imperative. While indirect laryngoscopy with a mirror may be adequate, endoscopy of the larynx and pharynx is an easily implemented and well-tolerated procedure that all otolaryngologists are well versed in performing (68). Visualization of the structures in question is superior and often times there is an opportunity for recording and photodocumentation. Signs of inflammation of the laryngopharynx are considered significant toward the diagnosis of LPR. The clinician needs to be careful, however, as these signs may also be considered nonspecific of a particular disease. Posterior laryngitis with thickening and pachyderma of the laryngeal posterior commissure and postcricoid mucosa has been classically associated with LPR (69,70). Signs of LPR, however, have been demonstrated to be more extensive and involve other subsets of the larynx. Granuloma of the vocal process is highly associated with LPR (71) as are stenoses of the larynx or subglottis (3). Changes within the endolarynx include pseudosulcus, vocal fold edema, and thickened

TABLE 66.1 THE REFLUX SYMPTOM INDEX

Within the last month, how did the following problems affect you? *Circle the appropriate response.*	0 = No Problem 5 = Severe Problem					
1. Hoarseness or a problem with your voice	0	1	2	3	4	5
2. Clearing your throat	0	1	2	3	4	5
3. Excess throat mucus or postnasal drip	0	1	2	3	4	5
4. Difficulty swallowing food, liquids, or pills	0	1	2	3	4	5
5. Coughing after you ate or after lying down	0	1	2	3	4	5
6. Breathing difficulties or choking episodes	0	1	2	3	4	5
7. Troublesome or annoying cough	0	1	2	3	4	5
8. Sensations of something sticking in your throat or a lump in your throat	0	1	2	3	4	5
9. Heartburn, chest pain, indigestion, or stomach acid coming up	0	1	2	3	4	5
TOTAL						

A score >13 suggests the presence of LPR.

TABLE 66.2 THE REFLUX FINDING SCORE

Subglottic edema	0 = absent 2 = present
Ventricular	2 = partial 4 = complete
Erythema/hyperemia	2 = arytenoids only 4 = diffuse
Vocal fold edema	1 = mild 2 = moderate 3 = severe 4 = polypoid
Diffuse laryngeal edema	1 = mild 2 = moderate 3 = severe 4 = obstructing
Posterior commissure hypertrophy	1 = mild 2 = moderate 3 = severe 4 = obstructing
Granuloma/granulation tissue	0 = absent 2 = present
Thick endolaryngeal mucus	0 = absent 2 = present

A score of >7 suggests LPR.
From Belafsky PC, Postma GN, Koufman JA. Title the validity and reliability of the reflux finding score (RFS). *Laryngoscope* 2001;111(8): 1313–1317, with permission.

mucus. The *reflux finding score* (RFS) is a validated checklist of items to look for in the laryngopharynx when considering LPR (Table 66.2; Figs. 66.1 to 66.4) (72).

Esophagoscopy

The role of esophageal endoscopy is different than that of laryngopharyngeal endoscopy in the diagnosis and management of LPR. While visualization of the laryngopharynx is considered paramount in making a diagnosis, esophageal visualization is more useful to rule out other pathology that either mimics the symptoms of LPR, or pathology that is associated with LPR (73). Some recommend an esophageal evaluation in those with known LPR to rule out important phenomena such as Barrett's intestinal metaplasia (74). This is important to consider even in those with well-treated LPR given a high association of esophageal pathology in those with laryngopharyngeal symptomology.

Endoscopy can be performed with either of two methods—flexible large bore transoral or flexible small bore transnasal telescopy. Transoral rigid esophageal endoscopy is not typically applied in reference to LPR and holds a more traditional role in management of anatomic abnormalities of the esophagus. Transoral flexible esophageal endoscopy with a large bore telescope is performed under sedation (monitored anesthesia) and is usually considered an outpatient operation or procedure. Transnasal endoscopy (TNE) has been well accepted in the otolaryngologic literature as a diagnostic and screening tool. It is very safe and effective. Most complications from upper endoscopy are associated with anesthesia and sedation (75). In the TNE procedure, the patient is ambulatory and awake. There is no sedation and only topical anesthetics are used. The procedure can be performed in the office and is well

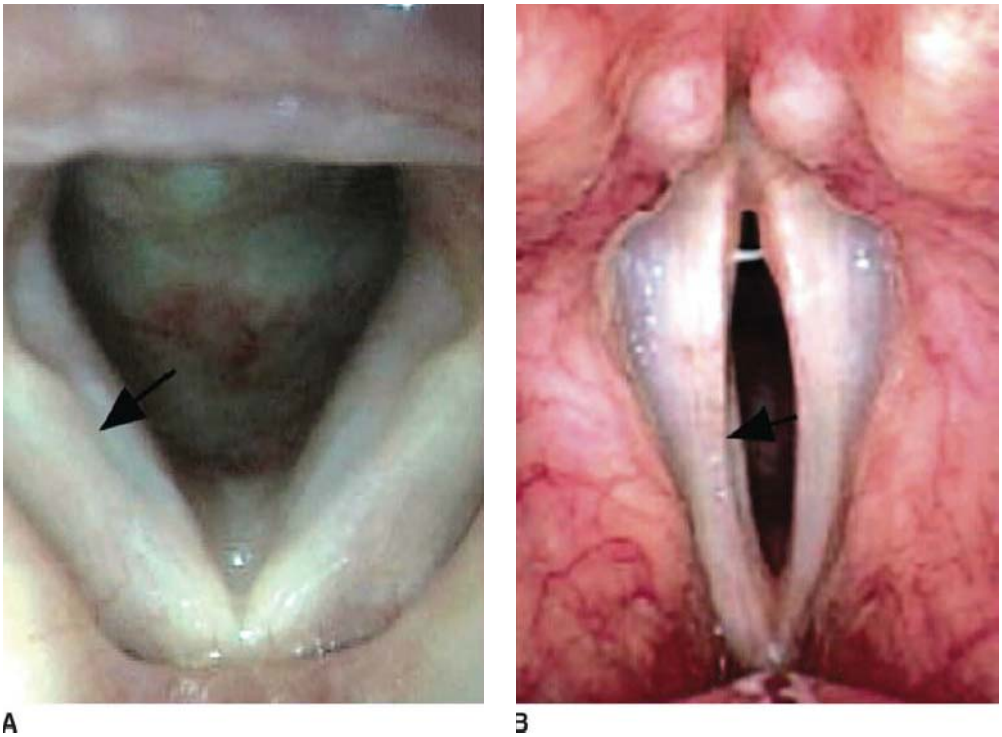

Figure 66.1 Comparison of pseudosulcus versus true sulcus vocalis. **A**: Bilateral pseudosulcus vocalis (*arrow*). Notice the subglottic edema extends past the vocal process all the way to the posterior larynx. Also present are posterior commissure hypertrophy, vocal fold edema, diffuse laryngeal edema, and partial ventricular obliteration. **B**: True sulcus vocalis of the right vocal fold (*arrow*). Notice that the sulcus is present in the midportion of the striking zone and stops at the vocal process of the arytenoid. From Belafsky PC, Postma GN, Koufman JA. Title the validity and reliability of the reflux finding score (RFS). *Laryngoscope* 2001;111(8):1313–1317, with permission.

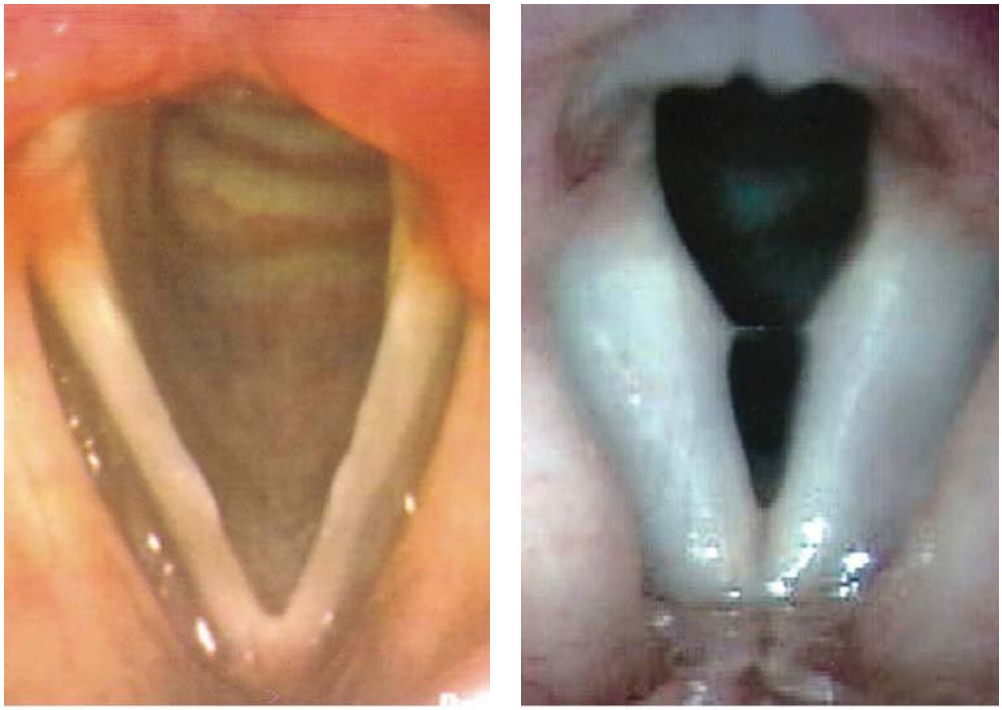

Figure 66.2 Ventricular obliteration. **A**: Open laryngeal ventricles. Note the sharp ventricular bands and the open space between the true and false vocal folds. Note small prenodules. **B**: Ventricular obliteration. Both the true and false vocal folds are swollen, thus obliterating the ventricles. Also present is mild posterior commissure hypertrophy. From Belafsky PC, Postma GN, Koufman JA. Title the validity and reliability of the reflux finding score (RFS). *Laryngoscope* 2001;111(8):1313–1317, with permission.

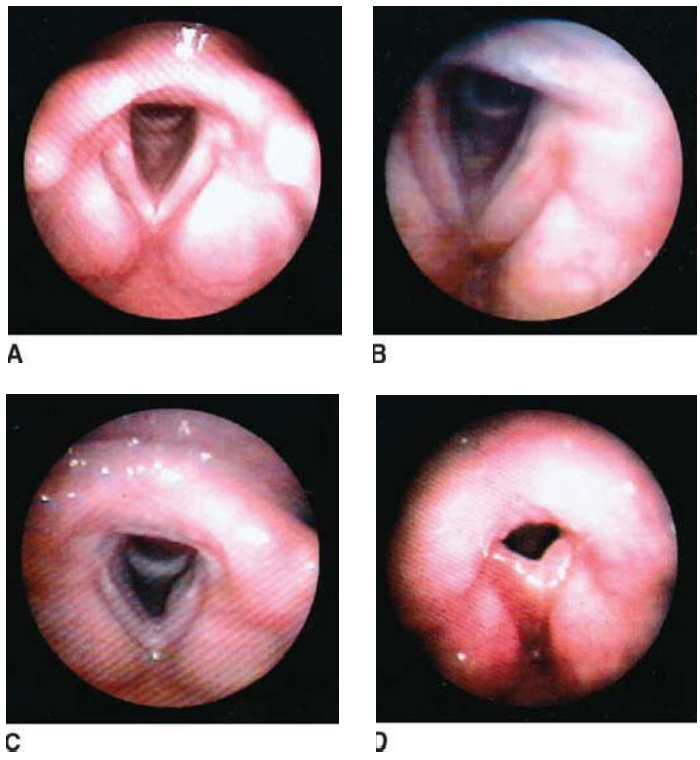

Figure 66.3 Vocal fold edema. **A**: Mild vocal fold edema. **B**: Moderate vocal fold edema. Pseudosulcus vocalis, posterior commissure hypertrophy, and partial ventricular obliteration are also present. **C**: Severe vocal fold edema. Sessile changes are noted. Also present are pseudosulcus vocalis, posterior commissure hypertrophy, and partial ventricular obliteration. **D**: Polypoid degeneration of the true vocal folds. Also present are severe posterior commissure hypertrophy, total ventricular obliteration, and diffuse laryngeal edema. From Belafsky PC, Postma GN, Koufman JA. Title the validity and reliability of the reflux finding score (RFS). *Laryngoscope* 2001;111(8):1313–1317, with permission.

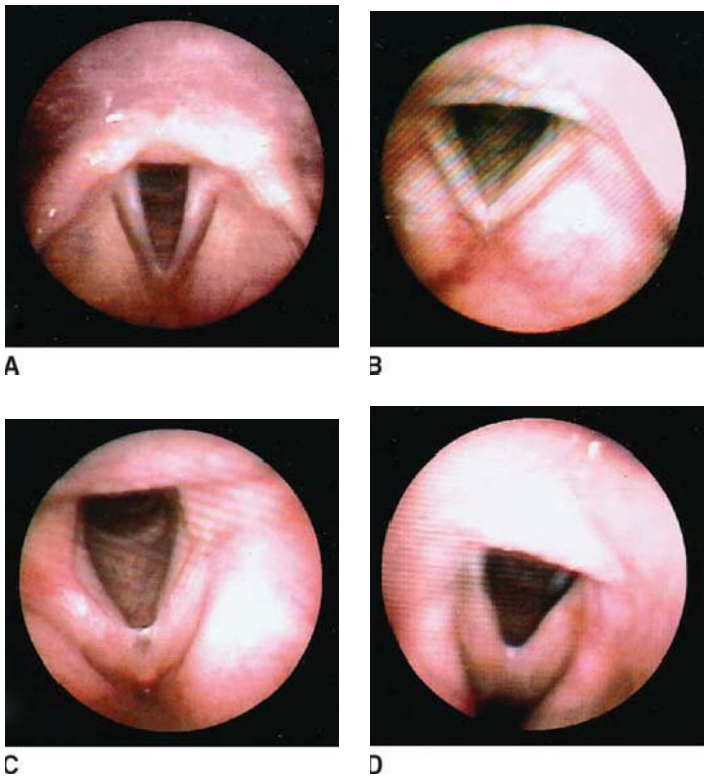

Figure 66.4 Posterior commissure hypertrophy. **A**: Normal posterior commissure. Cuneiform cartilages can still be visualized. **B**: Mild posterior commissure hypertrophy. Slight mustache-like configuration of posterior commissure. Also present are moderate vocal fold edema, pseudosulcus vocalis, and partial ventricular obliteration. **C**: Moderate posterior commissure hypertrophy. Straight line across the posterior larynx. Also present are moderate vocal fold edema, pseudosulcus vocalis, partial ventricular obliteration, and diffuse laryngeal edema. **D**: Severe posterior commissure hypertrophy Also present are several vocal fold edema, total ventricular obliteration, and diffuse laryngeal edema. (From Belafsky PC, Postma GN, Koufman JA. Title the validity and reliability of the reflux finding score (RFS). *Laryngoscope* 2001;111(8):1313–1317, with permission.)

tolerated by patients because of little down time and no need for a driver or companion's assistance in the periprocedural period. In their review of over 700 cases, Postma et al. (73) noted no major complications. In this and other reviews, only minor epistaxis and rare vasovagal response has been reported.

Reflux Detection

Detection of retrograde transport of liquid and gas from the stomach to the upper aerodigestive tract is considered the current gold standard of reflux testing. A variety of tools have been used to detect refluxate. The most widely used is a pH monitor and this tool comes in several varieties. Wired varieties are equipped with antimony probes that detect a change in endoluminal pH. These are commercially available with single (esophageal) and dual (esophageal and pharyngeal) acid detection capability. Triple and quadruple probes have been used experimentally. The coated wire probe is placed transnasally after calibration to the desired level in the esophagus. Single probes are commonly used in the gastroenterology literature to detect GER. As GER is quite different from LPR, single (distal esophageal) pH probe monitoring has little to no role in detection of LPR. For detection of LPR, the dual pH probe is most commonly used and placed for 24 hours while the patient is ambulatory, and at least theoretically, going about their normal routines. An intake log of food, drink, position (supine or upright), and any symptomology is kept by the patient and used for later interpretation of the study. Placement of the dual probes is not without controversy. The distal LES can be measured by pH pullback or by manometry (76). The upper probe can be placed just below, at, or just above the cricopharyngeus (77). Interpretation is also subject to debate. Distal esophageal events are defined as pathologic if they exceed a certain Johnson-DeMeester score (78). A similar scoring system does not exist for the upper probe interpretation. At the upper probe, pathologic reflux is considered by some as a single event while others suggest an acid exposure of 0.1% of the study less than pH 4 (3,79). Recent normative data demonstrate that as little as one reflux event to the pharynx is significant enough to diagnose LPR (11). Additional controversy and debates are made about consideration of a pH of less than 4 as significant as defined by convention in the gastroenterology literature. Data discussed earlier in this chapter suggest that peptic activity of refluxate exists at higher pH. Some have incorporated this and suggest that pH studies be interpreted at a cutoff of pH 5 or higher (80).

Many consider traditional wired transnasal pH probes encumbering to the patient in the clinical setting. A wireless probe system was developed to overcome this issue (81). The Bravo pH Monitoring System (Given Imaging Ltd., Yokneam, Israel) utilizes a capsule-contained pH probe coupled to a wireless transmitting system. This small capsule is attached to the esophageal mucosa under endoscopic guidance and then transmits data to a wireless device held at the patient's waistband. The probe usually stays in place for 3 to 5 days before it self-detaches with normal sloughing of the esophageal epithelium. Data is

collected for 48 hours. Criticism of this technique lies in its application to LPR. The probe must be placed in the esophagus and therefore upper esophageal or pharyngeal measurement cannot be performed.

Another limitation of the more traditional antimony pH electrodes is their need for a moist environment to remain accurate. One of the major obstacles in pH monitoring of the pharynx is the risk of the electrode drying as it frees itself from the liquid film at the mucosa. The Dx-pH Measurement System (Restech Corporation, San Diego, CA) was designed to overcome some of this limitation (82). This is a wired short probe that is placed transnasally at the level of the oropharynx and is capable of detection of both gaseous and liquid acid refluxate. It is also considered more comfortable than a standard pH probe because of its short length. Data on its application to LPR is still emerging, but at the time of this writing, it seems like a useful screening tool for LPR.

One of the major shortfalls of pH testing alone is the relative inability to detect reflux events at weakly acidic or neutral pH. The Bilitec 2000 system (Medtronic, Shoreview, MN) is a transnasal system that detects the presence of bile pigments via spectrophotography (83,84). Tack et al. (85) have recommended simultaneous pH and Bilitec monitoring in patients with refractory esophagitis after demonstrating a high degree of duodenal reflux in patients that failed PPI therapy. With respect to LPR, Poelmans et al. (86) demonstrated bile in throat phlegm utilizing a similar dual pH and Bilitec monitoring trial.

MII-pH monitoring now represents perhaps the ultimate in reflux detection (87). This device has the capability of detecting acid, weakly acidic, and nonacid events occurring at multiple stations within the esophagus, stomach, and pharynx. Furthermore, both contents and direction of flow can be differentiated—events can be separated into liquid or gas and can be identified as anterograde (swallow) and retrograde (reflux) direction. Patients who are acid suppressed on a PPI can still be evaluated for reflux (27,88).

The impedance detection device looks similar to a standard wired pH probe system, and indeed, many commercial models have an integrated pH probe system; hence the moniker of combined MII-pH probes. Impedance is a measure of electrical resistance. Multiple impedance electrodes are present along the length of the catheter probe system. Each probe is capable of detecting a rise or drop in intraluminal impedance. Gas has a very high impedance, normal mucosa is somewhat lower, and liquids such as saliva and refluxate are even lower. With multiple electrodes, directionality of an impedance delta can be ascertained, and if anterograde, is considered a swallow, and if retrograde, is considered a reflux or eructation.

Data with MII-pH testing and LPR are still emerging. The most recent studies have confirmed weakly and nonacidic reflux in those with LPR and those that fail acid-suppressive medical therapy (11,25–27,89). MII-pH seems to have an emerging role in identifying those who may benefit from operative therapy given the current limitations of medical therapy (90).

Radiologic Imaging

There exists a variety of imaging techniques available to image the esophagus including the barium swallow, modified barium swallow, and other techniques of videofluoroscopy. In general, a contrast material such as liquid barium is swallowed under fluoroscopic visualization (91). Although this method has a traditional application toward detection of reflux, in studies that compared imaging to pH probe monitoring, the sensitivity of reflux detection only ranged from 25% to 33% (92). Superficial mucosal pathology including esophagitis, dysplasia, and metaplasia may not be successfully seen on imaging. Most would recommend esophagoscopy and biopsy toward specific diagnosis of epithelial disease. Imaging, on the other hand, does have a significant role in diagnosis of anatomic or structural abnormalities such as tumor, rings, slings, and strictures. Manometry is thought to be a superior method of detecting motility disorders, however, there is a zone at the transition of striated to smooth muscle in the proximal esophagus that is not well detected on manometry. Videofluoroscopic studies can demonstrate EPR that is thought to be associated with LPR. This phenomenon is best assessed with an imaging study (93).

Tissue and Fluids Assay—Pepsin Detection

Pepsin has been posited to be a reliable marker for the diagnosis of EER (38). Synthesized only by the chief cells of the gastric fundus as the zymogen pepsinogen and subsequently converted to active pepsin via autolysis in the acidic environment of the stomach, pepsin is the primary proteolytic enzyme of the digestive system and one of the key deleterious agents of gastric refluxate (3,94). While the constitution of gastric refluxate is variable and components such as acid or bile salts may or may not be present, all refluxate contains pepsin. Like MII, pepsin assay has the capacity to detect nonacidic reflux and may be used to monitor reflux in patients undergoing treatment with PPIs. Superior to pH and MII testing, pepsin analysis may be performed on easily obtainable samples of saliva and sputum thereby facilitating testing of all patients including children or the neurologically impaired, as this would require no transnasal catheter placement or other invasive procedure. Patients could also be evaluated in their more normal state without dietary or lifestyle alteration that comes with the more invasive testing. Pepsin assay also offers the advantage of direct detection of refluxate at sites of airway damage potentially attributable to EER. Although pepsin assay alone does not indicate a causal relationship to airway damage, presence of pepsin outside of the stomach does indicate reflux and refluxate reaching the tested tissue or fluid. To date, this technique has demonstrated the

presence of pepsin in the laryngopharynx, esophagus, trachea, lung, sinus, middle ear, sputum/saliva, and exhaled breath (37,38,43,49,94–97). At the time of this writing, a pepsin diagnostic test remains confined to research laboratories and is not commercially available; however, it is anticipated that a pepsin in-office clinical test will be commercially available in the near future.

TREATMENT OF LARYNGOPHARYNGEAL REFLUX

When treating LPR, the goal is to eliminate symptoms, heal mucosal lesions, manage complications, and maintain symptom remission. It is thought that control of intragastric acid secretion and reduction of pharyngeal and laryngeal acid exposure is directly related to mucosal healing and symptom relief. Dietary and lifestyle adjustment (Table 66.3), medicines, and operations have been used to manage those with LPR.

LPR is often treated empirically, that is, based on symptoms and findings consistent with the disease (16). These symptoms and findings, however, can also be considered nonspecific and encompass a variety of etiologies of chronic laryngopharyngitis. Controversy exists whether to begin treatment based on a clinical diagnosis alone, or to defer this treatment until after confirmation by more objective data such as a pH probe study (98). Because behavioral maneuvers and acid suppressive medicines are considered safe and possibly effective, many recommend a 3 month period of empiric treatment and then evaluating again for treatment response before objective testing (i.e., pH monitoring) is employed. Others however recognize the limitations and potential risks of empiric treatment and suggest that medical management be delayed until after objective testing (65,99). One should keep in mind that the contemporary practice of medical therapy for LPR is not specifically U.S. FDA approved. Although clinical practice guidelines exist for treatment of GERD, no evidence-based guidelines truly exist (at the time of this writing) for LPR. Treatment of LPR and EER is largely based on uncontrolled observational studies or physiologic pH data (98,100). With LPR, the evidence-based definition of who receives empiric treatment with medicines and who has an esophageal endoscopy has yet to be completely established (Fig. 66.5).

TABLE 66.3 RECOMMENDED LIFESTYLE MODIFICATIONS FOR REFLUX

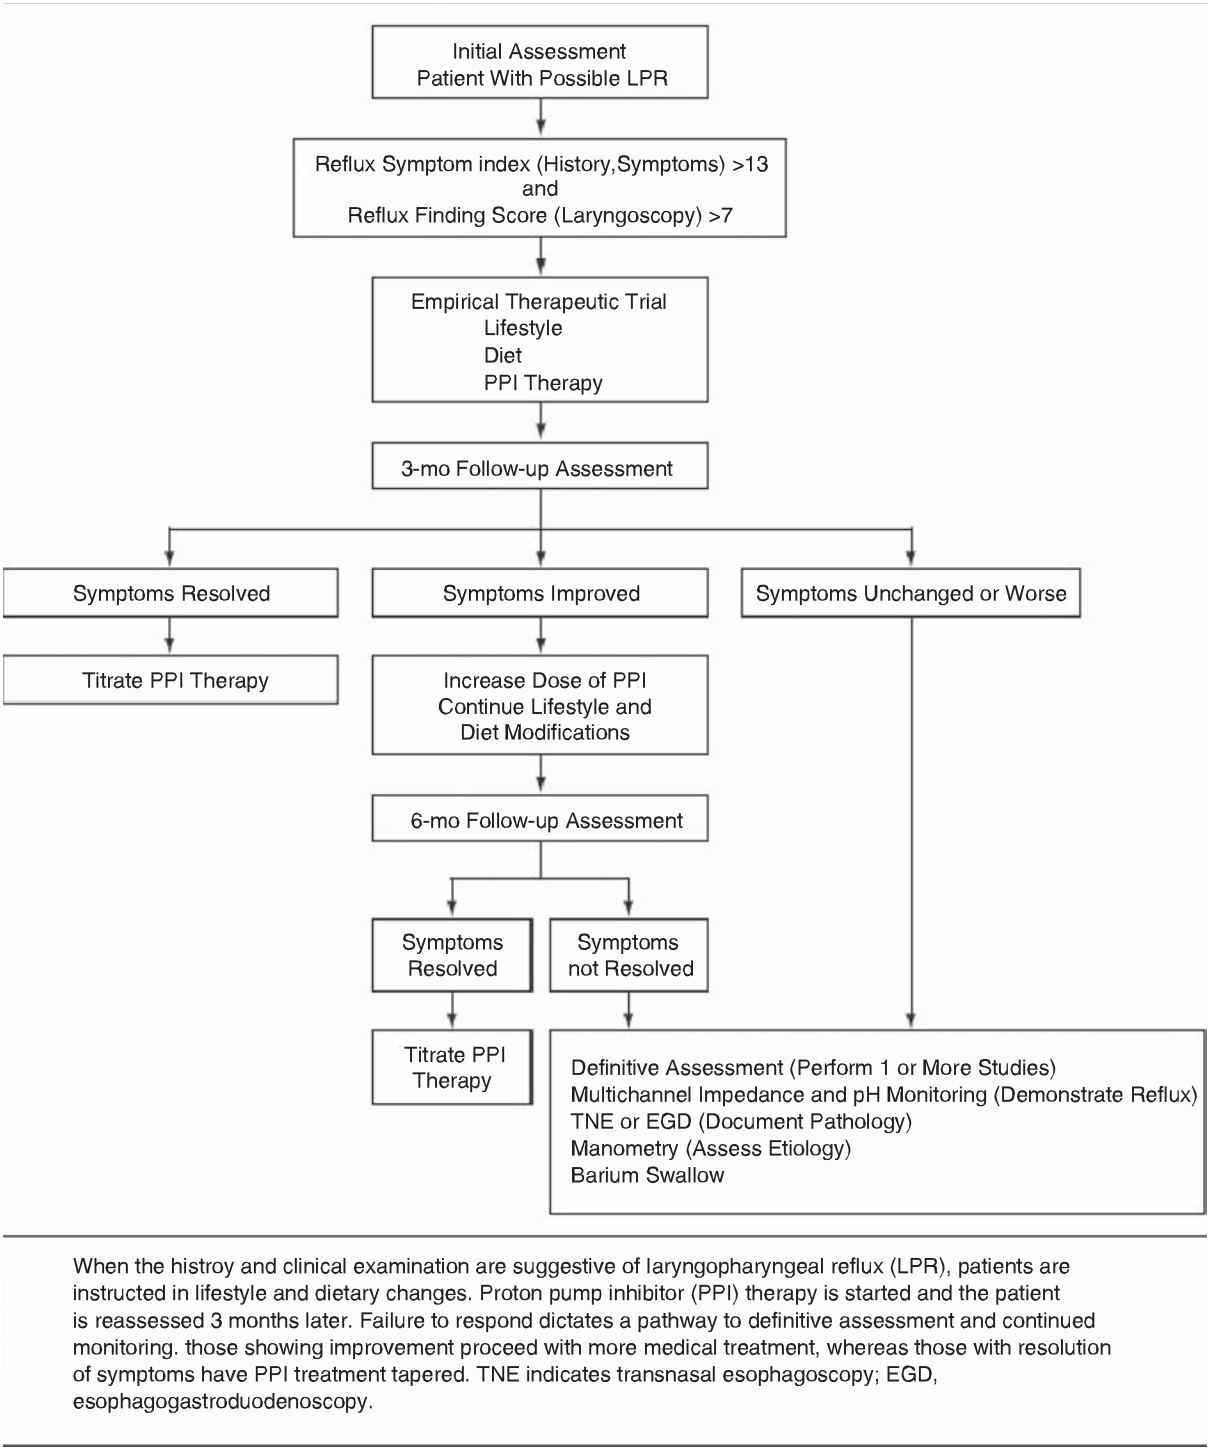
Weight loss (≤25 kg/m^2)
Small meal size
Avoid lying down within 3 h of eating a meal
Eat a low fat, low acid diet
Avoid carbonate beverages
Avoid spicy food and chocolate
Stop smoking
Reduce alcohol intake
Avoid tight-fitting clothes

These lifestyle modifications may be helpful in managing reflux disease, however, scientific data proving the effectiveness of these changes is still needed.

Weight Loss

The relationship between obesity and LPR is not well defined. Some studies show an increased risk of reflux symptoms in obese individuals (101), but other studies show no such association (102). However, patients with LPR are recommended to make dietary and lifestyle modifications. Diet and weight loss will decrease intra-abdominal pressure, stomach distension, and LES relaxations. Thus, most physicians advocate weight loss to help control reflux, with the goal of a body mass index of approximately 25 kg/m^2.

Dietary Factors



Patients with LPR often report worsening of symptoms with acidic and spicy foods. If patients report exacerbation of symptoms with certain foods they should decrease or eliminate them from their diet. Common mucosal irritants include citrus juices, tomato products, coffee, tea, cola, spicy foods, and alcohol. Carminatives such as chocolate or peppermint will lower LES pressure, increasing the frequency of reflux, and therefore should also be avoided. Carbonate beverages are not only acidic, but also promote reflux by gaseous gastric distension (103). It is likely that meal volume and subsequent gastric distension will affect reflux (104). Fatty or fried foods are also thought to promote reflux. Finally, reflux often occurs postprandially, so the supine position should be avoided for at least 3 hours after a meal. It is therefore recommended that patients eat small meals that are low in fat, low acid, and avoid lying down after a meal.

Medications

Medications such as anticholinergics, sedatives, tricyclic antidepressants, potassium tablets, iron sulphate, and nonsteroidal anti-inflammatory drugs decrease LES pressure promoting reflux and thus should be avoided when possible.

Smoking

Smoking tobacco is associated with reflux disease. Smoking decreases LES pressure, promoting reflux. The toxic irritants in tobacco also affect laryngeal mucous membranes and increase mucous viscosity causing excessive throat clearing. Furthermore, smoking-associated cough will increase intra-abdominal pressure thereby increasing reflux events.

When the histroy and clinical examination are suggestive of laryngopharyngeal reflux (LPR), patients are instructed in lifestyle and dietary changes. Proton pump inhibitor (PPI) therapy is started and the patient is reassessed 3 months later. Failure to respond dictates a pathway to definitive assessment and continued monitoring. those showing improvement proceed with more medical treatment, whereas those with resolution of symptoms have PPI treatment tapered. TNE indicates transnasal esophagoscopy; EGD, esophagogastroduodenoscopy.

Figure 66.5 Algorithm for assessment and management of LPR (from Ford CN. Evaluation and management of laryngopharyngeal reflux. *JAMA* 2005;294(12):1534–1540, with permission. Copyright © 2005 American Medical Association, all rights reserved)

Alcohol

Alcohol intake is also associated with reflux disease. Like tobacco, alcohol decreases LES pressure, but also increases gastric acid secretion and negatively affects esophageal motility and gastric emptying (105).

Tight-Fitting Clothes

Tight-fitting clothes will increase intra-abdominal pressure and thus should be avoided in patients with reflux disease.

Elevation of the Head of the Bed

As already mentioned, most LPR patients reflux during the daytime and have little to no reflux when supine (8). However, if the patient reports night-time symptoms, or has pH-documented supine reflux, elevation of the head of the bed by 6 inches may help decrease reflux by the action of simple gravity.

MEDICAL TREATMENT

Treatment of LPR is largely focused on increasing the pH of the refluxate. The harmful effects of pathologic reflux are controlled by neutralizing the stomach acid and suppressing its production. While acid neutralization and suppression therapies are effective for the treatment of GERD, their role in the treatment of LPR remain controversial. Studies performed to date report variable results to medical therapies.

Bicarbonate Gum

Chewing sugar-free bicarbonate gum will directly increase esophageal and pharyngeal pH by buffering acid and will indirectly increase pH via saliva production (106).

Prokinetic Agents

Prokinetic agents such as metoclopramide and cisapride are used in reflux patients who have dyspeptic symptoms such as nausea, vomiting, and abdominal bloating. These drugs increase LES pressure and accelerate esophageal acid clearance and gastric emptying. Their use has fallen out of favor in recent years (107). Problems with cardiac arrhythmias and drug-associated deaths led to removal of cisapride from the US market in 2000 (108). Their results as single agent therapy for GER or LPR have been disappointing. Some patients are intolerant of the medicines side effect profiles including diarrhea or cramping, and treatment success with acid suppression has been variable and limited.

Sucralfate

Sucralfate is used in the treatment of GERD and stress ulcers and may be useful in the treatment of LPR; however, there are no specific data to support this as a treatment of LPR. Sucralfate is a locally acting substance that reacts with HCl to form a cross-linking viscous material that acts as an acid buffer for up to 8 hours. It attaches to proteins on the surface of ulcers, such as albumin and fibrinogen, to form stable and insoluble complexes, creating a barrier against gastric refluxate. In addition, it prevents back diffusion of hydrogen ions and absorbs both pepsin and bile acids further preventing esophageal damage by reflux.

Alginate

Alginate antireflux preparations are widely used for the treatment of GERD. They react with stomach acid to form a gel raft that floats on top of the stomach, helping to keep gastric contents in the stomach and preventing GER. Several studies have shown the efficacy of Gaviscon Advance (Reckitt Benckiser, Kingston-upon-Thames, UK) in the treatment of LPR. This alginate preparation is licensed in the United Kingdom for the treatment of LPR, but is not currently available in the United States. Treatment with Gaviscon Advance, either alone or in conjunction with a PPI, was found to be significantly beneficial in improving symptoms, laryngeal findings, and patient QOL compared to control (109).

H_2 Receptor Antagonists

H_2 receptor antagonists, such as cimetidine, famotidine, ranitidine, and nizatidine, inhibit gastric acid secretion by blocking stimulation of the parietal cell. They competitively inhibit the binding of histamine to the basolateral membrane of parietal cells to suppress acid production. H_2 receptor antagonists are best used for "situational" relief of reflux symptoms induced by certain activities, for example, in patients who experience heartburn during running. It is recommended that H_2 receptor antagonists are taken 1 hour prior to the activity that causes reflux symptoms. While they are effective in up to 80% GERD patients (110), they are only effective in approximately 50% LPR patients (111). This is because H_2 receptor antagonists merely reduce acid production by blocking stimulation of the parietal cell. The laryngeal epithelium is more sensitive to injury from gastric acid compared to the esophagus and thus more complete acid suppression is required (3,10).

Proton Pump Inhibitors

PPIs (omeprazole, lansoprazole, esomeprazole, pantoprazole, rabeprazole, and dexlansoprazole) irreversibly inhibit the H^+/K^+ ATPase enzyme that catalyses acid secretion in the parietal cells. By targeting the terminal step in production they prevent secretion of HCl and thus are potent gastric acid-suppressing agents, which are very effective for the treatment of GERD. Studies investigating the efficacy of PPIs for the treatment of LPR have shown variable results and thus their use continues to be of much debate in otolaryngology and gastroenterology. Nonetheless, empiric therapy with PPIs remains the backbone of medical management of LPR.

Early studies investigating the efficacy of PPIs for the treatment of LPR revealed promising response rates. For example, Shaw et al. (112) reported objective improvement in two-thirds of reflux-laryngitis patients after 3 months of omeprazole. However, these early studies were uncontrolled and did not compare the effect of PPI to placebo.

Several groups then compared once-daily to twice-daily dosing of PPIs since the laryngeal epithelium is thought to be more sensitive to damage by gastric refluxate compared to the esophagus. They found a significant response rate in nonresponders when elevated to a twice daily dosing regimen (23,113). El-Serag et al. (114) performed the first prospective placebo-controlled trial of PPIs for the treatment of LPR, reporting significant improvement with BID PPI compared to placebo. Later in 2006, Vaezi et al. (64) reported a prospective multicenter randomized study evaluating the efficacy of PPIs in treating LPR. They found no difference in LPR response to PPI or placebo. However, these data may be inconclusive because the inclusion criteria likely produced a dilution effect. The majority of patients included in this study were marginal cases with minimally troubling symptoms based on their LPR Health-Related Quality of Life assessment and absence of pharyngeal acid on pH monitoring. In contrast, in 2008, Reichel et al. (115) reported that patients with symptoms and endoscopic signs of LPR showed a statistically significant improvement in both symptoms and findings on omeprazole for 12 weeks compared to placebo. A substantial placebo effect was noted at 6 weeks; however, this was no longer evident at 12 weeks. Qadeer et al. (116) performed a meta-analysis that included 8 double-blind randomized controlled trials with a total of 344 patients. The authors concluded no significant benefit of PPI over placebo. However, it should be noted that there was greater than 50% reduction in self-reported laryngeal symptoms with PPI treatment in five of the eight studies included in the analysis. It has been suggested that the high placebo response in the other three trials dampened the significance of PPI therapy for LPR. There is a clear discrepancy in the results of the studies performed to date investigating the efficacy of PPIs for LPR. It is thought that this is due to the different inclusion used and because the majority of these studies included patients with mild LPR. Studies with more stringent inclusion criteria, with patients with moderate to severe LPR, are needed. In support of this, in a Cochrane Database review of the use of PPIs for the treatment of hoarseness, none of 302 studies met the inclusion criteria (117). It is hoped that multicenter studies, which include moderate to severe LPR patients, will give more consistent results. A better diagnostic test is also desperately needed for LPR to ensure all patients entered into these clinical trials do actually have LPR. It has been suggested that the lack of a true gold standard diagnostic test for LPR results in many patients being misdiagnosed with LPR, which in turn weakens the treatment arm of studies investigating the efficacy of PPIs. While we await a better diagnostic and multicenter trials with more stringent inclusion criteria, most physicians continue to recommend empiric acid suppression with PPIs for 3 and up to 6 months for LPR.

In both empiric and long-term management of LPR with a PPI, one should consider the potential adverse effects of therapy (118). Relatively benign side effects of PPIs include bloating, constipation, or diarrhea. In the affected patient, these may limit therapeutic efficacy of medical management. Long-term sequelae of acid suppression may include malabsorption of vitamin B_{12} and calcium (119). An increased rate of hip fracture has been seen in patients with long-term high-dose twice-a-day PPI therapy (120). Acid suppression may also lead to an alteration of the gastric milieu and bacterial flora (119,121,122). Some studies have demonstrated an increased risk of pneumonia in those taking PPIs chronically (123). Lastly, drug–drug interactions need to be considered. There is emerging evidence that links PPI use to decreased anticoagulant activity of clopidogrel (Plavix) (124–126). This agent is commonly used in the management of cardiac and cerebrovascular disease and recent studies have demonstrated an increased rate of adverse events in those taking PPI and clopidogrel versus clopidogrel alone. Although PPIs are often considered safe medicines, one should exercise caution and attention to side effects when prescribing these medicines, especially on a long-term high-dose basis.

Surgical Management of Reflux

A surgical approach to EER and LPR is the most effective method of decreasing volume reflux of materials to the proximal esophagus or laryngopharynx, eliminating both acidic and nonacidic events. Fundoplication has been demonstrated to ablate reflux to the level of the pharynx (127). Airway symptoms can be eliminated even in patients who do not respond to medical therapy (128). A favorable outcome for surgical therapy has been shown to be more likely if (a) extraesophageal symptoms are nocturnal; (b) esophageal and laryngeal acid exposure is identified by pH monitoring; (c) there is an association between extraesophageal symptoms and reflux (both acidic and nonacidic); and (e) there is a positive response to medical therapy. Although it is preferred that there is an association between a patient's extraesophageal symptoms and reflux events and there is some response to medical therapy, this is not an absolute requirement to proceed with surgical management since it is well-known that many patients with symptoms associated with weak acid and nonacid reflux will not benefit from acid suppression medical therapy alone.

Surgical reconstitution of a physical and functional gastroesophageal (GE) junction can be accomplished using a variety of techniques (117). In a fundoplication procedure, a portion of the stomach is wrapped around the distal esophagus in an effort to reduce reflux through the GE junction by improved competence of the LES. Fundoplication may be complete (i.e., 360 degrees) wrap, as in the Nissen or Rossetti procedure, or partial (i.e., 270 degrees) wrap, as in the Toupet or Bore procedures. The most common reported GE junction operation for EER is the laparoscopic Nissen fundoplication (LNF).

The effectiveness of LNF as treatment for LPR has been evaluated in several studies in both adult and pediatric

cohorts (127,129–137). The majority of studies also demonstrate significant improvement of symptoms and signs of LPR in medically refractory patients treated with LNF. In a recent study (135), however, Swoger et al. were not able to demonstrate significant differences in symptom improvement in a small group of patients that underwent LNF who were prospectively compared to a control cohort that continued aggressive PPI therapy. This study however did show an 80% improvement in LPR signs in the LNF cohort that was not seen in the control group that continued on the PPI.

Ogut et al. (136) evaluated changes in scores of symptoms and signs of LPR using previously validated instruments. RSI and RFS were calculated in 38 patients with LPR who underwent LNF. Scores were taken at a presurgical baseline as well as 6 and 12 months postoperative. Additionally, voice-related acoustics were measured using a standardized method. This group of patients was compared to a larger cohort that underwent LNF but who did not have a baseline RSI that would support the LPR diagnosis. Significant differences with improvement in all measured parameters were noted. Symptoms and signs of LPR improved, as did the acoustic measures associated with dysphonia. As with the Swoger study (135), this group noted that symptoms improved but they did not completely disappear following LNF.

Although LNF seems to be an effective option for treatment of LPR, it is not without problems. As with any other surgical option, risks related to an operative approach are inherent. As the procedure is performed electively, the patient needs to be appropriately selected and other chronic medical conditions need to be considered. A patient with advanced cardiac or pulmonary disease may not be medically stable for an operative approach. Patients need to be informed of problems that may develop after creation of the fundoplication. There may be difficulty with vomiting or burping that can be distressing and uncomfortable. Some patients complain of solid dysphagia, bloating, or increased flatulence. It has been suggested that these adverse symptoms may be less evident with partial fundoplication procedures; however, while these have been demonstrated to be effective for GER, utility toward treatment of LPR have not been critically evaluated. Long-term analysis of LNF is generally positive, however, revisions are occasionally necessary (138,139). It is important to note that up to 20% of patients may need to return to PPI treatment of their condition after 10 years (140).

LNF is safe and effective at controlling volume reflux, however, given long-term recidivism of EER and LPR, it is not recommended for the typical LPR patient with benign symptoms such as throat clearing. A surgical approach is generally reserved for those with medically refractory EER, and those who experience the more severe sequelae of EER such as airway stenosis, reflux-associated asthma, dysplasia, or cancer, and should be considered as part of the spectrum of treatments available to the patient.

SUMMARY

LPR is a common disease of the upper aerodigestive tract heralded by chronic laryngopharyngitis. Symptoms are associated with chronic inflammation and include hoarse voice, throat clearing, cough, and globus sensation. Heartburn and other symptoms common to GERD are less associated with LPR as these are two distinct diseases. Patients with LPR tend to be upright refluxers with normal esophageal acid clearance; patients with GERD typically reflux while supine and have impaired esophageal clearance and motility. Diagnosis of reflux is often based on a constellation of symptoms and findings on indirect laryngopharyngoscopy. The clinician should be careful, however, and recognize that these symptoms and findings can also be considered nonspecific of a particular disease. More objective testing with dual pH or MII-pH probe studies is often initially deferred, but is more widely accepted as diagnostic of LPR. Treatment of LPR is typically empiric and based on suppression of acid, however, this concept incompletely addresses the nonacidic and weakly acidic components of reflux. Additionally, medical management has failed to demonstrate significant efficacy of symptom control over placebo in double-blinded studies. Antireflux surgery in the form of gastric fundoplication is the only treatment capable of reducing all components of reflux. Recommendation for this treatment is often reserved for those with advanced or more life-threatening sequelae of EER or LPR.

HIGHLIGHTS

- LPR is a common source of chronic laryngopharyngitis.
- LPR is different than gastroesophageal reflux (GER or GERD). Common symptoms of LPR include hoarseness, cough, throat clearing, globus sensation, and dysphagia. GER is more commonly associated with dyspepsia or heartburn.
- There are several mechanisms for disease in LPR. First, is the more obvious direct contact of refluxate to epithelium that leads to an inflammatory cascade. Unlike the lower esophagus or stomach, the upper aerodigestive tract has poor mechanisms of acid defense and clearance. Another mechanism suggests a neural basis, and is defined as an increase in vagal irritability secondary to distal esophageal reflux disease.
- EER has been implicated as having a major role in development of multiple conditions or diseases of the head and neck including OM, sinusitis, pharyngitis, laryngitis, chronic cough, airway stenosis, asthma, and other lower respiratory diseases.

- Laryngoscopy is required to make a diagnosis of chronic laryngitis associated with LPR. RSI and RFS can aid in diagnosis and monitoring of response to treatment.
- The current gold standard of reflux diagnosis is 24-hour ambulatory dual-probe pH monitoring. This may be supplanted in upcoming years with MII-pH monitoring, which can detect both acidic and nonacidic reflux events.
- Most treatment is based on acid suppression with oral medications; however, there is a reasonably high placebo rate and treatment failure rate. Most data show that acid suppression alone is insufficient to control reflux and only antireflux surgery is effective in this endeavor. Generalizable evidence is still lacking to recommend antireflux surgery to a broad group of patients with LPR.

67 Infection, Infiltration, and Benign Neoplasms of the Larynx

Craig R. Villari *Melissa M. Statham*

Multiple infectious and benign conditions can affect laryngeal biomechanics and detrimentally affect laryngeal function and vocal performance. A variety of clinical presentations is possible ranging from dysphonia or dysphagia to airway compromise depending on pathology, the affected laryngeal subsite(s), and premorbid laryngeal anatomy. Treatment is targeted to the specific pathology, which is usually diagnosed from a thorough history, physical examination, and detailed laryngoscopy, but may also require more specific laboratory or radiologic examination.

INFECTIONS OF THE LARYNX

Viral Laryngitis

The most common cause of infectious laryngitis is viral (1). Viral laryngitis is typically self-limited with a normal duration of 5 to 7 days (2). Patients are usually dysphonic but may also present with odynophagia. History may include a viral prodrome with upper respiratory tract symptoms and physical examination usually demonstrates edematous, erythematous vocal folds (Fig. 67.1) with loss of normal vibratory pliability. Treatment includes supportive care with hydration and removal of laryngeal phonotory trauma (phonation and coughing, pollutants). The most common viral pathogens in the upper respiratory tract include rhinovirus, influenza A, B, C, and parainfluenza viruses. Patients with substantive vocal fold edema from viral laryngitis are at increased risk of repetitive phonotrauma leading to more significant vocal fold injury, such as midmembranous vocal fold lesions, epithelial and subepithelial trauma/ulceration, and scar (3). As such, these patients should ideally be limited to relative or absolute voice rest. Evidence suggests that anti-inflammatory medication may decrease subjective discomfort and decrease odynophagia, but one would not expect such treatment to decrease duration of illness as it could not affect the underlying viral etiology (4). Systemic corticosteroids may be utilized judiciously to treat moderate to severe laryngeal edema associated with very substantial symptoms, especially in patients with significant vocal demands that cannot be mitigated with behavioral modification. Antibiotics are not indicated in patients presenting with symptoms typical of viral laryngitis (1). Acute dysphonia lasting longer than 2 weeks is unlikely to result from viral laryngitis, and other etiologies should be investigated, including a detailed laryngoscopy.

Bacterial Laryngitis

Although rare, the physician should begin to consider a bacterial etiology when the supportive measures discussed above fail to decrease symptoms or if symptoms worsen after an initial plateau of symptoms. Initial clinical presentation may be similar to that of viral laryngitis, but supraglottitis and epiglottitis may result. As with the pediatric population, these conditions require escalated care, given the potential for airway demise. The causative bacteria are also similar to those in the pediatric population and include *Haemophilus influenzae*, *Streptococcus* species, and *Staphylococcus* species. *Haemophilus* species remain the most common but methicillin-resistant *Staphylococcus aureus* infections have been reported (1,5–7).

Diagnosis relies on endoscopic examination (Fig. 67.2) of the larynx. Radiologic imaging may be used to supplement endoscopic evaluation, and findings can include the classic "thumb-print" sign of supraglottic inflammation. Treatment depends on the clinical presentation with attention focused on airway competence. In a recent study, only 2 of 10 adult patients with supraglottitis evaluated over a 6-month period required airway intervention (8). Despite the majority of patients not needing airway protection, increased work of breathing and/or stridor must

Figure 67.1 Acute laryngitis: note global laryngeal edema and erythema.

be given proper credence. Medical treatment is targeted to the pathogen identified by culture. Additional supportive measures such as hydration and steroids are indicated (9).

Though not common in the United States, rhinoscleroma can also affect the larynx. Caused by *Klebsiella rhinoscleromatis*, patients tend to have laryngeal involvement (13/22 patients) and may need emergent tracheotomy to maintain airway patency (3/13 with laryngeal involvement) (10). In that series, all tracheotomy patients were decannulated with appropriate antibiosis. Pathologic examination demonstrates the gram-negative coccobacillus of *Klebsiella* on culture, as well as Mikulicz cells on mucosal biopsy.

Fungal Infection

Fungal laryngitis often occurs in immunocompromised patients, such as patients with systemic causes for immunosuppression (HIV, chemotherapy, diabetes, etc.) and individuals who are locally immunocompromised because of steroid inhaler use (11). Such infections are overwhelmingly candidal in etiology and will respond to systemic antifungal treatment (11,12). Patients will present with laryngopharyngeal symptoms, such as dysphagia and dysphonia. Physical examination demonstrates white plaque-like epithelial lesions of the mucosa surfaces, which may be focal or diffuse (Fig. 67.3). Conservative treatment with a systemic antifungal and a topical antifungal are appropriate, but short-interval evaluation is necessary to assess resolution as persistent lesions merit biopsy and possible culture of lesions.

Though the majority of fungal infections are *Candida sp.*, other fungal organisms, such as blastomycosis, coccidioidomycosis, and histoplasmosis may also infect the larynx. These infections target immunocompromised patients as seen with *Candida sp.* infections but tend to occur in endemic geographic regions. Blastomycosis and histoplasmosis are prevalent in the Mississippi and Ohio River valleys, and coccidioidomycosis is endemic in the southwestern United States and Central America. However, patients may become infected outside of endemic areas (13). Biopsied lesions require culture with periodic acid Schiff and histologic examination to evaluate possible granulomatous conditions such as tuberculosis (14). Hematoxylin and eosin (H&E) staining demonstrates pseudoepitheliomatous hyperplasia with possible ulceration. Microscopic broad-based budding cells are a pathognomic feature of blastomycosis. Clinically, patients can present with a range of symptoms and physical exam findings, spanning from dysphonia to occult airway compromise (15,16). Treatment involves long-term systemic antifungal therapy with agents such as amphotericin or triazole.

Mycobacterial Infection

Laryngeal tubercular infection from *Mycobacterium tuberculosis* is classically associated with active pulmonary disease but can present as isolated laryngitis (17,18). Laryngeal

Figure 67.2 Bacterial laryngitis: note posterior glottic purulence.

Figure 67.3 Fungal laryngitis: note white fungal plaques with marginal erythema on midmembranous vocal folds.

M. tuberculosis infections follow similar natural history to pulmonary tuberculosis and most commonly present as lesions in the posterior glottis. Patient factors include increased prevalence in underdeveloped countries, areas of over-crowding and communal living, and immunocompromised populations. While laryngeal infections present with similar symptoms as pulmonary infections (cough, hemoptysis, unintentional weight loss, fever, night sweats), patients may also present with laryngopharyngeal symptoms such as dysphonia, dysphagia, and odynophagia. Physical examination can demonstrate exophytic masses that mimic malignancy (19,20). Pathologic examination demonstrates caseating granulomas that are pathognomonic to *M. tuberculosis* infection. Treatment is targeted with multidrug regimens with culture guidance, as multidrug resistant *M. tuberculosis* strains are on the rise.

Other Infections

Less common infections of the larynx include leprosy and syphilis. *Mycobacterial leprae* and *Mycobacterium lepromatosis*, the causative infectious agents of leprosy, cause dramatic systemic and laryngeal epithelial changes. As with the other laryngeal infections, patients can present with variable severity in symptoms, with the most severe being occult aspiration or complete upper airway obstruction requiring tracheotomy (21,22). The World Health Organization recommends multidrug treatment with combinations of dapsone and rifampin with possible adjunctive clofazimine.

Syphilis is caused by *Treponema pallidum* infection and generally presents in stages. The primary stage generally presents to the otolaryngologist as a painless oropharyngeal chancre. During the secondary stage, patients can present with laryngeal manifestations, including leukoplakia, exophytic mass(es), and very rarely, decreased vocal fold mobility (23,24). Diagnosis involves serologic studies (venereal disease research laboratory or rapid plasma regain) and/or dark-field microscopy to visualize the pathopneumonic spirochetes sampled from suspect mucosal lesions. The mainstay of treatment is penicillin. For those patients with penicillin sensitivities, definitive allergy testing and desensitization may be required prior to treatment.

Idiopathic Ulcerative Laryngitis

Idiopathic ulcerative laryngitis (IUL) was first described in 2000 and a large clinical series was presented in 2011 (3,25). This condition involves dysphonia and severe cough following an upper respiratory tract infection and ulceration(s) of the midmembranous vocal fold. IUL appears to occur more in females than males (3). An etiologic agent(s) has not been identified and medical therapy with antibiotics, antifungal, and proton pump inhibitors are typically used but without an obvious positive response. These patients should be observed with serial office endoscopy (preferable video recorded) and the urge to perform a biopsy should be resisted. Biopsy will most likely be nondiagnostic and result in scar formation at the ulcer site. Patients should be counseled regarding the duration of the condition (average 3.3 months with a range from 2 to 10 months) and the possibility of vocal fold scar formation following the resolution of the ulcer(s) (3). If progression of the ulcer(s) occurs during serial examination a biopsy may be warranted.

INFILTRATION OF THE LARYNX

Multiple inflammatory processes can affect the larynx. These differ in their underlying presentation and pathologic and histologic features. As a group, these conditions generally cause decreased vocal fold pliability and/or lesions of the vocal folds, supraglottis, or subglottis. Symptoms correspond to the severity of vocal fold infiltration and potentially degrees of airway compromise.

Wegener Granulomatosis

Wegener granulomatosis is associated with necrotizing granulomatous inflammation and vasculitis of small blood vessels. The disease tends to affect the upper airway, the lungs, and the kidneys (26). The otolaryngologist may identify a patient because of nonhealing ulcers in the nasal cavity or, more rarely, subglottic airway stenosis. Diagnosis relies on thorough physical examination, nasal and laryngeal endoscopy, and testing for classical antineutrophil cytoplasm antibody (c-ANCA). Interestingly, 10% to 20% of those with airway symptoms have been reported to have a negative c-ANCA test (26).

The best treatment for these patients involves a multidisciplinary approach. Medical management with systemic corticosteroids and/or cyclophosphamide is used to obtain remission, and medications such as methotrexate, trimethoprim methoxazole, or azathioprine are used for maintenance therapy (26). Surgical treatments include subglottic expansion (subglottic releasing incisions with balloon or rigid dilation) and intralesional injection of corticosteroids (27). Subglottic stenting is generally avoided in favor of tracheotomy for recalcitrant presentations (28). In the setting of inactive Wegener granulomatosis with resultant subglottic stenosis, cricotracheal resection is also a viable treatment option.

Rheumatoid Arthritis

Rheumatoid arthritis affects millions of people worldwide with a predilection for females. It affects the larynx in just over one-fourth of cases (29). In comparison to unaffected control subjects, patients with rheumatoid arthritis had more frequent loss of higher frequency phonation, generalized dysphonia, decreased vocal fold mobility, and

laryngeal edema (30). These symptoms are modulated by the active status of the patient's disease. Active rheumatoid arthritis tends to present with a substantial laryngitis with erythematous arytenoid mucosa (30–32). Chronic rheumatoid arthritis also selectively targets the arytenoid cartilages, but more specifically seems to affect the cricoarytenoid joint causing ankylosis and possible joint fixation (26). Patients may also present with rheumatoid nodules, also known as bamboo nodes, which are focal subepithelial lesions, typically on the superior surface of the membranous vocal fold. Treatment of rheumatoid arthritis relies upon medical management with immunomodular and anti-inflammatory treatments. Although outcomes data are sparse, surgical management may be indicated to manage airway symptoms or to judiciously remove rheumatoid nodules to improve phonation (32,33). (See Chapter 68) Alternatively, serial vocal fold steroid injections are a less-invasive treatment that may improve vocal outcome (34).

Amyloidosis

Amyloidosis is an autoimmune condition characterized by extracellular deposition of fibrillar proteins in affected tissue. Laryngeal involvement is rare and may not be associated with primary systemic amyloidosis. However, laryngeal amyloidosis may be present in conjunction with other systemic conditions such as multiple myeloma (35,36). Patients usually present with bulky deposition of amyloid protein with variable degrees of infiltration of the vocal fold, paraglottic space, and the supraglottis. Presenting features include cough, dysphonia, dysphagia, and possible stridor. Biopsy is required for diagnosis as amyloid has a pathognomonic apple green birefringence after staining with Congo red (Fig. 67.4). Referral is needed to examine for underlying secondary causes, such as systemic amyloidosis. There are reports of complete resolution with radiation therapy, but this treatment modality has not gained mainstream acceptance (37). Surgical intervention is usually undertaken to address specific symptoms and can improve vocal deficits. Recurrence is quite common (38).

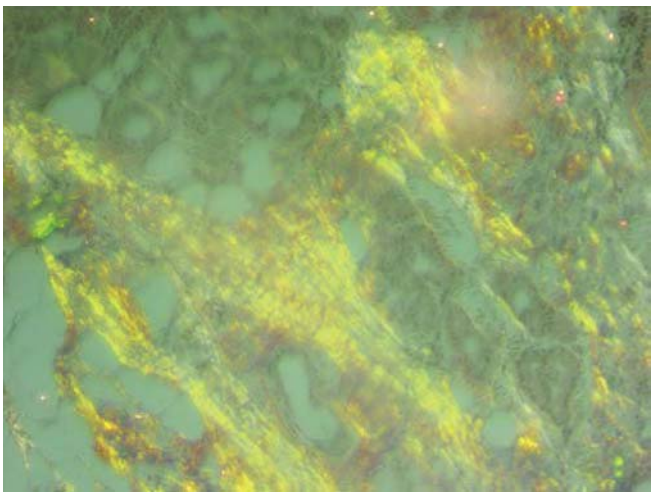

Figure 67.4 Amyloidosis after Congo red staining: note apple-green birefringence with polarimetric filtered microscopy.

Relapsing Polychondritis

Relapsing polychondritis is characterized by intermittent recurrent episodes and inflammation of cartilaginous structures. While the ears and nose are most commonly affected, the larynx can also become involved. Early studies demonstrate 14% of patients have laryngeal involvement at presentation but that up to half of patients eventually develop airway symptoms (39). Radiographic studies, such as magnetic resonance imaging (MRI) and computed tomography (CT) can identify cartilaginous changes. Patients may present to the otolaryngologist with ear, nasal, and/or airway complaints such as exertional dyspnea or stridor. Purulent chondritis of the laryngeal framework has been described as a sequela of superimposed infection (40). Medical management is paramount as maintenance includes low dose corticosteroids and/or methotrexate. Dapsone has also shown to be beneficial (41). Surgical intervention may be indicated to secure the airway with tracheotomy. A small case series of patients underwent airway reconstruction to provide more long-term airway stability (42).

Systemic Lupus Erythematous

Like rheumatoid arthritis, systemic lupus erythematous (SLE) has a predilection for females. Its effects are not usually limited to the larynx as roughly two-thirds of patients never experience laryngeal symptoms. Patients can present with a wide variety of laryngopharyngeal complaints, which include dysphonia and dyspnea. A study including 12 patients with SLE found that 11 had laryngeal abnormalities (43). Physical signs ranging from edema or ulceration to vocal fold paralysis can be seen on examination (44). However, a direct causal relationship between SLE and the above laryngeal pathology has yet to be demonstrated.

Pemphigus and Pemphigoid

Pemphigus and pemphigoid are related autoimmune conditions differentiated by the target of their autoantibodies. While both conditions lead to a robust inflammatory reaction that can possibly lead to epithelial injury, pemphigus autoantibodies are directed against intraepithelial targets while pemphigoid autoantibodies target subepithelial antigens. Immunofluorescence of tissue biopsy is used to identify the characteristic autoantibodies for definitive diagnosis.

Patients may present with signs of disease within the nasal cavity or the larynx. The prevalence of laryngeal involvement seems to differ between the diseases for unknown reasons. One study demonstrated that 21 of 53 (40%) patients with head and neck manifestations of

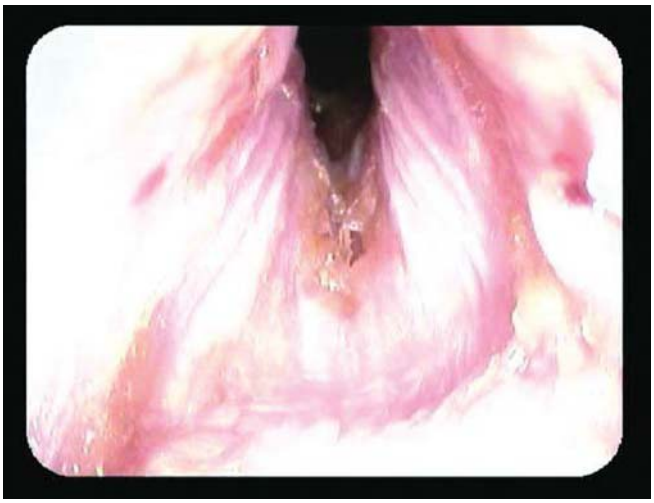

Figure 67.5 Laryngeal pemphigus in typical supraglottic location.

pemphigus had laryngeal involvement (45). However, a separate study of pemphigoid patients demonstrated that 10 of 38 (26%) patients with head and neck symptoms had laryngeal involvement (46). Other studies have demonstrated relatively similar prevalence in pemphigus (47). Both pemphigus and pemphigoid appear to have a predilection for supraglottic mucosa (Fig. 67.5). High-dose corticosteroids are utilized to control active disease and are decreased for maintenance therapy. Other immunomodulators, such as azathioprine, cyclophosphamide, and cyclosporine, have also been utilized for medical management. Surgical intervention is limited to diagnostic biopsy and/or airway intervention, such as tracheotomy or less invasive airway surgery (dilation) to provide a stable airway.

Sarcoidosis

Sarcoidosis is an autoimmune condition defined pathologically by noncaseating granulomas. Patients most commonly affected are young adult African American women. Laryngeal involvement is seen in 3% to 5% of cases and usually affects the supraglottis (Fig. 67.6) (48). Laryngeal complaints from sarcoidosis, such as nonproductive cough and dyspnea, may be difficult to differentiate from the pulmonary manifestations of the disease. Diagnosis of sarcoidosis relies on multiple modalities as there are usually multiple organ systems involved. The establishment of laryngeal sarcoidosis relies on laryngoscopic evaluation, with hallmark exam findings of submucosal infiltration in the infraglottic, paraglottic space, and the supraglottis. Involvement of the epiglottis leads to a distortion and thickening and has been commonly referred to as a turban epiglottis. Sarcoidosis remains an elusive diagnosis; however, biopsy of lesions classically reveals noncaseating granulomas.

Treatment mainly relies on corticosteroids, but other immunomodulators, such as azathioprine, have also been administered with good treatment success (49). Surgical intervention is limited to diagnostic biopsy, excision of symptomatic lesions, or management of obstructive airway lesions.

External Beam Radiation

As the role of external beam radiation has increased for the treatment of head and neck malignancies, many of these patients later present with laryngopharyngeal complaints, such as dysphonia, dysphagia, and globus sensation post-treatment. Electron beam radiation induces gradual, dose-dependent fibrotic changes to include muscle atrophy and fibrosis in the larynx as well as desiccation of mucosa (Fig. 67.7). Fibrosis within the lamina propria can be appreciated as decreased mucosal pliability on stroboscopy. Patients will exhibit atrophy that is disproportionate to their expected age-related vocal fold volume loss. Vocal fold hypervascularity is a common finding due to prior vasculitis incurred during radiation therapy. Improvement in voice is commonly reported following laryngeal radiation for early laryngeal cancer, but voice outcomes associated with late radiation fibrosis of the vocal folds remains

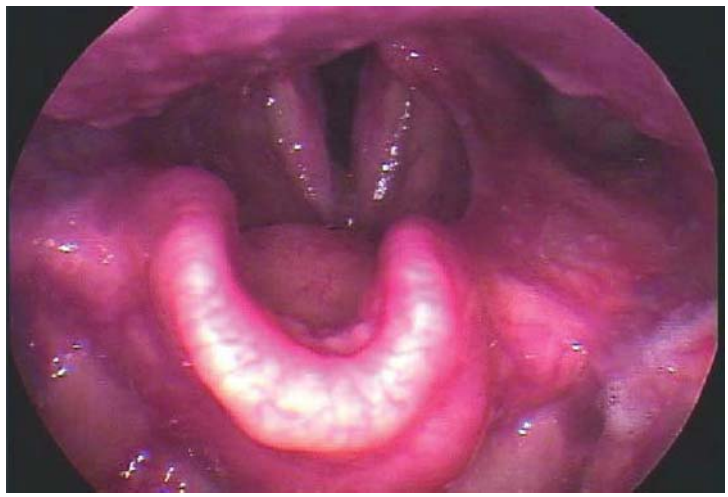

Figure 67.6 Sarcoidosis in typical supraglottic location.

Figure 67.7 Radiation effects on the larynx: note global erythema, slight atrophy of muscular anatomy, and limited light reflex indicating decreased secretory function of the mucosa.

uncertain (50,51). A prior report of postradiation vocal quality suggests that vocal fold stripping or excisional biopsy rather than limited biopsy for initial diagnosis and continued tobacco smoking after treatment are significantly associated with an increased risk of perceived worse voice quality after treatment (52).

As radiation oncologists develop more sophisticated techniques to avoid collateral damage to uninvolved structures, the extent of radiation changes may decrease.

BENIGN NEOPLASIA OF THE LARYNX

When one excludes nonneoplastic vocal fold lesions, such as vocal fold polyps, nodules, and cysts (see Chapter 68), benign tumors of the larynx are varied and quite rare. Diagnosis relies on thorough history with appropriate examination and imaging.

Hamartoma

Hamartomas are rare, benign lesions that can present as congenital malformations or lesions later in life. They are generally loosely organized neoplasms with multiple types of tissue, all of which are native to the affected subsite of the larynx. Hamartomas can be incidentally identified or cause significant airway symptoms, especially in a young child. Presentation and symptomatology are related to the location of the neoplasm, and hamartomas have been mostly commonly identified in the supraglottis and subglottis (53,54). Excisional biopsy is both diagnostic and curative if resection is complete (55).

Chondroma

Chondromas are benign tumors consisting of cartilaginous cells. They are slow-growing lesions that do not metastasize, and they generally present as a smooth, submucosal lesion. Laryngeal chondromas may be difficult to differentiate from low-grade chondrosarcomas and clinically follow a similar course. While the bulk of these tumors present within the posterior cricoid cartilage, lesions have been found within other subsites of the larynx as well as the hyoid bone (56,57). Patients may be relatively asymptomatic, but lesions can cause airway obstruction or external neck masses (56). CT is generally the preferred imaging modality to define the extent of the lesion (58). Surgical excision is the treatment of choice for chondromas. Surgery has been traditionally performed via open procedures involving laryngofissure, but, more recently, endoscopic ablation techniques have been shown to be successful (59). Comparative efficacy between open and endoscopic surgical excision is unknown.

Rhabdomyoma

Rhabdomyomas of the larynx are benign tumors comprising striated muscle. Laryngeal involvement is the most common location for rhabdomyomas of the head and neck (60). These tumors present in variable locations within the larynx and have been documented to involve both intrinsic and extrinsic laryngeal musculature (61,62). Diagnosis with biopsy or magnetic resonance is indicated, and complete resection is curative.

Respiratory Papillomatosis

Though primarily seen in the pediatric population, adult-onset recurrent respiratory papillomatosis (RRP) is not an uncommon presentation. For further information regarding juvenile onset RRP, please refer to Chapter 94.

Caused by human papillomavirus (HPV) subtypes 6 and 11, RRP occurs most commonly at the level of the vocal folds. The virus can be transmitted vertically or by sexual transmission. RRP can present anywhere within the upper aerodigestive tract from the nasal vestibule to the bronchioles with a predilection for areas of transition from pseudostratified columnar to stratified squamous epithelium.

Lesions can be relatively small, noticeable only because of resultant dysphonia from decreased vocal fold mucosal wave propagation, dysphonia related to mass-effect that impairs glottal closure, or variable degrees of airway obstruction (Figs. 67.8 and 67.9). Though benign, they do have significant morbidity and have the potential for malignant transformation (63,64). A recent study including 54 adults demonstrated that dysplasia was identified in 50% of patients, and dysplasia was diagnosed on biopsy specimens at an average of 16.2 months from initial diagnosis. Of the initial 54 patients, 3 progressed to carcinoma *in situ* while 1 patient progressed to squamous cell carcinoma (64). Use of inhaled corticosteroids, increasing number of procedures, distal spread of disease, and previous exposure to cidofovir have been implicated as risk factors for dysplastic reaction (65). In addition, history of

Figure 67.8 Adult RRP occluding anterior glottis, limiting phonation.

radiation therapy, cigarette smoking, and systemic immunosuppression have been implicated in malignant transformation (66).

The verrucous papillomatous growth of the lesions are pathognomonic. Though multiple treatment modalities are available, conservative removal of disease is the first-line treatment. If cold instrumentation is to be utilized, careful attention must be dedicated to only removing the papilloma and leaving the superficial lamina propria undisturbed. Ablation with CO_2 or potassium titanyl phosphate (KTP) lasers has also been shown to be a successful treatment modality for both initial and subsequent treatments (67). A great benefit of fiber-based laser treatment is that it can be performed in an awake patient using a channeled endoscope through which the fiber can be advanced. Awake procedures decrease use of operative resources and eliminate the need and dangers of general anesthetic. Regardless of the surgical technique utilized, the physician must avoid deepithelialized surfaces in juxtaposition to avoid anterior glottic webbing and/or posterior glottic stenosis.

Figure 67.9 Adult RRP nearly occluding entire glottis.

While surgical removal of lesions remains the first-line treatment for RRP, other adjuvant therapies have been developed. Cidofovir is an antiviral shown to decrease disease burden in both intralesional injection and inhaled forms (68,69). Both treatment modalities have been shown safe, but hepatotoxicity has been identified with the injected form. Interferon-alpha and indole-3-carbinol (an extract found in cruciferous vegetables) have both been used to control disease propagation (70).

The United States Food and Drug Administration (FDA) approved Gardasil, a vaccination against HPV subtypes 6, 11, 16, and 18, in June of 2006 as a means of potentially preventing cervical cancer. While cervical cancer is mainly caused by HPV subtypes 16 and 18, the vaccination against subtypes 6 and 11, could drastically affect the prevalence and presentation of RRP. Currently, there is no definitive association between vaccination and disease modulation, thus vaccination is not presently indicated in patients with prior exposure (71).

Hemangioma

Laryngeal hemangiomas are more prevalent in the pediatric population, and this is presented in Chapter 104. In contrast to pediatric hemangiomas, which usually present in the subglottis, adult laryngeal hemangiomas present in the supraglottis (Fig. 67.10) (72). Hemangiomas are usually asymptomatic but can cause airway obstructive symptoms (73). As these are incredibly rare tumors, no standardized treatment exists. A conservative approach emphasizing medical management with either corticosteroids or radiation therapy was historically advocated. Though successful in the pediatric population, laser ablation was initially avoided in adults for concern that the vasculature would exceed CO_2 laser coagulation capacity. However, a report of four laryngeal hemangiomas ablated without incident calls that initial theory into question (74). Propanolol has also been successful in treating laryngeal hemangiomas in children, but there are no reports of its use in the adult population (75).

Benign Salivary Neoplasia

Pleomorphic adenoma, a benign salivary neoplasm, may arise within the larynx. Scattered case reports identify fewer than 20 instances within the literature. More than half of the cases appeared in the supraglottis, and patients most commonly present with dysphonia. Surgical resection was reported as curative, though follow-up was limited (76).

Fibroma

Laryngeal fibromas are exceedingly rare with fewer than a dozen cases reported. Histologic examination demonstrates abundant extracellular matrix with interspersed

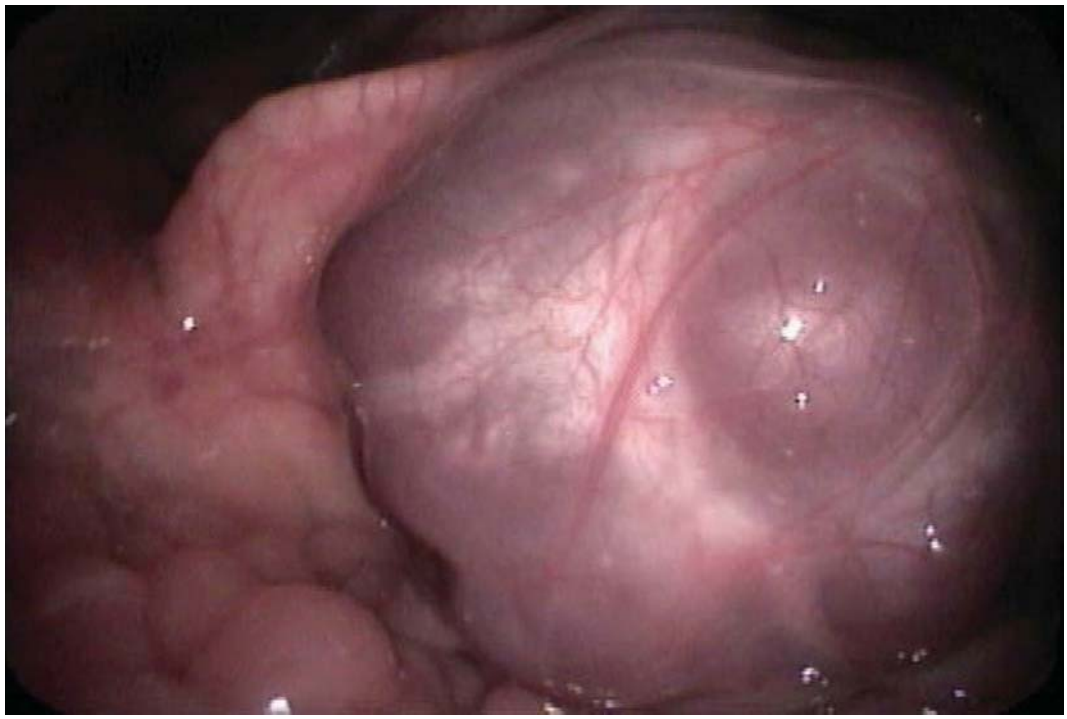

Figure 67.10 Adult supraglottic hemangioma. Cobblestone-appearing lingual tonsils are visible at the inferior aspect of this image. The epiglottis is completely obscured by this hemangioma.

paucicellular areas, and the extracellular matrix tends to be composed of "cytologically bland spindle cells." The reported cases all appear to be isolated lesions that presented with dysphonia and cough (77). Radiographic imaging (CT and MRI) can delineate the full extent of the lesion in planning for surgical resection. Excision with margins is advocated to minimize chance of recurrence (78).

Schwannoma

Schwannomas arise from nerve sheath fibers and account for less than 1% of all laryngeal tumors. The endoscopic appearance may be mistaken for a laryngocele and commonly appear as smooth submucosal mass within the pyriform sinus or aryepiglottic space (79). Patients may present with globus sensation, dysphagia, dysphonia, and if large, airway obstruction (80). Imaging with CT and/or MRI help to plan surgical resection. Histopathologic examination demonstrates the classic Antoni A and Antoni B areas seen with other schwannomas. The associated nerve was not identified in the available case reports. Some patients have postoperative dysphonia and vocal fold paresis, possibly implying recurrent laryngeal involvement (79).

Granular Cell Tumor

Granular cell tumors can occur anywhere within the body but are often seen within the head and neck (81). The larynx, however, is a rare location for these neoplasms. They are neural in derivation and, within the larynx, tend to grow slowly and isolate within the vocal folds themselves. Presenting symptoms include hoarseness, stridor, dysphagia, and cough. Biopsy must be completed to evaluate for malignant neoplasm as there is an association with pseudo-epitheliomatous hyperplasia, which can mimic squamous cell carcinoma. Serologic staining of biopsy specimens will yield positive results for S-100, neuron-specific enolase, vimentin, and CD 68 (81). Complete resection with microlaryngeal phonosurgical instruments and principles can yield cure with good vocal outcome.

LARYNGOCELES AND SACCULAR CYSTS

While laryngoceles and saccular cysts are not neoplasms, they present as benign appearing masses in the larynx. The laryngeal saccule is a mucous gland containing appendage that lies between the false vocal fold and the thyroid cartilage. It is an out pouching of the normal laryngeal ventricle and extends as a blind-ended sac posterolateral to the edge of the laryngeal surface of the epiglottis. The function of the saccule is unknown although it has been theorized that it may represent a vestigial air sac. Both laryngoceles and saccular cysts involve expansion of the saccule to form a mass. Laryngoceles by definition must have air contained within their lumen, while saccular cysts are strictly fluid-filled masses.

Laryngoceles contain air due to patent communication with the laryngeal lumen. Further classification of laryngoceles depends on their location. They can be defined as

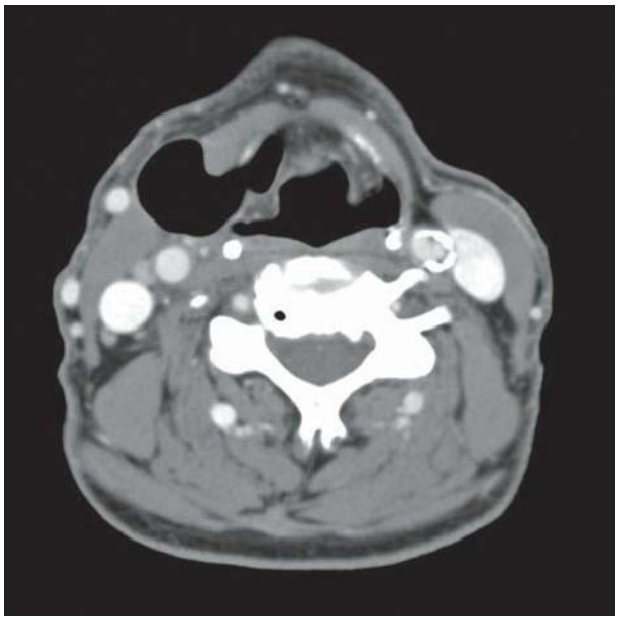

Figure 67.11 Combined laryngocele. Axial CT showing air-filled dilation of the saccule extending through the thyrohyoid membrane into the neck.

internal, external, or combined. Internal laryngoceles are strictly confined within the thyroid cartilage, external laryngoceles lie exclusively outside the cartilaginous laryngeal framework, and combined laryngoceles span both the inside and outside of the thyroid cartilage (82,83) (Fig. 67.11).

Saccular cysts are also classified according to their location; anterior and lateral. Anterior saccular cysts appear as rounded fluid-filled masses emanating from the anterior portion of the ventricle and extend medially into the lumen of the larynx (Fig. 67.12). They lie superior to the glottal level at or near the anterior commissure, and interfere with phonation or airway depending on their size. Lateral saccular cysts expand within the paraglottic space and appear similar to internal laryngoceles as a submucosal fullness in the ventricular fold.

Although the etiology of saccular masses is unclear, they result from abnormal dilation of the saccule. It has been suggested that those who routinely develop high transglottic pressures (glass blowers, trumpet players) are at a higher risk of developing laryngoceles. It is thought that saccular cysts arise secondary to obstruction of the saccular orifice as they have been found in patients with laryngeal carcinoma or following an upper respiratory tract infection (84). Congenital saccular cysts can occur in infants and present as a weak cry, stridor, or cyanosis (83).

Patients with laryngoceles and saccular cysts report symptoms consistent with a laryngeal mass: dysphonia, stridor, chronic cough, a neck mass, and occasionally dysphagia. Severity of symptoms depends on the size and location of the lesion. Small or nonobstructing lesions may be asymptomatic. The diagnosis is most commonly made by physical examination including transnasal or transoral laryngeal imaging and neck exam. In the case of

Figure 67.12 Anterior saccular cyst. Fluid-filled mass arising from the saccule and protruding into the laryngeal lumen.

anterior saccular cysts, a mass can be seen emanating from the vestibule to the laryngeal lumen while lateral saccular cysts and laryngoceles present as a submucosal mass in the false vocal fold. External and combined laryngoceles can present as a neck mass that enlarges with valsalva. Both laryngoceles and saccular cysts can become acutely infected to form a laryngopyocele or an infected saccular cyst. Super-infection can lead to rapid expansion and acute presentation with worsening symptoms, fever, and occasionally, airway obstruction.

Fine-cut CT is a useful adjunctive tool diagnostically. The presence of air within the lesion differentiates laryngoceles from saccular cysts. The location and extent of the lesion can be accurately assessed with a fine-cut CT scan. Endoscopic excision of these lesions is the mainstay of treatment and the recurrence rate is very low with long-term follow up (84).

SUMMARY

The larynx can be subject to infectious agents, inflammatory conditions, and neoplasia. The initial management of the patient must be to ensure a stable, secure airway. Once the airway is ensured, a thorough history and physical examination, followed by detailed laryngeal endoscopy

and directed biopsy, can usually narrow the differential diagnosis and guide the physician to appropriate diagnostic testing. Treatment should address the patient's symptoms and ideally ensure both airway stability and future vocal performance.

HIGHLIGHTS

- Multiple infections, inflammatory, and benign processes can affect the larynx. Each has its own unique presentation and treatment considerations.
- Infectious laryngitis is most commonly viral in etiology, and should be initially treated with voice rest and supportive measures in most cases. Bacterial, fungal, and mycobacterial infection is considerably more rare.
- Inflammatory and infiltrative processes of the larynx can occur from Wegener granulomatosis (typically subglottic involvement), sarcoidosis (typically supraglottic involvement), amyloidosis, and autoimmune processes (such as rheumatoid arthritis, SLE, and pemphigus/pemphigoid)
- The most common benign neoplasm of the larynx is laryngeal papillomatosis. Laryngeal chondromas, hamartomas, schwannomas, fibromas, pleomorphic adenomas, and granular cell tumors are far more rare.

Benign Vocal Fold Lesions and Phonomicrosurgery

68

John W. Ingle *Clark A. Rosen*

Benign vocal fold lesions are a common cause of dysphonia. Their diagnosis and subsequent care can be a complex and important quality-of-life issue to individuals who suffer from this set of disorders. The ability to communicate without dysphonia is important to the population at large for both occupational and social reasons. A growing percentage of the occupations in the world are voice and communication dependent as opposed to labor dependent; thus, it is vital to have the ability to use the voice throughout the day in a clear, efficient manner without voice loss or without causing undue negative attention because of dysphonia (1).

The overriding treatment principle for caring for patients with benign vocal fold lesions is the assessment and improvement of the patient's functional status regarding an ability to communicate with the voice. Many ways exist to improve the functional status of the voice, including treatment of associated medical conditions, voice therapy (see Chapter 71), and surgery. This chapter is designed to discuss a variety of benign vocal fold lesions that commonly cause dysphonia from the categories of epithelial lesions, lamina propria pathology, and vascular pathology. A large portion of benign vocal fold lesions and subsequent dysphonia arise from lesions of the lamina propria due to presumed greater sensitivity to trauma associated with inflammation, coughing, voice misuse, and/or voice overuse. Over the last several decades, a specialized form of laryngeal microsurgery—phonomicrosurgery—has evolved. The principles and concepts of this type of surgery are presented below.

BENIGN EPITHELIAL LESIONS OF THE VOCAL FOLD

Epithelial abnormalities of the vocal folds are caused by infectious processes (fungal), keratosis of the epithelium, papillomatous growth of the epithelium, or malignant degeneration of the epithelium. Infections, papillomatosis, and cancers of the epithelium of the vocal fold are covered in other chapters of this book (Chapters 66, 67, 94, and 123). Nonmalignant epithelial abnormalities can be grouped under the category of keratosis. Keratosis includes both white (leukoplakia) and red (erythroplakia) lesions of the vocal folds. The terms "leukoplakia" and "erythroplakia" are descriptive only and have no prognostic or diagnostic value. The primary concern of keratotic lesions of the vocal folds is the potential for these lesions to transform from a benign process to a malignant process. The clear etiologic factors for the formation of these lesions and potential for their subsequent transformation is not clear. Irritation from tobacco smoke has been implicated. In addition, vocal misuse and overuse and irritation from refluxed gastric contents (laryngopharyngeal reflux disease) have also been scrutinized and associated with the development of keratotic lesions of the vocal folds.

The diagnosis and treatment of keratotic lesions include a careful diagnostic evaluation including microlaryngoscopy with high-power magnification and excisional biopsy to rule out a malignant process. This is done best using the principles and approaches of phonomicrosurgery, specifically microflap surgery, to remove the keratotic lesion of the vocal fold in a controlled, conservative, subepithelial, and oriented fashion (see below). After a definitive diagnosis has been made, management includes removal of the most common etiologic agents, tobacco smoke exposure, laryngopharyngeal reflux disease, and vocal abuse (see Chapters 21, 66, and 71).

Vocal misuse and overuse can be related to the patient's phonatory pattern, environment, and overall demands. In addition, a theory of excessive vocal fold collision and impact forces created to attempt to compensate for glottal insufficiency leading to keratosis is held by some. The glottal insufficiency can be caused by vocal fold atrophy, paralysis, paresis, or scarring. Until the underlying glottal

insufficiency is addressed with an augmentation procedure (medialization laryngoplasty or vocal fold injection augmentation), the keratotic activity will persist and recur following excision. Often the glottal insufficiency is not recognized and it results in recurrent keratosis following surgical excision. This theory has never been validated but should be considered in the most recalcitrant cases of keratosis.

Close observation and photo documentation of keratotic lesions are essential for long-term care and treatment of patients with this disease. Once infectious and malignant processes have been ruled out, patients can be observed in the office with serial examinations and especially helped with the aid of photo documentation to monitor for any specific change in the nature of the keratotic lesion(s). If the patient does not have significant functional limitation from the keratosis and the lesion is stable, repeated surgical removal is not indicated. Any discrete change in the nature, size, or location of the keratosis should prompt a surgical excision of the keratotic lesion(s) for pathologic review (2).

BENIGN LESIONS OF THE VOCAL FOLD LAMINA PROPRIA

Midmembranous Vocal Fold Lesions

The lamina propria of the vocal fold is a key component to vocal fold vibration and, thus, voice quality depends on the elastic properties of the lamina propria. The lamina propria is frequently injured by direct trauma, such as surgery, radiation therapy, or repeated collisional impact associated with phonation (vocal abuse). Most benign, midmembranous vocal fold lesions caused by trauma occur from repeated injury to the vocal fold lamina propria. Most of these lesions occur in the subepithelial space but also can be found near the vocal ligament. These lesions, which typically occur in the midmembranous vocal fold, are often bilateral. This region of the vocal fold has been termed "the striking zone," because of the theoretical concept of maximal vocal fold collision or impact forces resulting in their formation (3).

Benign, midvocal fold lesions cannot be defined by morphology and stroboscopy alone. Great difficulty in discussion and management of these lesions stems from the lack of accepted nomenclature for defining the lesions. This has resulted in great confusion and lack of clarity regarding etiology, diagnosis, and treatment. Without being able to clearly define distinct lesions within the larger group of benign vocal fold lesions of the lamina propria, it has been impossible to assess treatment methods and efficacy. To this end, a recent move has been made to implement a rigorous and clearly defined vocal fold lesion nomenclature paradigm (4). This classification scheme defines nine distinct benign midvocal fold lesions: (a) vocal fold nodules; (b) vocal fold polyp; (c) vocal fold cyst-subepithelial; (d) vocal fold cyst-ligament; (e) fibrous mass-subepithelial; (f) fibrous mass-ligament; (g) reactive vocal fold lesion; (h) nonspecific vocal fold lesion; and (i) pseudocyst. Outlined below is a brief description of each of these vocal fold lesions based on their morphologic appearance, stroboscopic pattern, response to voice therapy, and intraoperative findings. Please refer to Figures 68.1 to 68.12 for some examples of these lesions.

1. **Vocal fold nodules** are always bilateral and fairly symmetric. Their stroboscopic pattern shows normal or minimal reduction of the mucosal wave activity during stroboscopy. These lesions reduce in size or disappear in response to behavioral modification of voice use (voice therapy). Note any lesions that do not improve with behavioral modification are not vocal fold nodules. Refer to Figure 68.1 for an example of vocal fold nodules.
2. **Vocal fold polyps** can be unilateral or bilateral lesions and are typically exophytic lesions that are often clear in appearance or associated with a vocal fold hemorrhage and heme colored (hemorrhagic polyp). These lesions have minimal reduction of the mucosal wave vibratory activity on stroboscopy and typically do not change in size in response to voice therapy. Intraoperatively, these lesions are composed of gelatinous unorganized material in the subepithelial space. Refer to Figures 68.2 and 68.3 for examples of vocal fold polyps.
3. **Vocal fold cysts** can be unilateral or bilateral and located either near the ligament or in the subepithelial space. Practically, the subepithelial space is defined as the region immediately underneath the vocal fold epithelium. When the vocal fold pathology (cyst, polyp, or fibrous mass) is adherent to the undersurface of the microflap as it is elevated, it is located in the subepithelial space. When the pathology is located "deep" to the microflap following cordotomy, the pathology (cyst or fibrous mass) is classified as a ligamentous lesion. A vocal fold cyst does not respond to voice therapy and,

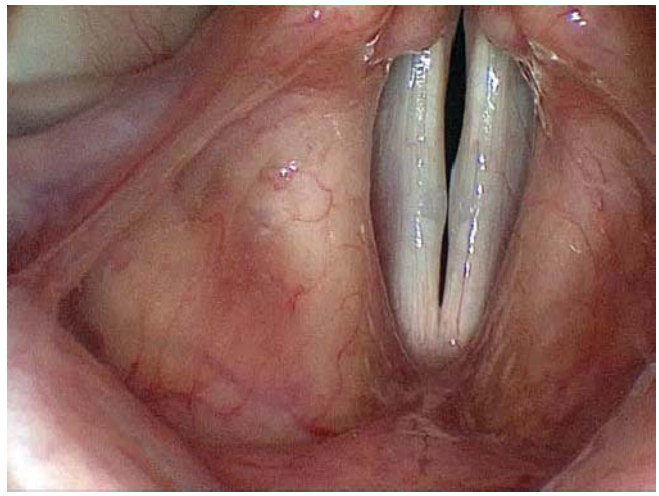

Figure 68.1 Vocal fold nodules.

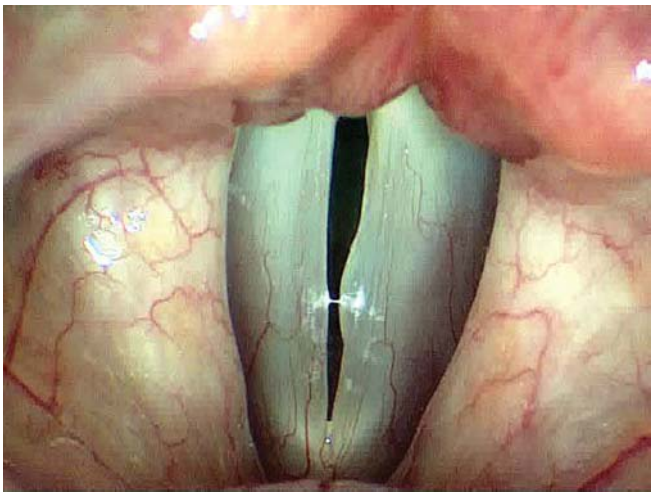

Figure 68.2 Vocal fold polyp.

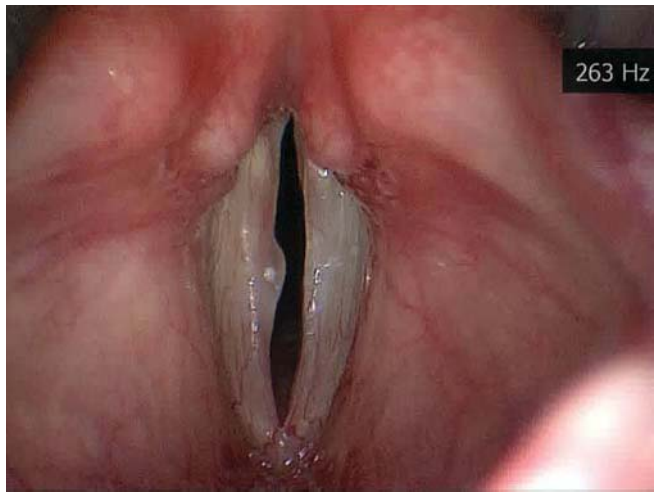

Figure 68.4 Vocal fold cyst-subepithelial.

depending on the location (subepithelial or ligament) and size, the stroboscopy pattern is either minimally impaired or significantly impaired (usually ligamentous). The intraoperative finding for a vocal fold cyst is the presence of a lesion with a distinct capsule in either of the above-described locations. Refer to Figures 68.4 to 68.6 for examples of vocal fold cysts.

4. **Fibrous mass of the vocal fold** is a lesion that can be unilateral or bilateral and can be located in the subepithelial or ligamentous area. These lesions do not respond to voice therapy and often induce a significant impairment in the mucosal wave activity during stroboscopy. Intraoperatively, the lesion is seen as a fibrous gray, unorganized, unencapsulated lesion in the midmembranous vocal fold in either the subepithelial or ligamentous region. Refer to Figures 68.7 to 68.9. These lesions often have thin extensions of the "fibrous material," extending anteriorly or posteriorly toward the anterior commissure or vocal process, respectively.

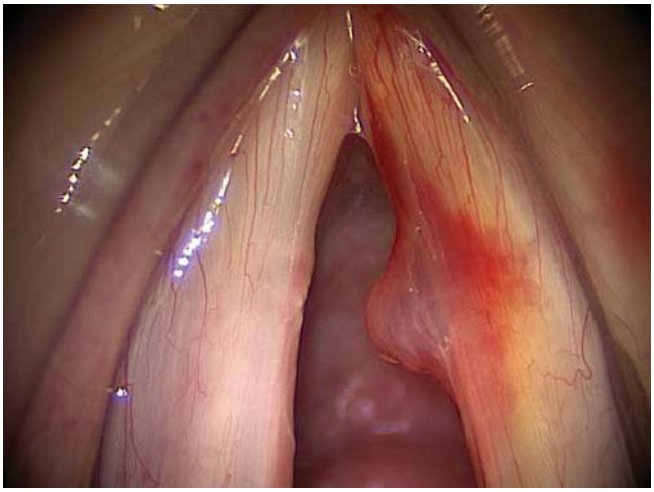

Figure 68.3 Vocal fold polyp (with associated hemorrhage).

5. **Reactive Vocal Fold Lesion**
   A reactive vocal fold lesion has good vibratory characteristics seen on stroboscopy and always occurs in response to a contralateral lesion (vocal fold polyp, vocal fold fibrous mass, vocal fold cyst). Commonly, the reactive lesion has an indentation where the contralateral lesion has created a concavity on the free edge of the lesion due to repeated trauma during vocal fold vibration. This appearance of the two lesions interdigitating with each other during vocal fold closure and vibration is often called a "cup and saucer" deformity. This lesion often will reduce in size with behavioral therapy. Refer to Figure 68.10 for an example of a left true vocal fold reactive lesion associated with a right true vocal fold polyp.
6. **Nonspecific vocal fold lesion**
   Nonspecific vocal fold lesion can be unilateral or bilateral, and is denoted by either subepithelial or ligamentous pathology that is not responsive to nonsurgical interventions (voice rest, medical therapy of comorbidities, and voice therapy) but does not impair function sufficiently to necessitate phonomicrosurgical removal. Thus, when a lesion is classified as a nonspecific vocal fold lesion, the clinician immediately knows that the patient has persistent vocal fold pathology in the face of significant functional improvement and a high functioning level after maximal medical therapy (nonsurgical). Refer to Figure 68.11 to see the vocal folds of a patient who met the clinical criteria for bilateral nonspecific vocal fold lesions.
7. **Pseudocyst**
   Pseudoscyt is a superficial subepithelial pathology that, by definition, corresponds to glottal incompetence most often associated with vocal fold scar but can also be associated with a vocal fold paresis or paralysis. The clinical nature of this lesion includes a very superficial, almost "water blister" appearance of the lesion, with a very thin epithelial covering to the

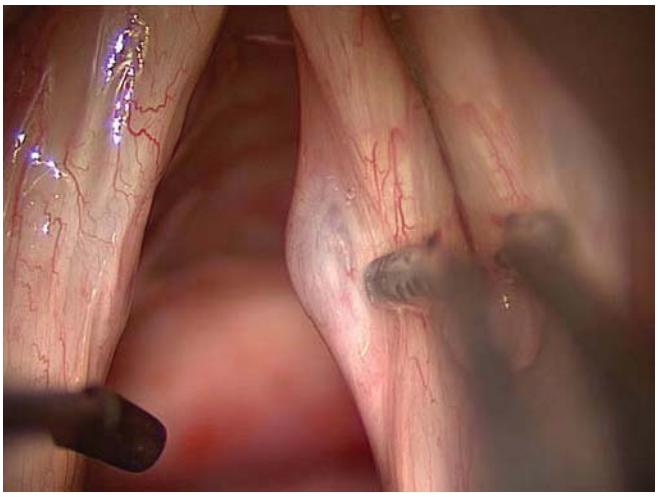

Figure 68.5 Vocal fold cyst-ligament.

Figure 68.7 Fibrous mass-subepithelial and bilateral.

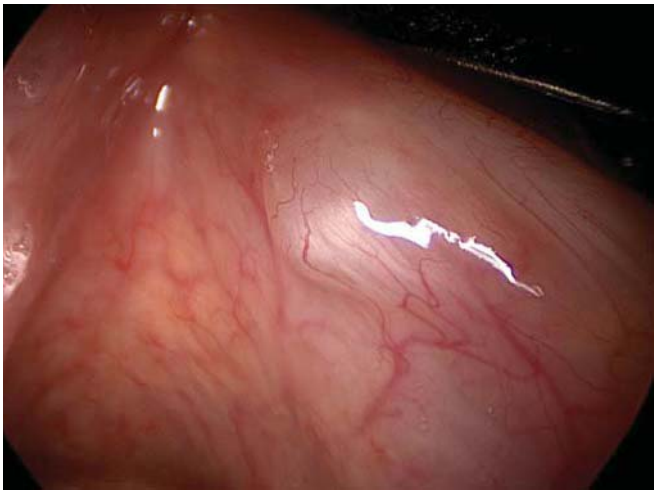

Figure 68.6 Vocal fold cyst-ligament (30-degree telescopic view of same lesion as Fig. 68.5).

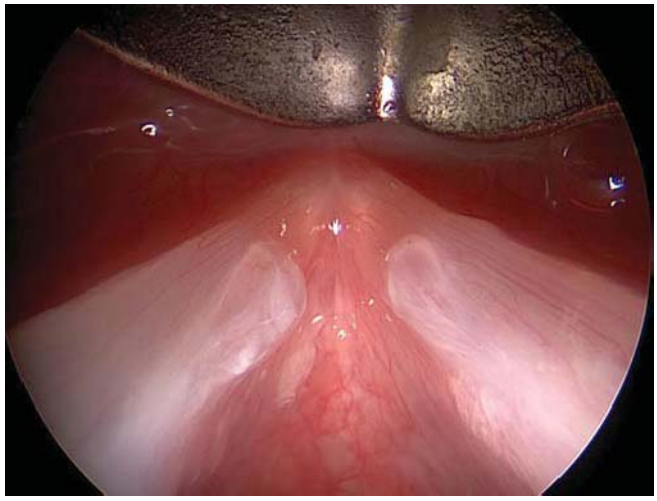

Figure 68.8 Fibrous mass-subepithelial and bilateral (70-degree telescopic view of same lesions as Fig. 68.7).

lesion without any evidence of encapsulation nor negative impact to the mucosal wave of the affected vocal fold. If this lesion is removed surgically without the glottal incompetence being addressed, it has a high likelihood of recidivism. Refer to Figure 68.12 to see an example of a left true vocal fold pseudocyst with associated right true vocal fold scar.

The definitive diagnosis of most midmembranous benign lesions of the lamina propria requires evaluation following resolution of any acute inflammatory processes, stroboscopy, voice therapy treatment, and possibly intraoperative findings. The treatment approach for these lesions is fairly standardized, given that most patients should receive nonsurgical treatment for these lesions, which consists of medical therapy for comorbid medical conditions (e.g., allergies, reflux) and voice therapy (see Chapter 71). At the initial evaluation session and after maximal nonsurgical medical therapy, assessment of the patient should include

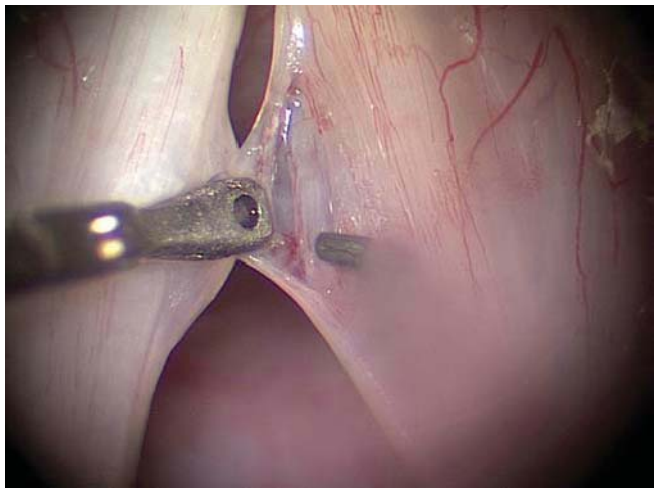

Figure 68.9 Microflap excision of the fibrous mass-subepithelial, seen in Figures 68.7 and 68.8.

Figure 68.10 Reactive vocal fold lesion of left true vocal fold.

functional measures and stroboscopy (see Chapter 65). The decision to proceed with surgery, which is highly individualized, should be based on the patient's voice quality, functional needs, and demands following maximal nonsurgical treatment modalities. After conservative nonsurgical therapy has been implemented, the patient should be asked "can you do what you need to do with your voice at the present time?" If the patient still has significant functional limitations with the voice, then a discussion regarding surgical treatment of the vocal fold lesion(s) is reasonable.

Another advantage of the above-described vocal fold nomenclature system is that these lesions have different prognostic implications and can be helpful in counseling the patient regarding expected clinical course and treatment outcome. In general, patients with subepithelial pathology have a greater likelihood of excellent vocal fold recovery than do patients with disease within the ligament and, similarly, patients with vocal fold nodules, reactive lesion, and vocal fold polyp have a better prognosis for a high degree of vocal recovery after treatment than do those with a vocal fold cyst and fibrous mass (5).

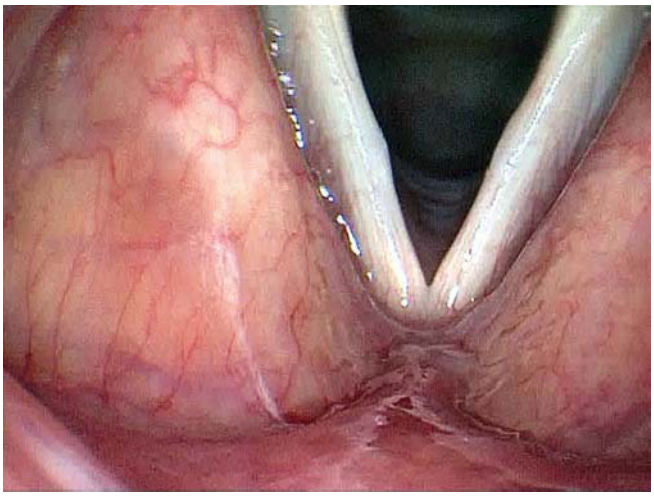

Figure 68.11 Nonspecific vocal fold lesion, bilateral.

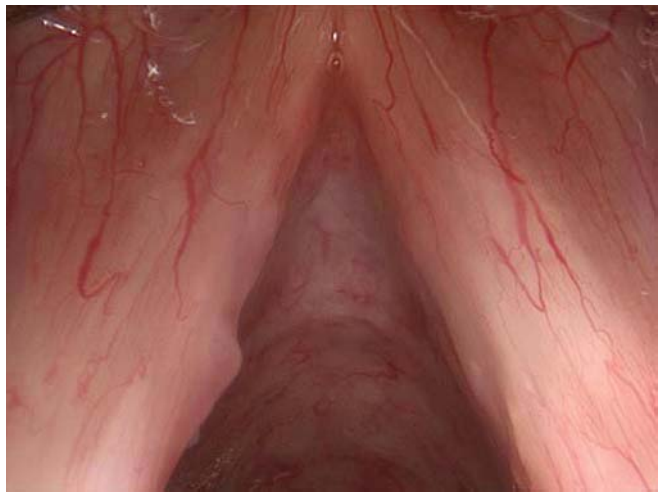

Figure 68.12 Pseudocyst of the left true vocal fold and associated right vocal fold scar defect.

Vocal Fold Scar and Sulcus Vocalis

Vocal fold scar and sulcus vocalis are abnormalities of the lamina propria of the vocal fold that result in poor vocal fold vibratory function (loss of viscoelasticity) and often glottal insufficiency. The former is a hallmark of vocal fold scar and sulcus vocalis, and the latter is dependent on the nature of the vocal fold pathology. For reasons that are unclear, some patients with vocal fold scar develop a "deposition" form of the vocal fold pathology where the normal lamina propria of the vocal fold is substantively taken over (replaced) by thick, fibrous scar tissue that can match the normal size of the lamina propria or can even slightly expand the size of the vocal fold as the vocal fold epithelium becomes adherent to the vocal ligament. The theory behind this form of vocal fold scar involves repeated hemorrhage into the vocal fold, resulting in serial deposition of scar tissue, which eventually replaces and even expands the lamina propria. Other patients with vocal fold scar and all patients with sulcus vocalis have an opposite effect: the lamina propria is reduced or lost during the formation of the disease process without any subsequent replacement at all. This results in a loss of vibratory function and a change in the size and dimension of the vocal fold. These pathologic occurrences cause glottal insufficiency. Limited research has looked at the etiology of vocal fold scar and sulcus vocalis. Clinical reports, however, indicate that most of the patients with these disorders have a history of repeated vocal abuse (phonotrauma). Refer to Figures 68.13 and 68.14 to view the vocal folds of a patient with bilateral sulcus vocalis. There is also a belief that sulcus vocalis can occur as a congenital deformity. These patients have an abnormal sounding cry and abnormal phonation from birth forward and, typically, have a very severe form of sulcus vocalis. The varying degrees and types of deformation that sulcus vocalis can present have been described as either a type I, type II, or type III sulcus vocalis deformity (6).

Figure 68.13 Sulcus vocalis, bilateral.

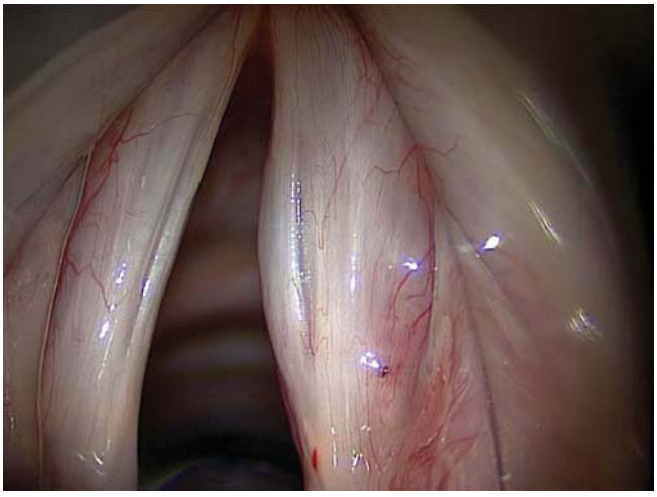

Figure 68.14 Sulcus vocalis, bilateral. (After right deep true vocal fold injection augmentation with Radiesse Voice Gel.)

Treatment for vocal fold scar and sulcus vocalis can be successful, depending on the patient's motivation, voice demands, and quality of available voice therapy and surgeries. Surgical treatment is directed at addressing a stiffened and volumetric-deficient lamina propria (7). As in the treatment of all benign voice disorders, nonsurgical treatment for vocal fold scar and sulcus vocalis should be implemented first. This involves treatment of comorbid medical problems, voice therapy, and sometimes singing voice therapy. Following these treatment options, if significant functional limitations are still present, the patient may be a candidate for surgical treatment for vocal fold scar or sulcus vocalis. The surgical approaches for this disorder are focused at the specific functional limitation (voice quality vs. volume or vocal fatigue) and the dominant pathophysiologic problem. For patients with problems of vocal fatigue and volume and correlated significant problems with glottal insufficiency, a vocal fold augmentation procedure (vocal fold injection or medialization laryngoplasty, refer to Fig. 68.14) is helpful as a first and possibly sole therapy. For patients with vocal fold scar or sulcus vocalis and severe dysphonia without any problems of glottal incompetence, surgical procedures that address the vibratory or elastic characteristics of the lamina propria are indicated. These procedures include direct implantation of fat into the vocal fold via a microflap approach or Gray mini-thyrotomy, collagen injection into the lamina propria, or the mucosal slicing technique of Pontes (8–10). Direct implantation of fat into the lamina propria for vocal fold scar and sulcus vocalis is a technically demanding and difficult surgery. When successful, however, the fat graft material provides excellent vibratory characteristic to the injured vocal fold. Superficial vocal fold injection of collagen-based materials is presently limited by technical difficulty in depositing the material in the area of scar or sulcus vocalis and currently available collagen-based materials (11). In the future, different materials that more appropriately match the native extracellular matrix proteins may be available to improve this treatment approach.

The mucosal slicing technique of Pontes involves an attempt to reorganize the lines of stress throughout the severely scarred and damaged vocal fold lamina propria by making multiple, parallel mucosal slices of varying lengths. This technique has not been widely utilized. It is also reported that recovery from this surgery is prolonged, and patients should be advised that a 9- to 12-month time period is required for voice improvement.

Miscellaneous Vocal Fold Lesions

Rheumatologic Lesions of the Vocal Folds

Rheumatologic lesions of the vocal folds involve an inflammatory and fibrotic process occurring within the vocal fold, associated with various rheumatologic disorders such as rheumatoid arthritis. These lesions, which occur deep within the lamina propria, typically around the vocal ligament, cause severe dysphonia because of the vocal fold stiffness, changed size, and the infiltrative nature of the lesion(s). These lesions should be differentiated from the typical benign midmembranous vocal fold lesions, such as vocal fold polyp, cyst, and fibrous mass. Refer to Figure 68.15 for an example of bilateral midmembranous rheumatologic lesions. Patients may present with a rheumatologic lesion of the vocal fold without prior diagnosis of their rheumatologic condition. Thus, it is important that patients have a rheumatologic evaluation and treatment before surgical excision of the vocal fold lesions when a rheumatologic condition is suspected (see Chapter 67).

Conditions including Wegner granulomatosis, amyloidosis, sarcoidosis, and rheumatoid arthritis can exhibit manifestations in the larynx. Wegner granulomatosis is classically known for its predisposition to the subglottis, but patients can present with dysphonia before obstructive symptoms. Primary amyloidosis of the respiratory tract most commonly involves the larynx and presents as a submucosal mass. Sarcoidosis can present as epiglottic noncaseating granulomas, which rarely need surgical

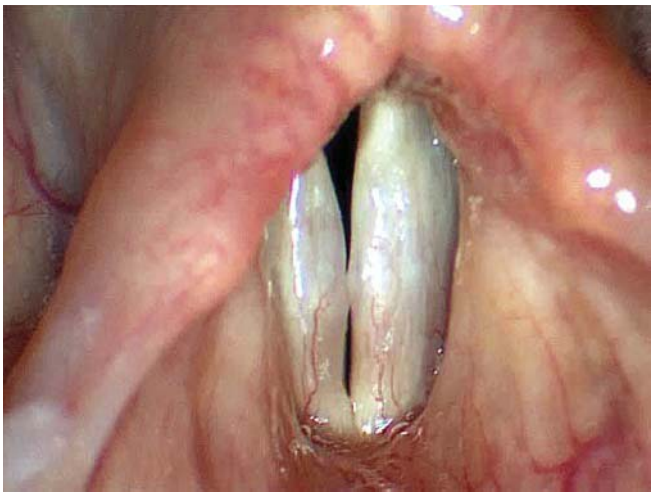

Figure 68.15 Rheumatologic lesions of the bilateral true vocal folds.

Figure 68.16 Vocal process granuloma.

intervention as they often exhibit spontaneous remission. The presence of cricoarytenoid joint rheumatoid arthritis does not show any relation to age, disease duration, or severity of disease. Furthermore, patients with cricoarytenoid rheumatoid arthritis (RA) can present with acute and intermittent symptoms, which can make the diagnosis difficult (See Chapter 67). Methotrexate, when used for rheumatologic disease, may promote rheumatologic deposits within the vocal folds, given that they have a propensity to cause rheumatologic nodule formation in other parts of the body. Collaboration with the patient's rheumatologist is essential to provide optimal care for this condition. Voice and surgical therapy should start after the patient has been maximally treated for the rheumatologic condition.

Vocal Fold Granuloma

The term vocal fold granuloma (also known as vocal fold contact ulcer) is a misnomer, given that this condition is an inflammatory mass originating from chronic inflammation and irritation of the perichondrium of the arytenoid cartilage. It is not a granulomatous disease as defined by histopathology, such as sarcoidosis or tuberculosis. Vocal fold granulomas typically occur near or at the vocal process of the arytenoid cartilage and can be subdivided into two groups: intubation related and not intubation related. The former, which occurs following endotracheal intubation, is characterized by rapid resolution of the lesion once all the offending agents are removed or eliminated (e.g., endotracheal intubation, laryngopharyngeal reflux [LPR], and vocal abuse or chronic cough). Patients with an intubation-related vocal fold granuloma, typically, can be treated conservatively, and over several months their lesions will resolve spontaneously. Patients with a granuloma that is not intubation related are typically more difficult to treat. These patients require a detailed evaluation from a glottal competence, laryngeal reflux, and vocal behavior perspective because these conditions are the most common etiologic agents for a vocal fold granuloma that is not intubation related. Refer to Figure 68.16 for an example of a chronic left vocal process granuloma that was not related to intubation. Surgery should be reserved until all associated comorbid medical conditions (allergy and laryngopharyngeal reflux disease) and appropriate voice use issues have been addressed unless a concern of malignancy exists. A delayed approach to surgical removal is wise given the high degree of recidivism with these lesions following surgery. When surgery is performed for vocal fold granulomas, the surgeon must remember that any additional irritation to the underlying arytenoid perichondrium will likely result in a recurrent vocal fold granuloma. Thus, vocal fold granuloma should be removed, using an approach that involves minimal trauma to the underlying perichondrium of the arytenoid cartilage (see "Phonomicrosurgery of the Vocal Folds" below). An alternative to surgical excision of vocal fold granuloma after all nonsurgical treatment modalities (voice therapy, LPR treatment, etc.) have been addressed is the use of botulinum toxin A (btxA) injection to the thyroarytenoid–lateral cricoarytenoid muscle complex (12). The btxA injection is thought to reduce the vocal fold closing force and thus allowing the vocal fold granuloma site to heal. This approach has not been thoroughly studied, causes prolonged breathy dysphonia during the treatment period, and in many cases does not address the underlying etiologic cause of the vocal fold granuloma.

A different type of vocal fold granuloma is a membranous vocal fold granuloma, which differs from granulomas classically present on the vocal process of the arytenoid. Membranous vocal fold granulomas occur after microlaryngeal surgery and typically arise at the surgical site in the early postoperative course. All patients with membranous vocal fold granulomas should be treated with a proton pump inhibitor and the condition usually resolves spontaneously under this management. Surgical excision is of little benefit and in most cases can accelerate the formation of additional granulation tissue (13).

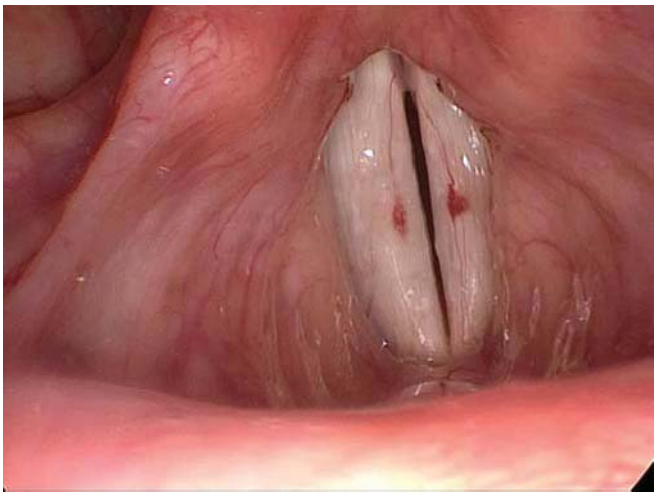

Figure 68.17 Vascular lesions of the bilateral true vocal folds.

Vascular Lesions of the Vocal Folds

Abnormal vascular lesions of the vocal folds are subepithelial blood vessels that have been termed "vascular ectasias" or "venous lakes" of the vocal fold (3). These lesions, which are characterized as having a transverse course within the vocal fold (perpendicular to the longitudinal axis of the vocal fold), are often associated with vocal fold lesions and past or present phonotrauma. It is not clear if these vascular lesions occur because of the vocal fold lesions or vice versa. Most patients with vascular ectasias of the vocal fold do not require surgical treatment unless they have a history of documented vocal fold hemorrhage or that the lesion is located along the striking edge of the vocal fold and the clinician has a high-index suspicion that this lesion is extremely susceptible to vocal fold hemorrhage. Surgical treatment of these lesions should be done with great precision and with cold steel excision or pulsed angiolytic laser ablation (3,14). The role of angiolytic lasers in the management of vocal fold vascular lesions has recently become more prominent. Both pulsed potassium-titanylphosphate (KTP) and pulse dye lasers (PDL) have been found to be both efficacious and relatively safe in singers (14). Vessel rupture may be less frequent with pulsed KTP versus PDL (14). The chromophore for these lasers is hemoglobin rather than water, as with CO_2 lasers, resulting in more precise delivery of laser energy to the abnormal blood vessel and thus, less thermal injury risk. Refer to Figure 68.17 for an example of interesting bilateral vascular lesions of the true vocal folds.

Reinke Edema

Reinke edema of the vocal folds is a poorly understood chronic condition involving the development of a gelatinous, inflammatory exudate within the subepithelial space of the vocal fold, unilateral or bilateral. This condition is most commonly associated with the triad of laryngopharyngeal reflux disease, vocal abuse, and tobacco abuse. Not all patients with Reinke edema must have all three etiologic factors present, but typically patients will have two of these three when Reinke edema is present. Reinke edema causes increased mass of the vocal folds, which results in a lowering of the voice pitch and a decrease in the phonatory efficiency and stability of the voice, resulting in frequent voice breaks, and harshness and raspiness of the voice (see Chapter 65). Treatment of Reinke edema should first and foremost involve treatment of the underlying causative factors (reflux, phonotrauma, and tobacco abuse). After these conditions have been addressed, patients can be treated with a combined approach of voice therapy and surgery. The success rate of surgical treatment of Reinke edema is usually favorable, especially when redundant mucosa is carefully excised (15). Recurrence or lack of perceptual voice improvement can be problematic in some patients. Elimination of the causative factors for Reinke edema has a significant impact upon the long-term prognosis after surgery (16). The amount and timing of voice therapy in relationship to surgery is controversial and should be done on a case-by-case basis. Refer to Figures 68.18 and 68.19 for an example of a Reinke edema of the true vocal folds.

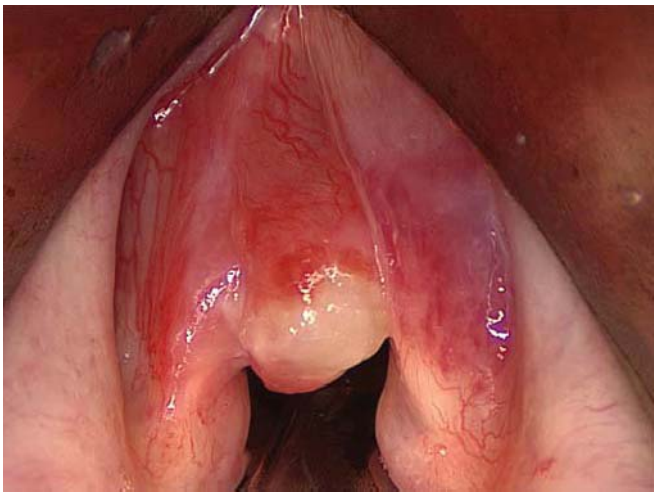

Figure 68.18 Reinke edema of the bilateral true vocal folds, left greater than left.

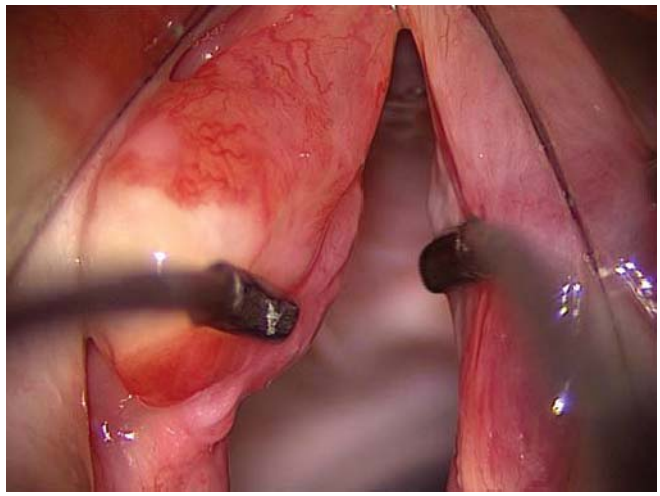

Figure 68.19 Displacement of left true vocal fold Reinke edema from Figure 68.18.

PHONOMICROSURGERY OF THE VOCAL FOLDS

Overview

Phonomicrosurgery encompasses a variety of operations that have the primary goal of improving voice quality. These are elective operations that involve precision microsurgical removal of benign vocal fold pathology, most often from the subepithelial space of the vocal fold. The surgical procedures and principals are based on vocal fold physiology, specifically Hirano cover-body theory of the vocal fold vibration (see Chapter 58). Given the importance of the interaction between the epithelium and the superficial area of the lamina propria (cover) and the underlying deep layer of the lamina propria and muscle (body), phonomicrosurgery was born and has evolved to minimally disrupt the normal microarchitecture of the vocal fold while removing dysphonia-inducing pathology. The overarching goal is to limit dissection to as superficial plane as possible and to maximally preserve epithelial and lamina propria. The latter tenet is important to facilitate primary wound healing versus secondary wound healing. This is thought to allow maximal functional recovery (vocal fold mucosal vibration) following surgery.

Prephonomicrosurgery Considerations

Phonomicrosurgery is an elective surgery and, thus, pressure should not be placed on the patient to decide to proceed with surgery. The risks and benefits of the surgery should be detailed to the patient and, most importantly, a realistic and thorough evaluation of the patient's present vocal functional limitations and abilities (speech and singing) should be reviewed. Often, this review process should be done over several weeks and involve the patient, otolaryngologist, family members, speech–language pathologist, and possibly a singing voice specialist. When all nonsurgical treatment modalities have been exhausted and significant vocal functional limitations exist, it is appropriate to proceed with phonomicrosurgery.

Important preoperative measures before phonomicrosurgery include avoiding (a) nonsteroidal anti-inflammatory medications or other anticoagulation medications and (b) significant vocal abuse and misuse immediately before surgery. Preoperative voice therapy (one to two sessions) is extremely important in preparation for phonomicrosurgery for a variety of reasons: (a) psychological preparation for surgery and postoperative voice rest, (b) to modify and improve improper speaking technique, and (c) to lay the foundation for postoperative voice therapy, from both a psychological and a behavioral perspective. Preoperative voice therapy stresses to the patient the importance of changing inappropriate vocal techniques and use patterns in the postoperative period, thus reducing the chances of vocal fold pathology recidivism.

Before phonomicrosurgery, patients must realize that they will be on absolute voice rest and reduced voice use for a variable period of time (from 3 to 14 days) and that they must adjust their voice demands to comply with the surgeon's restrictions regarding voice use.

Preoperative consent for phonomicrosurgery should involve the risks of general anesthesia and injury to the temporomandibular joint (TMJ), dentition, and lingual nerve. The latter has been shown to be temporary, lasting an average of 2 weeks to a maximum of 1 month (17). A discussion regarding postoperative voice quality following phonomicrosurgery should be taken seriously and done by the surgeon before the phonomicrosurgical procedure. It should involve the small but real risk of either no improvement of voice quality (1% to 2% incidence) or a reduction in vocal function or voice quality (1% to 2% incidence).

All patients should undergo preoperative stroboscopy. Before phonomicrosurgery, the surgeon should review the patient's most recent stroboscopy. Preferably, this review is done the day of surgery or 1 to 2 days before the surgery. The optimal situation would be to have the preoperative stroboscopy examination available for review in the operating room immediately before (as well as during) the procedure. This allows the surgeon to correlate stroboscopic findings with surgical findings and make important decisions on pathology location, incision placement, and dissection and excision degree.

Equipment for Phonomicrosurgery

Specialized laryngoscopes are required for phonomicrosurgery. In general, the larger the laryngoscope, the better for phonomicrosurgery, which allows improved exposure and access to the surgical site(s). Multiple large and specialized laryngoscopes exist and a wide variety of laryngoscopes are necessary to manage all types of phonomicrosurgical lesions and procedures. It is important to have specialized laryngoscopes for special laryngoscopy needs.

Key microlaryngoscopy instruments used for phonomicrosurgery involve specialized blunt microelevators, cup forceps, scissors, curved alligators, and small suctions (3, 5, and 7 French). Phonomicrosurgery cannot be done properly and safely without these specialized instruments. In addition, a specialized set of instruments have been developed for microflap retraction. These are called triangular or Bouchayer forceps. The microelevators should be blunt and have several different angles and sizes to allow the surgeon to work in various angles in different positions within the vocal fold, specifically, dissecting the vocal fold lesion off the overlying microflap. A microsurgical knife (sickle or diamond shaped) should be always available for phonomicrosurgery. This knife tends to get dull very quickly and, thus, this knife should be replaced with every case or at least on a very frequent basis. A dull knife can result in tearing of the mucosa and can significantly limit the efficacy of phonomicrosurgery. Several small special cup forceps have been developed to facilitate several specific situations that are encountered in phonomicrosurgery. One of these cup forceps is a round, 1-mm diameter, angled-up cup forceps. This forceps has a sharp cutting

edge but a limited cutting surface, only the most distal 180 degrees of the forceps cup.

Suspension of the laryngoscope is a basic aspect of phonomicrosurgery. Two basic designs for placing the laryngoscope into a fixed and stable position exist. These are categorized as a gallows suspension device and a rotation or fulcrum device. The gallows suspension laryngoscope is advantageous and favorable, given that its more appropriate upward vector of pull of the laryngoscope can provide optimal exposure of the endolarynx with minimal risk of dental injury, especially to the maxillary teeth (18). This device is not the one most commonly used because of traditional and historical use of rotational/fulcrum devices (Lewy suspension).

Long Hopkins rod telescopes with various visualization angulations are an essential component to phonomicrosurgery. Rarely is the surgery performed using these telescopes, but they do provide the surgeon with multiple angles of visualization for varied perspective of the vocal folds and its related pathology. The 30- and 70-degree telescopes, which are approximately 4 to 5 mm in diameter and 30 cm long, should be used immediately before phonomicrosurgical incision; they are often used during phonomicrosurgery as well as at the end of the surgery to ensure that all appropriate pathology has been removed. These angled telescopes are readily available in most operating rooms, given they are used regularly for cystoscopy.

The microscope used for phonomicrosurgery should be of the highest quality and provide the surgeon with a stable method to view the endolarynx. This microscope should be the same microscope that is used for precision otologic procedures (e.g., stapes surgery and other middle ear operations). Furthermore, the microscope should be compatible with a CO_2 laser micromanipulator attachment. Typical focal length of the lens used on the surgical microscope for phonomicrosurgery is 400 mm. This allows an adequate space between the proximal end of the laryngoscope and the microscope for placement and use of hand instruments for phonomicrosurgery. Another important feature of the surgical microscope is an articulated eye piece; this allows for optimal surgeon ergonomics, which is important for lengthy phonomicrosurgery cases as well as for the long-term health of the phonomicrosurgeon (19).

Lasers have a limited role in phonomicrosurgical procedures. The CO_2 laser with the micromanipulator has also been used to incise vocal fold tissue. No distinctive advantages for the use of this laser exist for this application, and the risks of thermal injury and costs of the instrument outweigh any potential benefits. Most phonomicrosurgery can and should be done with "cold steel" instrumentation. The CO_2 laser allows an "instrument free" approach to surgery of the vocal folds and in a small crowded surgical space, this can be an advantage. However, for most phonomicrosurgical situations, this is not a key problem and thus the CO_2 laser is rarely indicated for this reason alone. Angiolytic lasers including pulsed KTP and PDL have been used for laryngeal surgery, but the indication and validation of this new technology for most phonomicrosurgical procedures, except for papilloma disease, has not been determined.

PHONOMICROSURGERY PROCEDURES, TECHNIQUES, AND METHODS

A working relationship based on mutual respect, communication, and teamwork with your anesthesia colleague(s) is essential for successful phonomicrosurgery. Phonomicrosurgery involves general anesthesia; complete muscle relaxation should be implemented following the induction of general anesthesia and the muscle paralysis continuously monitored throughout the surgery. Preoperatively, anesthesia should administer intravenously (IV) steroids and glycopyrrolate (unless contraindicated). Endotracheal tube placement is extremely important, given that misplaced or traumatic placement can cause injury to the vocal folds and may result in cancellation of surgery. Endotracheal tube placement should be done to minimize the risk of trauma to the vocal folds (i.e., under completely controlled conditions, no stylet if possible, etc.). Furthermore, the otolaryngologist should be present during the intubation to monitor the situation and be available to assist with placement if required. In a similar fashion, controlled extubation at the end of phonomicrosurgery is another important aspect of the necessary teamwork between the anesthesia team and the phonomicrosurgeon.

The ventilation options for phonomicrosurgery are endotracheal intubation, jet ventilation, or apneic methods. Most phonomicrosurgery is best performed using endotracheal intubation with a small (5.0 or 5.5) specialized endotracheal tube. This provides both a still operating field and complete control of the airway. Sometimes, the endotracheal tube can obstruct the surgical site and may need to be repositioned or completely removed. Jet ventilation for phonomicrosurgery, which should be done only on an as-needed basis, is best done with a midtracheal jet ventilation catheter (Hunsaker tube, Medtronic Xomed Co., Jacksonville, FL). Tracheal jet ventilation is preferred to supraglottic jet ventilation because it provides the surgeon with less vibration and desiccation of the vocal fold tissues during phonomicrosurgery. These suggestions result in a still operating site and less risk of vocal fold desiccation.

Phonomicrosurgery patients are placed in a supine position on the operating room table. The optimal head and neck position for exposure of the endolarynx with the laryngoscope is having the neck flexed on the body and the head extended on the neck (20). A shoulder roll, which places the patient in a suboptimal position for optimal laryngoscope placement, should not be used. Neck flexion can be achieved by using an articulated head on the operating room table with the head extension on the neck being done by the surgeon, and then secured with the suspension device. Dental and alveolar ridge protection before insertion of the laryngoscope is important.

The optimal position of the laryngoscope within the endolarynx is determined by the vocal fold pathology

and pending surgical procedure. In general, however, the laryngoscope should be positioned immediately above the vocal fold pathology, specifically, resulting in retraction of the false vocal fold tissues. Take care to avoid contacting the superior surface of the vocal fold, given that this will significantly alter the anatomic orientation and nature of the vocal fold and often distort the vocal fold pathology.

Any Gallows suspension device used should be positioned to provide upward and slightly forward (caudal) suspension of the laryngoscope in the endolarynx. This special angulation of the laryngoscope will provide optimal laryngoscopic visualization and minimal adjacent tissue injury or damage. For a rotation or fulcrum laryngoscope device holder, it is of utmost importance to remember to provide special care and attention to the maxillary teeth as the laryngoscope holder is put into place. This is especially important given that as the fulcrum holder is adjusted, each degree of upward rotation at the distal tip of the laryngoscope results in an equal amount of downward pressure at the proximal aspect of the laryngoscope on the maxillary alveolar ridge.

A Velcro strap or silk tape can be applied to the external neck (in the area of the cricoid or trachea) in a downward and slightly cephalad vector to improve the endolaryngeal exposure on an as-needed basis. The surgeon checks the improved view through the laryngoscope while applying this external counter pressure. A small amount of gauze or a foam pad can be positioned between the tape or strap and the neck skin to prevent any injury to the overlying skin of the larynx and care should be taken to avoid placing pressure on the carotid arteries.

Using the 0-, 30-, 70-, and, as needed, 120-degree telescopes to visualize the endolarynx in a "three-dimensional" fashion is of great value. This is done after the laryngoscope is suspended. This allows for unique visualization of the vocal fold pathology, photo documentation, and surgical planning. Specifically, decisions are often made about where the optimal location is for an incision when evaluating the vocal fold pathology, especially with the 30- and 70-degree angled telescopes.

After placement and suspension of the laryngoscope and telescopic examination, the surgical microscope is brought into position and attention should be drawn to the position of the laryngoscope in relation to the microscope and the surgeon. A microscope with an articulated eyepiece is essential. Optimal hand control of instrumentation during phonomicrosurgery occurs when the forearms can be supported with a stable device, such as an operating room chair with arm supports in the region of the elbows, forearms, or wrists. The wrists are the best location for precise control and, thus, some type of surgical support should be identified (an ophthalmology or plastic surgery operating room chair with arm supports) that will allow the most steady and stable hand and wrist motions. After proper ergonomic planning, the surgeon should not experience any strain or tension in the shoulders or arms (19). The utility of trendelenburg or reverse trendelenburg adjustments should also be considered when optimizing ergonomics.

Binocular vision at high-powered magnification (the microscope's highest level of magnification) must be maintained during all aspects of the procedure. This will require minor but important adjustments to the position of the microscope and laryngoscope to ensure that the viewing access of the microscope is coaxial with the longitudinal aspect of the laryngoscope. This is an extremely important component to phonomicrosurgery and should not be overlooked. The novice phonomicrosurgeon will initially struggle with this task, but patience and practice will ensure success.

The microflap approach to submucosal pathology is a key aspect to most phonomicrosurgery operations. The key principles of the microflap approach to submucosal pathology include (a) making an incision through the epithelium at the closest possible location to the submucosal pathology; (b) minimal disrupting of the surrounding tissue to the vocal fold pathology; and (c) staying in as superficial a plane as possible. After the vocal fold pathology is palpated and an incision is planned, hemostatic measures should be implemented. The topical application of 1/10,000 epinephrine on a cottonoid can be used to achieve improved hemostatis. Consideration should be given for the utility of a subepithelial injection. An injectable solution of 1/10,000 epinephrine is used with a laryngeal injector to infiltrate Reinke space surrounding the vocal fold lesion. The subepithelial infiltration technique can result in elevation of the mass, increased epithelial tension, and less traumatic dissection from the superficial lamina propria and underlying vocal ligament. After the implementation of hemostasis, an incision is then made with a sharp knife. The incision for the microflap should be over or immediately lateral to the vocal fold pathology (Fig. 68.20), which results in minimal disruption of normal vocal fold mucosa. It is important to note that the tip

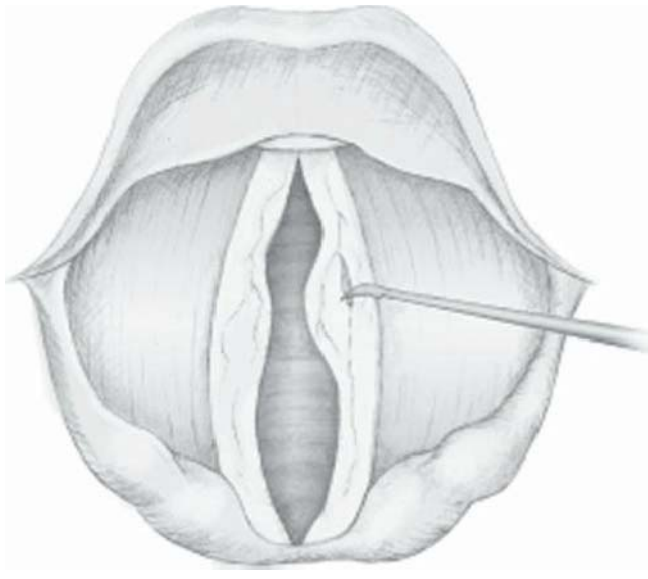

Figure 68.20 Incision immediately lateral to submucosal pathology for microflap approach for removal of the vocal fold lesion.

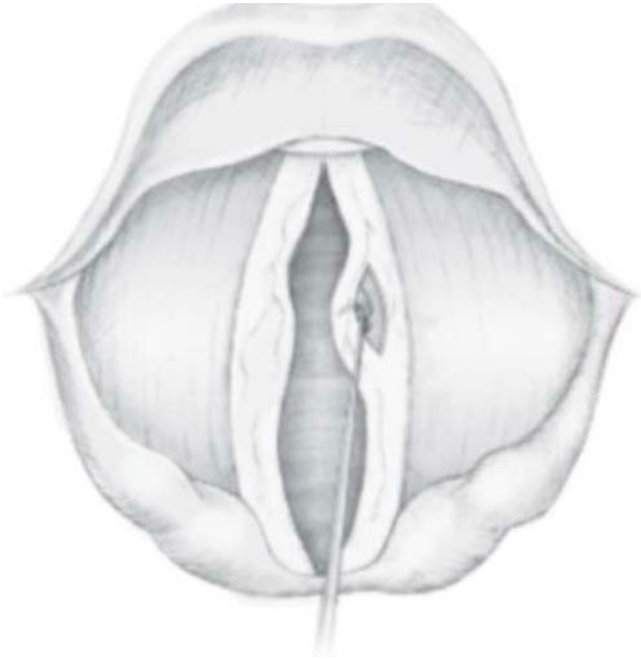

Figure 68.21 Microflap elevation.

of the knife should be used to penetrate the epithelium and then the surgeon must take great care to stay as superficial as possible while the incision is completed. After the incision has been made, the vocal fold pathology may be palpated and directly visualized through the incision. A small curved elevator can be used to start the elevation of the microflap in a plane between the vocal fold pathology and the overlying epithelium (Figs. 68.21 and 68.22). This plane is the single hardest activity of phonomicrosurgery and should be done with great patience and caution. It is often easiest to initiate and develop this plane anterior and posterior to the vocal fold lesion. Once a plane is developed anteriorly and posteriorly to the lesion, then careful submucosal dissection with a small, fine, blunt elevator, (curved or angled) completes the elevation and creation of the microflap (Fig. 68.23). In some instances the microcurved scissors need to be used to release fibrous bands in adherent areas of the submucosal pathology off the overlying microflap or, similarly, when the submucosal pathology is adherent to the deeper aspects of the vocal fold in the area of the vocal ligament (Figs. 68.24 and 68.25). Take great care not to tear or fenestrate the microflap as it is tediously and carefully elevated off the submucosal pathology. Often, various angulated or curved elevators are required to perform this aspect of the procedure. Most benign vocal fold submucosal pathology is located in the immediate subepithelial plane and, to a varying degree, is often adherent to the overlying microflap. This is the case in approximately 75% of cases (4). However, situations occur in which the pathology is not adherent to the microflap and located deeper within the vocal fold (in the area of the vocal fold ligament). This is especially true for vocal fold cysts and fibrous mass pathology. When these pathologies are encountered,

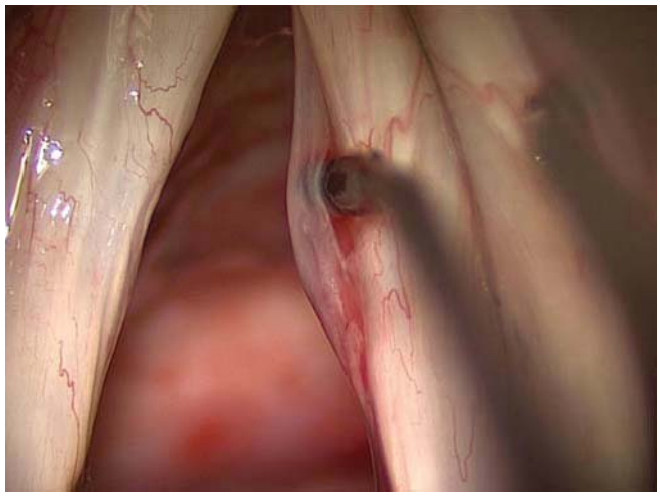

Figure 68.22 Careful elevation of the microflap overlying the vocal fold cyst-ligament. Same cyst also seen in Figures 68.5 and 68.6.

the surgeon will notice that the microflap elevation is easily accomplished. Subsequently, during the second aspect of the dissection, in which a plane between the vocal fold pathology and the vocal ligament is created, the dissection can be found to be quite difficult (Fig. 68.25). When this is the case, take great care to use either a blunt dissection technique or microscissors to release the adhering bands from the vocal fold ligament to the pathology, always erring on the side of the pathology (in a superficial fashion). After the superficial and deep planes around the submucosal pathology have been elevated, some additional connections may remain within the vocal fold anteriorly and posteriorly. These bands can be released with blunt dissection or microcurved scissors (Figs. 68.24 and 68.25). This

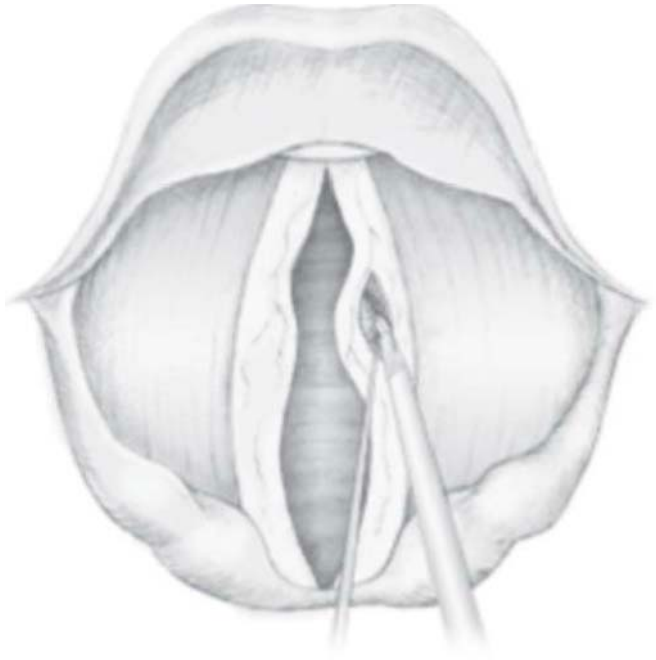

Figure 68.23 Removal of submucosal pathology via microflap.

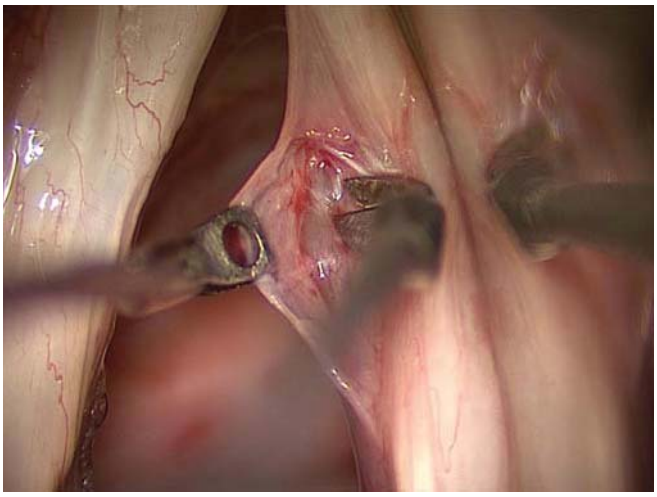

Figure 68.24 Release of fibrous bands over the vocal fold cyst-ligament with microcurved scissors.

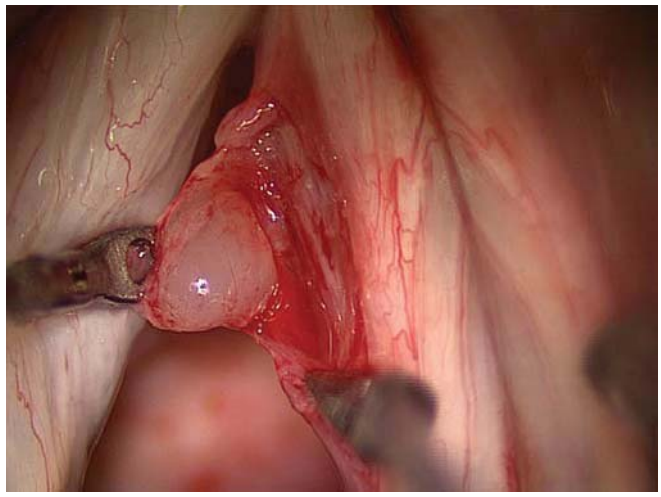

Figure 68.26 Vocal fold cyst-ligament undergoing final release with microcurved scissors.

allows the submucosal pathology to be removed and sent for pathologic examination (Fig. 68.26). It is then important to carefully examine the surgical site to look for remnants of the lesion (Fig. 68.27). The microflap is then redraped. (Figs. 68.28 and 68.29). After the microflap has been redraped, palpate the free edge of the vocal fold to determine if any residual submucosal pathology remains that requires further attention.

The free edge of the vocal fold should be straight after the pathology is removed; if not, further inquiry into either the undersurface of the microflap or the deeper aspect of the vocal fold is required. If any residual pathologic tissues (e.g., fibrous material or scar) remain, remove this tissue in a conservative and reasonable fashion. This material can be removed with a microelevator or microcup forceps. Extreme care is required at this juncture of the surgery because too aggressive removal of this material can result in significant scar formation as well as a permanent deformity of the free edge of the vocal fold. At the completion of the vocal fold lesion(s) excision, the free edge of each vocal fold should be completely straight without exophytic mucosal tags and without a divot along the vocal cord free edge at the surgical sites (Figs. 68.28 and 68.29).

Almost all phonomicrosurgical procedures are followed by some period of voice rest. This period can range from 2 days to 14 days, depending on the specific nature of the surgery, compliance of the patient, and the surgeon's philosophy and previous experience. In addition to voice rest, the patient should be encouraged to stay well hydrated, and to continue empiric treatment with a proton pump inhibitor and gastroesophageal reflux disease behavior modification to minimize the possibility of an acid reflux event(s) during the postoperative period.

At the end of the prescribed strict voice rest period, postoperative stroboscopy should be performed to evaluate the recovery and healing process of the vocal fold. Recovery is

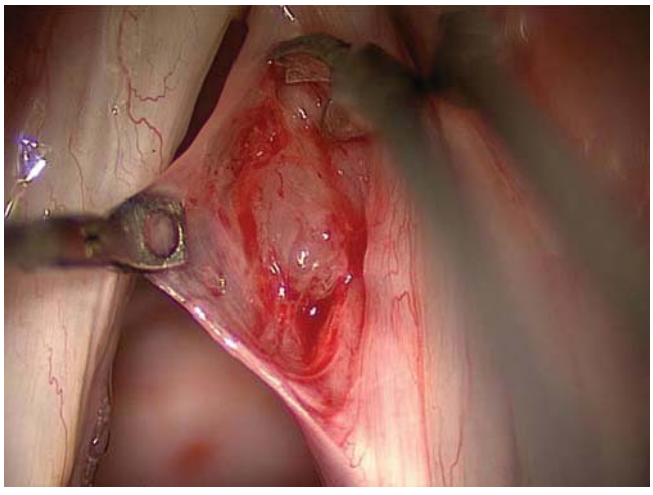

Figure 68.25 Difficult dissection of vocal fold cyst with adherent bands to the vocal ligament.

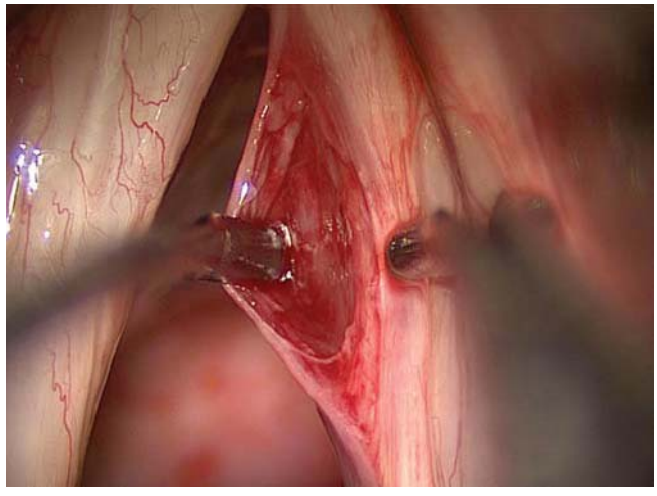

Figure 68.27 Inspection of the microflap and vocal ligament after phonomicrosurgical excision of a vocal fold cyst-ligamentous.

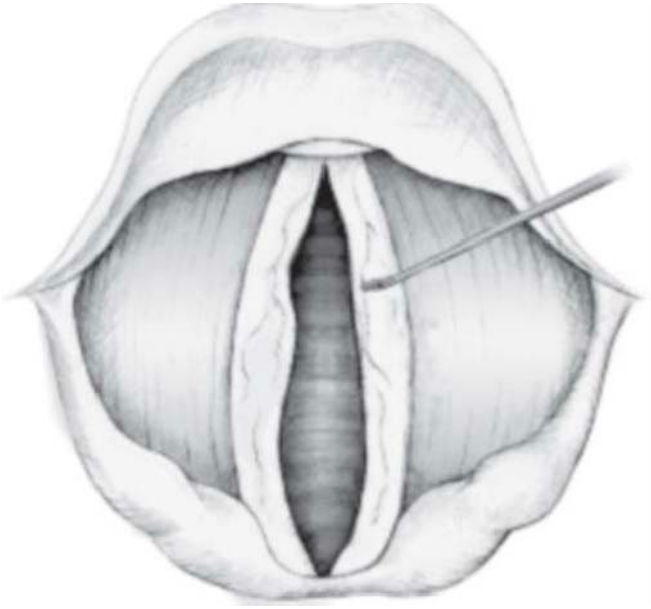

Figure 68.28 Redraping of microflap following submucosal pathology removal.

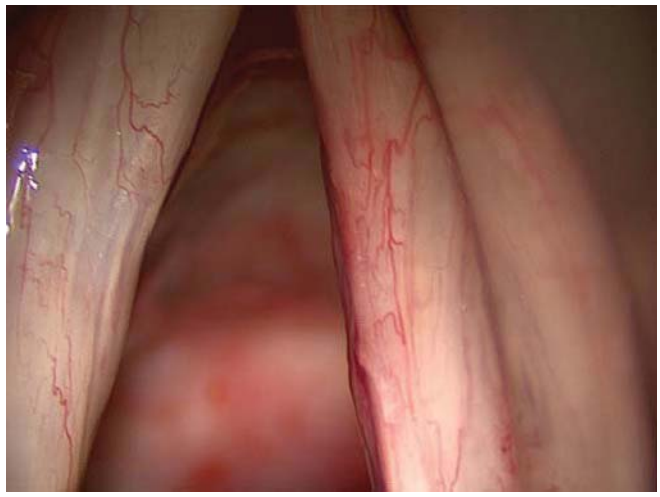

Figure 68.29 Microflap redraped after phonomicrosurgical excision of a vocal fold cyst-ligament.

demonstrated by the return of mucosal pliability. The timing of mucosal wave return can vary among patients and with the type and depth of a vocal lesion. Stroboscopy can help to identify an aberrant healing process such as significant postoperative scar formation. With the identification of adequate epithelial coverage, the patient can be transitioned to light voice use, which is usually defined as speaking using a breathy, "airy" type of voice for 5 to 10 minutes per hour. Light voice use is often used for an additional 7 to 10 days after the period of strict voice rest. Rarely does an indication exist for postoperative antibiotics or a prolonged steroid course after phonomicrosurgery. Some surgeons may use IV or intramuscular steroids perioperatively to minimize postoperative edema.

It is important to utilize a speech–language pathologist to assist the patient in transitioning from complete voice rest to light voice use to ensure that the patient is using the optimal postoperative voice technique to facilitate healing and prevent injury during this important time period. Postoperative voice therapy can then be initiated to optimize the rehabilitation following surgery.

COMPLICATIONS

Complications from phonomicrosurgery include failure of the microflap to appropriately redrape and adhere to the vocal fold. When this occurs, epithelial ingrowths underneath the microflap occur and surgical excision of the microflap is mandated. This is a rare complication. Excessive edema and even necrosis can occur to the microflap; this typically occurs when the microflap is overly traumatized or injured during the surgical procedure. Often, when this occurs, the vocal fold will heal adequately on its own with appropriate time and care. Also unusual, but important to recognize, is postoperative granuloma formation of the membranous vocal fold at the surgical site (13). This lesion differs from the well-known vocal process or "contact" granuloma. A membranous granuloma should be suspected when a lesion appears early in the postoperative course and should not be mistaken for a recurrence of the lesion. The membranous granuloma often responds to several weeks of proton pump inhibitor and rarely needs repeat surgical excision. Consideration and counseling should be given in patients with TMJ syndromes, who may experience increased symptoms after phonomicrosurgery. Lingual nerve injuries (e.g., numbness of the tongue and a change in taste sensation) occur in approximately 10% to 20% of patients following phonomicrosurgery. These symptoms are usually transitory and, thus, the patient should be informed that these postoperative changes will resolve on their own within the first month following surgery (17).

The outcomes after phonomicrosurgery can vary depending on patient selection, postoperative care, adherence to voice rest, management of comorbid disease such as LPR, and changes in damaging voice habits. Many otolaryngologists hesitate to operate on singers and performing artists due to concerns of poor postoperative outcomes. However, nearly all singers and performing artists with poor voice function secondary to persistent lesions of the superficial lamina propria have all shown improvement in subjective and objective measures in a study of 185 artists (21). Large multicenter studies are necessary to further establish the outcomes of phonomicrosurgery in a wider variety of individuals. Standardized measures such as the voice-related quality of life, voice handicap index-10, and computerized voice analysis should be routinely implemented to evaluate outcomes in individuals as well as larger groups of patients (22,23). Further understanding of vocal fold wound healing and the factors that maintain normal lamina propria may yield tangible therapies to modulate healing and maximize outcomes.

HIGHLIGHTS

- The most common benign vocal fold lesions involve subepithelial masses (e.g., vocal nodules, fibrous mass of the vocal fold, and vocal fold cysts). Differentiation of these lesions involves stroboscopy, longitudinal evaluation of the lesion(s), and sometimes intraoperative findings.
- Vocal fold scar and sulcus vocalis are entities that involve a significant derangement of the lamina propria of the vocal fold without focal accumulation of a mass type lesion. These pathologies typically involve severe dysphonia, which is caused by poor mucosal vibratory characteristics and glottal insufficiency.
- Phonomicrosurgery is an elective, precise surgery aimed to improve vocal function based on vocal fold physiology principles.
- Phonomicrosurgery, which requires use of small, delicate surgical instrumentation, is done with maximal control via high-power microlaryngoscopy for optimal results.
- Conservative removal of submucosal pathology with preservation of overlying normal epithelium allows healing by primary intention and optimal voice quality following phonomicrosurgery.
- Microflap approach to submucosal pathology of the vocal fold is an essential component of most phonomicrosurgical procedures and is a challenging surgical task that requires patience, appropriate instrumentation, and surgical skill and experience.
  - Preoperative stroboscopy is essential for evaluation and operative planning. Postoperative stroboscopy should be routinely used after the period of voice rest has been completed to monitor for the return of a normal mucosal wave.
- Preoperative and postoperative voice therapy is essential to prepare patients for postoperative voice rest and to improve poor voice habits that may play a role in the pathology of the benign lesion.

69 Treatment of Vocal Fold Paralysis

VyVy N. Young *C. Blake Simpson*

Vocal fold paralysis (VFP) can have a profound impact on a patient's quality of life. Bilateral vocal fold paralysis (BVFP) is life threatening because of airway compromise, and occasionally, unilateral vocal fold paralysis (UVFP) is potentially life threatening, if poor airway protection leads to aspiration pneumonia. In the case of UVFP in a professional voice user, severe dysphonia or aphonia can lead to loss of income or unemployment. For these reasons, prompt and sometimes aggressive treatment of VFP is frequently indicated. The surgical armamentarium available to treat UVFP and BVFP continues to expand, and otolaryngologists should be aware of the myriad treatment options available to the patient. This chapter outlines the many changes that have occurred in the diagnosis and treatment of VFP during the past few years, highlighting the armamentarium that is available to the treating otolaryngologist.

For the purpose of clarity, this chapter deals primarily with adult VFP and is divided into two distinct topics: UVFP and BVFP.

UNILATERAL VOCAL FOLD PARALYSIS

Etiology

The etiology of UVFP involves dysfunction of either the brainstem nuclei, the vagus nerve, or the recurrent laryngeal nerve (RLN) supplying the involved side of the larynx (Fig. 69.1). Corticobulbar fibers from the cerebral cortex descend through the internal capsule and synapse on the motor neurons in the nucleus ambiguus. The nucleus ambiguus is the area within the brainstem (medulla) from which arise the fibers that will contribute to the vagus nerve. Lower motor neurons leave the nucleus ambiguus and travel laterally, exiting the medulla between the olive and the pyramid as a series of eight to ten rootlets. These rootlets coalesce into a single nerve root, known as the vagus nerve, which then exits the skull base via the jugular foramen. The vagus nerve descends in the carotid sheath, giving off three major branches: the pharyngeal branch, the superior laryngeal nerve, and the RLN. The SLN supplies sensation to the glottic and supraglottic larynx, as well as motor input to the cricothyroid (CT) muscle, which controls vocal fold lengthening and pitch. The RLN arises from the vagus nerve in the upper chest and loops under the aortic arch (left) or subclavian artery (right) and ascends back into the neck, traveling in the tracheoesophageal groove. The nerve enters the larynx posteriorly, adjacent to the CT joint. The RLN innervates the ipsilateral posterior cricoarytenoid (PCA), interarytenoid (IA) (an unpaired muscle), lateral cricoarytenoid (LCA), and thyroarytenoid (TA) muscles. Thus, the RLN supplies all of the intrinsic laryngeal muscles with the exception of the CT muscle. Ipsilateral RLN transection results in near-complete vocal fold immobility. (The ipsilateral CT muscle does not contribute to vocal fold adduction or abduction). It is important to remember, however, that the IA muscle is unpaired, and contralateral RLN input to the IA can lead to some adduction of the vocal fold on the paralyzed side (Fig. 69.2) (1).

The causes of unilateral VFP are myriad, but can be broken down into categories to highlight the relevant pathophysiology (2). These are shown in (Table 69.1).

In the past, nonlaryngeal malignancy was generally cited as the most common cause of UVFP, while iatrogenic nerve injury likely represented the most common cause for otolaryngologic referral. Recently, a large retrospective study over 20 years demonstrated a reversal of this trend, such that iatrogenic surgical trauma has now become the most common etiology for unilateral vocal fold immobility (3).

Traditionally, thyroidectomy was often thought to account for most of these iatrogenic cases. However, more recent data have shown that nonthyroid surgeries such as carotid endarterectomies and anterior cervical spine

surgery are the causative etiology approximately twice as often as thyroidectomy, 31% versus 16% of all causes, respectively (3). Merati et al. (4) also reported a 47.6% rate of iatrogenic injury in 84 patients with acute vocal fold motion impairment, including 27.5% following cervical spine procedures and 15% after thyroidectomy. While iatrogenic VFP caused by anterior cervical spine surgery is clearly on the rise, it is unclear whether this increase is caused by a change in surgical technique or by a rise in the overall number of these surgeries being performed. The overall incidence of this complication has previously been reported to be around 1% but more recent studies have found a higher rate (11%) of early persistent RLN palsy (5). Netterville et al. (6) has noted that the complication is almost exclusively right-sided and is probably caused by a stretch injury of the RLN by the Cloward retractor. The shorter, more oblique course of the right RLN seems to predispose it to injury (6). Other common iatrogenic surgical causes of UVFP include esophagectomy, thymectomy, neck dissection, mediastinoscopy, and cardiothoracic surgery, including aortic surgery, coronary artery bypass grafting, and pulmonary lobar resection (2,7,8). Endotracheal intubation (9), prolonged nasogastric tube placement, and even esophageal stethoscope placement have been implicated as occasional causes of VFP (Table 69.2).

Nonlaryngeal malignancies are another common cause of unilateral VFP. The most common scenario involves bronchiogenic carcinoma of the lung associated with a left RLN paralysis. The cause in these cases is usually mediastinal spread of the malignancy into the aortopulmonary window. These paralyses rarely resolve spontaneously, and deserve early intervention. Other nonlaryngeal malignancies include thyroid, esophageal, and skull base (i.e., paraganglioma) tumors. Because of the common association of nonlaryngeal malignancies with VFP, it is imperative that all unexplained VFP cases be evaluated by means of an appropriate imaging study that looks at the full course of the cervicothoracic vagus and RLN (1).

The neurologic event most commonly associated with unilateral VFP is stroke, usually of the brainstem. In these patients, however, other neurologic symptoms (e.g., paraplegia) or additional cranial nerve (CN) involvement are the rule, and isolated unilateral VFP in this setting is highly unlikely (1). Many of these patients have severe dysphagia and aspiration caused by ipsilateral laryngopharyngeal sensory and motor deficits. Such patients can be challenging to treat, and may fail to improve despite adequate medialization surgery of the paralyzed vocal fold.

Uncommon neurologic causes of VFP include Arnold-Chiari malformation, amyotrophic lateral sclerosis (ALS), Guillain-Barré syndrome, Eaton-Lambert syndrome,

TABLE 69.2 SURGICAL OR IATROGENIC CAUSES OF VFP

Surgery or Procedure	Mechanism of Nerve Injury or Relevant Anatomy
Anterior cervical spine	Retraction; stretch injury of RLN (right more common) (6)
Esophagectomy	RLN injury in tracheoesophageal groove
Carotid endarterectomy	Vagal injury during dissection
Mediastinoscopy	RLN injury, usually left
Coronary artery bypass grafting	1. Retraction or direct injury to vagus or RLN during internal mammary artery harvest for grafting (8) 2. Hypothermic nerve injury from ice cardioplegia (7)
Pulmonary resection	Usually left upper lobe or RLN injury
Endotracheal intubation	Possible pressure neuropraxia from compression of anterior rami of RLN caused by a high-riding endotracheal cuff in the subglottis (9)

RLN, recurrent laryngeal nerve.

Parkinson disease, Shy-Drager syndrome, progressive bulbar palsy, myasthenia gravis, multiple sclerosis, and postpolio syndrome. Almost all of these disorders will have other obvious signs of progressive neurologic disease in addition to unilateral VFP and, in many cases, the neurologic condition has already been diagnosed before the patient presents with voice complaints. Most of these progressive neurologic conditions present with much more complicated (yet often subtle) findings on head and neck examination, such as a bowed vocal fold or vocal fold atrophy (Parkinson, ALS, postpolio syndrome), unexplained vocal fatigue with subtle reduced vocal fold mobility (myasthenia gravis in particular), vocal spasms (ALS), tongue fasciculations (ALS), and dysarthria (ALS, bulbar palsy). It is important to obtain a neurology consultation when a progressive neurologic disease is suspected.

Idiopathic and miscellaneous causes of unilateral VFP are also seen frequently. A few case reports suggest that "idiopathic" UVFP may be caused by herpes simplex infection (HSV1) of the vagus nerve or its branches. The injury is presumed to be an inflammatory neuropathy, similar to the cranial neuritis observed with Bell palsy (10). Although this theory is widely regarded as true, little scientific data have been published to demonstrate that HSV neuritis is the causative agent in "idiopathic" UVFP. In addition, no studies exist that evaluate the benefit of corticosteroids or antiviral medications in the treatment of this condition. Limited data are available to document the natural history of this "idiopathic" UVFP, although Blau and Kapadia (11) reported spontaneous recovery in approximately 50%. Dworkin and Treadway (12) also described spontaneous recovery in 25% of patients with more than 3-month follow-up. It is apparent that additional study is needed to evaluate the cause and treatment of "idiopathic" UVFP. Lastly, it is important to remember that idiopathic UVFP is a diagnosis of exclusion, once a detailed history and appropriate imaging studies fail to demonstrate a cause.

Rarely, medications can cause VFP. The most notorious substances are the Vinca alkaloids (vincristine and vinblastine), which are known to cause neurotoxicity. The VFP in this case is dose related and usually resolves over a 4- to 6-week period after stopping or adjusting the dose of the medication. Both unilateral and bilateral VFP have been reported (13). Cisplatinum, also a potential source of neurotoxicity, has been implicated as a cause of reversible bilateral VFP (14,15).

Systemic diseases can (also rarely) cause vocal fold immobility, because of either paralysis or joint fixation. Such diseases include gout, sarcoidosis, tuberculosis, rheumatoid arthritis, and hypothyroidism (only in cases of myxedema) (16). Again, these systemic diseases would be expected to have myriad symptoms in addition to unilateral vocal fold immobility, and these conditions should *not* be suspected in cases of isolated VFP.

In the case of endotracheal intubation leading to unilateral vocal fold mobility, it is important to rule out the possibility of arytenoid cartilage dislocation or subluxation as the true cause of an immobile vocal fold. This is best done with laryngeal electromyography (LEMG) (see below and also Chapter 70.) Other traumatic causes of VFP include blunt or penetrating injuries to the neck.

History

Vocal Quality and Swallowing

The evaluation of UVFP begins with a thorough history and physical examination. The symptoms of UVFP are well known to all otolaryngologists. These symptoms are related to glottic insufficiency resulting from some degree of lateral displacement of the paralyzed vocal fold. The primary symptom of UVFP is dysphonia, or hoarseness. The voice can vary from simple vocal fatigue in mild or well-compensated cases, to almost complete aphonia in severe cases. Much of the quality of the voice is determined by the muscular tone and position of the affected vocal fold and each patient's unique glottal compensatory strategy during phonation. An atrophic and poorly compensated VFP typically presents with a breathy, weak voice caused by air escape. The voice may also have a "watery" or "wet" quality to it if secretions are retained in the pyriform sinus, as is typical in high vagal injuries. With time, most patients eventually progress to a stronger but not normal voice using various compensatory strategies. Supraglottic hyperfunctional strategies are common. These patients constrict the supraglottic tract either laterally, apposing the false folds, or in an anterior posterior dimension, apposing the epiglottis to the arytenoids or the arytenoid cartilage to the contralateral false fold. This hyperfunctional muscular contraction leads to a characteristic rough, pitch-locked, low-frequency voice. This voice can sound similar to that of a patient with primary muscular tension dysphonia, and the diagnosis of VFP may not be suspected (17). "Unloading" of the voice, as described later in this chapter, is used to help analyze these patients. In contrast, other patients may develop an unnaturally high-pitched voice that is breathy in quality. This has been referred to as a "paralytic falsetto," and is characterized by a mean increase in fundamental frequency 85 Hz above "natural" pitch. This condition is thought to be caused by compensatory contraction of the ipsilateral CT muscle, which remains innervated in isolated RLN paralysis (18).

Swallowing difficulties are often encountered, specifically aspiration of liquids, along with a weak and ineffective cough. Some dysphagia for solids may also be present, especially in brainstem or high vagal injuries, because of the concomitant denervation of the pharyngeal constrictors. Risk of aspiration is heightened in these instances as well, because of the loss of ipsilateral laryngeal sensation from SLN involvement.

Vocal Inventory

It is important to obtain a vocal inventory of the patient's voice responsibilities (both work related and social). Vocal professionals rely on a serviceable voice for their livelihood, and these patients should be questioned regarding their upcoming work schedule to help determine the urgency of early surgical intervention (19). Most professional voice users will opt for temporizing vocal augmentation (e.g., Gelfoam, carboxymethylcellulose, and hyaluronic acid) so that they can return to work as soon as possible. Standardized patient-based voice handicap instruments are useful during the initial assessment and for documenting treatment progress (see Chapter 65).

Airway

A patient with UVFP can occasionally complain of being "short of breath"; however, careful history will show that the patient is not experiencing airway obstruction, as seen with BVFP. These patients are actually reporting a breathlessness that principally occurs during conversation and is caused by inefficient laryngeal closure. Poor glottal closure impairs the capacity to project the voice because of a "leaky" valve. Many patients increase respiratory effort and laryngeal muscle activity in an attempt to achieve glottal closure and produce a louder voice. These compensatory behaviors are mostly ineffective, placing undue strain on the paralaryngeal musculature, and resulting in vocal fatigue. This leaky laryngeal valve obviously requires increased respiratory drive to function, further contributing to the breathless feeling many patients report. In addition, exertional activity that requires lifting, pushing, and pulling can be difficult for patients with UVFP, because of the lack of an effective valsalva mechanism.

Physical Examination

General

Examination of the neck for adenopathy and thyroid masses should be performed. CN X neural compression and infiltration by a neck or thyroid neoplastic process can lead to VFP in advanced cases. Palatal movement when phonating /a/ should be observed. Palatal paralysis in combination with ipsilateral VFP may indicate a "high" vagal lesion. In the case of palatal paralysis, the palate retracts toward the uninvolved "good" side (e.g., in a left vagal paralysis, the palate retracts to the right). A complete cranial nerve examination should evaluate for other involved nerves, especially CN XI and XII because of the close proximity these have to CN X at the skull base. Involvement of these adjacent cranial nerves warrants a thorough radiographic evaluation of the base of the skull.

Laryngeal

The appropriate evaluation for VFP starts with the recognition of unilateral vocal fold immobility on examination. Indirect (mirror) laryngoscopy and rigid 70 or 90 degrees laryngoscopy are helpful, but do not replace flexible laryngoscopy. Flexible laryngoscopy is the only method to view vocal fold mobility in its natural state. Tongue protrusion, and the immobility produced by grasping it with a piece of gauze during indirect and rigid office laryngoscopy, changes the biomechanics of the larynx and can affect laryngeal examination findings. It is important to obtain an unencumbered, extended viewing period of the vocal folds during a variety of tasks. The best way to obtain this is flexible laryngoscopy.

When evaluating for suspected UVF paralysis or paresis, it is useful to ask the patient to perform an "ee-sniff" maneuver, where the patient alternates between phonating an "e" vowel and sniffing vigorously. This causes the vocal folds alternately to adduct and abduct maximally and is an excellent way to judge the degree of paresis or paralysis. Any *ab*duction of the affected vocal fold indicates incomplete paralysis (paresis), which generally has a better prognosis than total paralysis. It is important not to falsely attribute a small amount of *ad*duction of the affected vocal fold as representing evidence of partial innervation. RLN sectioning leads to paralysis of the ipsilateral TA, PCA, and LCA, but not the IA. The IA is a midline muscle, and has dual innervation from both RLN; therefore, some residual adduction may be present in complete unilateral VFP, because of innervation from the contralateral RLN.

A paralyzed vocal fold can be in a variety of positions, including lateral (cadaveric), median, paramedian, and intermediate (Fig. 69.3). It was once thought that the position of the paralyzed vocal fold had some topognostic

Figure 69.3 Laryngoscopic view of right VFP, during phonation. Note the lateralized position of the right vocal fold, and the glottal gap along the entire length of the vocal folds. Typically, the glottal gap is maximal at the posterior aspect of the vocal fold, as is seen in this patient. From Academy of Otolaryngology- Head and Neck Surgery: Patient of the Month Program, Volume 31, Number 7. Simpson CB: Breathy dysphonia. Hamilton, Ontario: BC Decker Inc., 2002, with permission.

significance (e.g., that lateral vocal fold position indicated complete CN X paralysis caused by RLN and SLN involvement). This theory was later disproved by Woodson (20). The final position of the vocal fold after nerve injury seems to be caused entirely by the degree of reinnervation and synkinesis present, and nothing else.

Some clinicians focus on the position of the arytenoid when evaluating vocal fold immobility. In most cases, it is much more fruitful to focus on the vocal fold movement itself, rather than on the arytenoid cartilage position, in determining vocal fold immobility. In some cases of vocal fold immobility, however, an overhanging arytenoid cartilage obscures the observation of the underlying vocal fold, making it impossible to ignore its position. This overhanging, anteriorly displaced arytenoid cartilage is sometimes mistaken for an arytenoid cartilage dislocation (Fig. 69.4). Electromyography (EMG) data from patients with an immobile vocal fold accompanied by an "overhanging" arytenoid cartilage, however, will almost always show complete denervation or poor reinnervation of the TA muscle (21). Therefore, in nontraumatic cases, anterior displacement or an overhanging, sagging arytenoid cartilage should *not* raise the suspicion for arytenoid dislocation.

The actual incidence of arytenoid cartilage subluxation and dislocation is a source of much debate. Many investigators believe it is an exceedingly rare clinical entity, and is almost exclusively caused by external trauma associated with motor vehicle crashes and penetrating injuries. Some laryngologists feel that intubation-related cricoarytenoid (CA) cartilage dislocation is virtually nonexistent, owing to the extremely strong supporting CA ligaments (Netterville, personal communication). A few small case reports, however, have demonstrated endotracheal intubation-associated arytenoid cartilage dislocations. A study by Sataloff et al. (22) has described 26 CA dislocations and subluxations over a 9-year period; however, only six cases in the series were EMG-confirmed cases of intubation-associated arytenoid cartilage dislocation.

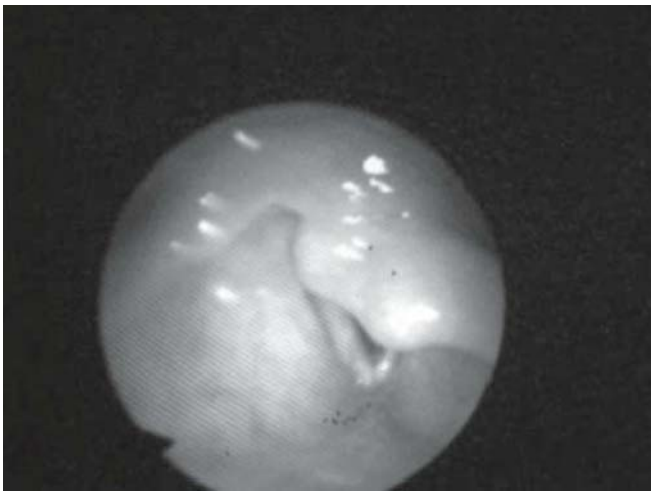

Figure 69.4 Laryngoscopic view of a patient with left vocal fold immobility and an overhanging arytenoid. LEMG confirmed that the immobility was caused by a neuropathic process, not CA joint dislocation or subluxation.

Clues that can raise the suspicion of an arytenoid cartilage dislocation when evaluating unilateral vocal fold immobility include the following:

1. Arytenoid cartilage edema
2. Difference in vocal fold level. Generally, an anterior arytenoid cartilage dislocation would result in a lower vertical position of the vocal process on the affected side. Note that vocal fold height differences are also commonly seen with VFP.
3. Absence of a "jostle sign," which is a brief lateral movement of the arytenoid cartilage on the immobile side during glottic closure caused by contact from the mobile arytenoid.

Because none of the above is pathognomonic for arytenoid cartilage dislocation, a high degree of suspicion and further diagnostic testing (such as LEMG or CA joint palpation) are needed to confirm this entity.

In some patients with UVFP, compensatory supraglottic contractions (i.e., "plica ventricularis") obscure vocal fold movement. In these cases, "unloading" of the voice is a useful technique to eliminate this unwanted effect. This may be achieved with humming or with prolonged phonation of "who." This technique is invaluable in many cases of compensated, long-standing VFP and glottic incompetence that have been misdiagnosed as "muscle tension dysphonia" or "plica ventricularis" (Fig. 69.5A and B).

Videostroboscopy is a helpful part of the workup of vocal fold movement abnormalities. Videostroboscopy may show incomplete closure or a large glottal gap in uncompensated VFP and, in these cases, useful information from the strobe examination may be limited if vibration of the vocal folds cannot be initiated. In many cases of VFP, however, the paralyzed vocal fold shows increased amplitude of vibration because of the atrophic, "floppy" nature of the denervated vocalis muscle. In cases of mild or moderate vocal fold *paresis*, the increased amplitude seen on stroboscopy may be the only sign of vocal fold weakness (Fig. 69.6) (23).

Other potentially useful information obtained via stroboscopy concerns vocal fold height differences and the status of vocal process contact during phonation. These parameters help determine the need for arytenoid cartilage adduction, when evaluating patients for laryngeal framework surgery.

A simple test to evaluate the degree of glottic incompetence is to measure the patient's maximal phonation time (MPT). This is done by simply instructing the patient to take a deep breath and to phonate an "ee" vowel for as long as possible. Normal MPT for a healthy adult is approximately 25 seconds. In cases of VFP, the MPT typically is reduced to 10 seconds or less. Shorter MPT values indicate more severe glottic incompetence, worse voice,

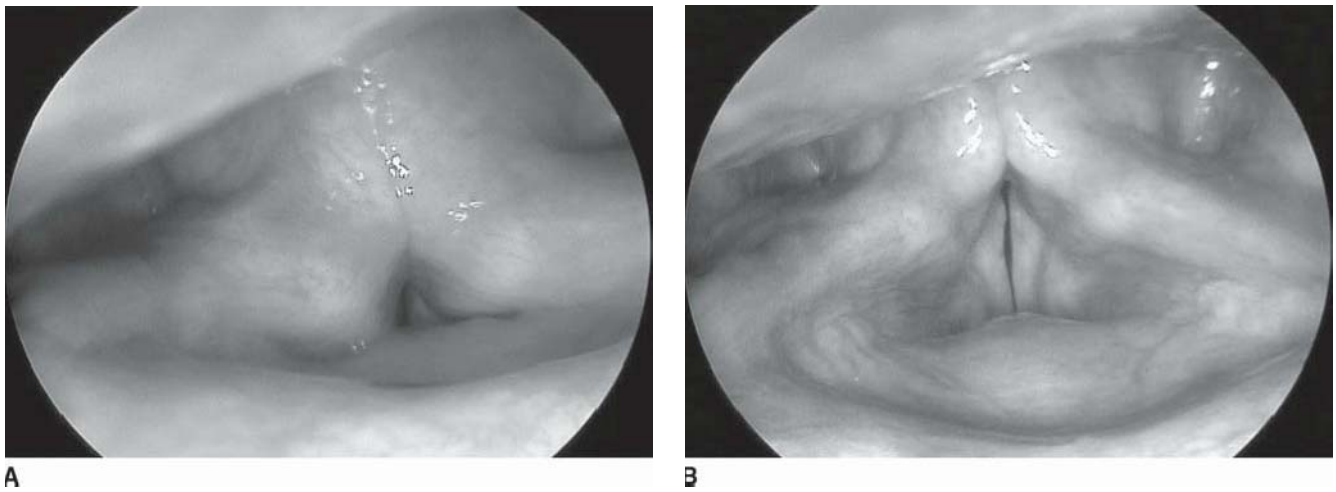

Figure 69.5 **A:** Laryngoscopic view of a patient with left VFP and compensatory supraglottic muscular constriction during phonation. Vocal fold movement and glottal closure are difficult to evaluate. **B:** Laryngoscopic view of the same patient after "unloading" (removing the supraglottic compensatory activity). The vocal folds can now be clearly seen, and a small glottal gap is noted caused by right VFP with an atrophic or "bowed" vocal fold.

and increased vocal fatigue. MPT values of 5 or less indicate severe, uncompensated VFP that may need arytenoid adduction (AA) in addition to medialization laryngoplasty (ML) (24). Poor pulmonary reserve from asthma or chronic obstructive pulmonary disease can reduce MPT significantly, so results need to be taken in context of the patient's pulmonary status and effort levels. MPT should be expected to improve (i.e., increase) after successful medialization surgery for VFP. The main limitation of MPT is the inability to distinguish between upper and lower airway sources of dysfunction. A clinically more useful indicator of glottic incompetence is the S:Z ratio. In the presence of glottic insufficiency, duration of /z/ phonation is significantly decreased but the duration of /s/ phonation remains unchanged. This phenomenon results in an increased S:Z ratio (greater than 1.4) in these patients as compared to normal controls (1.0) (25).

Lastly, it should be noted that "unilateral vocal fold immobility" is a physical finding, and not a diagnosis; the cause of the immobility must be determined. In most cases of unilateral vocal fold immobility, paralysis is indeed the underlying cause and the evaluation should reflect this accordingly. Other causes of unilateral vocal fold immobility may include CA joint arthritis (rheumatoid arthritis, gout); CA joint effusion, subluxation, or dislocation (external trauma or traumatic endotracheal intubation); or neoplastic infiltration ("occult" squamous cell carcinoma in the ventricle or paraglottic space with invasion of the RLN). In general, the history will suggest whether CA joint derangements are the culprit, and careful flexible laryngoscopy combined with computed tomography (CT) scan will reveal neoplastic infiltration as the cause of vocal fold immobility. In cases where one cannot confidently exclude the CA joint involvement or neoplasm in cases of unilateral vocal fold immobility, LEMG and a laryngoscopy (either in the office or in the operating room [OR]) with palpation for passive mobility of the vocal folds is warranted (see Chapter 73) (26).

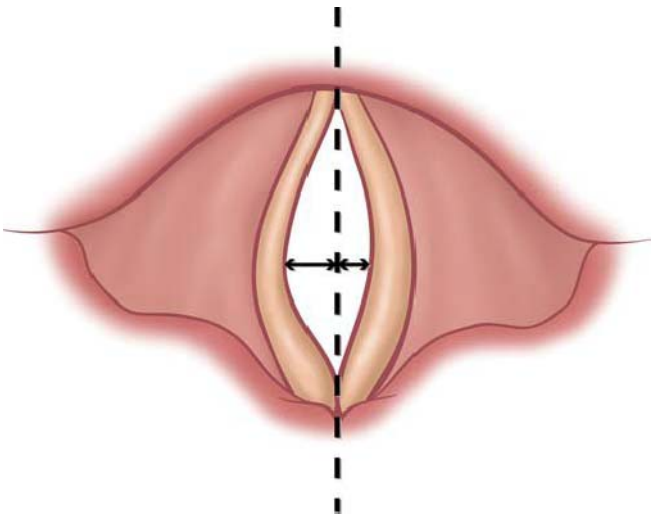

Figure 69.6 Illustration of laryngovideostroboscopy during phonation. The vocal folds are in the open phase at maximal amplitude. Note the increased amplitude (excursion of the vocal fold laterally from the midline) of the left vocal fold compared with the right. This is consistent with an atrophic, paretic left vocal fold. Workup

Serology

There is little yield from ordering screening laboratory tests such as chemistry panel, complete blood count, urinalysis,

Venereal Disease Research Laboratory, or fluorescent treponemal antibody absorption test, thyroid function tests, autoimmune panels, or erythrocyte sedimentation rate. Terris et al. (27) studied 84 patients with UVFP in which serologic studies had 0% yield in determining the cause. If additional elements of the history and physical examination point toward a systemic process as the cause of UVFP, directed serology tests may be indicated. In general, however, a "shotgun" approach to the workup of uncomplicated UVFP is unnecessary and wasteful.

Imaging Studies

As screening tools, barium swallow and thyroid scans have virtually no yield in determining the cause of VFP and are not advocated in the diagnostic workup (28). In contrast, a modified barium swallow or functional endoscopic evaluation of swallowing to evaluate swallowing and aspiration risk (29) is frequently helpful in managing cases of dysphagia in the workup of VFP.

In cases where a clear-cut temporal relation exists between surgical iatrogenic trauma and VFP, no additional radiologic workup is necessary. In cases where no cause can be found for the VFP, imaging studies are essential. Some disagreement exists to what constitutes an "adequate" radiologic assessment for unexplained VFP. Most investigators agree that a CT scan (with contrast) or magnetic resonance imaging (MRI) encompassing the base of the skull through the upper chest is adequate. The radiologist should be informed that the entire course of the vagus down to the take-off point of the RLN in the thoracic cavity needs to be included in the study. Benninger et al. (1) have argued that CT or MRI of the neck combined with chest radiography constitutes an adequate workup. They noted that 100% of pulmonary or mediastinal malignancies associated with VFP were detected on routine chest radiography, and that imaging of the chest by CT was unnecessary. Others disagree with this approach. Glazer et al. (28) demonstrated that of 18 metastatic mediastinal masses seen on CT, only 5 were visualized on routine chest radiographic study. Koufman et al. (30) advocate the addition of MRI of the brainstem in cases of obvious "high vagal" lesion (palatal paralysis + VFP), because this is a difficult area to image and small lesions can be missed.

The utility of imaging studies in the setting of vocal fold paresis is less well defined, as the presence of partial vocal fold motion is considered by many to be indicative of a lower likelihood of a radiographically identifiable compressive lesion of the RLN. These authors do not routinely perform radiologic evaluation of patients with vocal fold paresis.

Laryngeal Electromyography

LEMG has an increasingly crucial role in the workup of unilateral vocal fold immobility. The findings of LEMG are important in determining prognosis, differentiating UVFP and CA joint pathology, diagnosing suspected vocal fold paresis, and directing treatment decision making (31–36).

Useful information from LEMG is obtained between *1 and 6 months* after the onset of VFP. Evaluation outside of these parameters can render the information misleading (too early), or of limited usefulness (too late) (37). Munin et al. (37) have shown that serial LEMG provide better prognostic information in the determination of UVFP recovery.

Qualitative LEMG has been a long-time tool in the evaluation of VFP. More recent reports describe *quantitative* aspects of LEMG that provide additional information regarding prognosis (38,39). The term "spontaneous activity" refers to fibrillation potentials (spontaneous discharges during rest). This finding is consistent with active nerve denervation (Fig. 69.7B). "Recruitment" is the finding of increase in the number and rate of motor unit discharges as contraction is increased (as the patient increases the loudness of the vocalization); this can be reduced or absent with nerve injury. Normal motor unit potentials (MUP) are biphasic or triphasic, whereas polyphasic MUP indicate early reinnervation (Fig. 69.7C). Clear-cut cases of normal (class I) and grossly abnormal (class V) give good prognostic information. Statham et al. (38) have recently demonstrated that motor unit recruitment can be quantitatively measured within the TA muscle complex by a "turns analysis," evaluating the number of "turns," or peaks of the measured MUP signal. Their report evaluated both control and UVFP patients and revealed that a mean decrease in turns below 400 at maximal effort is reflective of a neurogenic lesion (Fig. 69.8).

Additionally, synkinesis reflects a misdirected reinnervation following RLN injury and/or reinnervation from nonnative nerves and is demonstrated by MUP in the TA muscle complex during vocal fold abduction tasks (such as a sniff) (Fig. 69.9A and B). The presence of synkinesis has been shown to be a poor prognostic indicator (34). Smith et al. (39) demonstrated that use of *quantitative* LEMG improves the ability to predict return of vocal fold motion, with 100% positive and 89.5% negative predictive values in their study utilizing this technique. Clearly, LEMG in general, and quantitative LEMG specifically, represent a clinically useful tool in the management of patients with VFP.

Treatment

The treatment of unilateral VFP (40) can be broken into three management strategies:

1. Observation for 6 to 12 months, reserving treatment for patients with continued symptoms
2. Referral to speech pathology for voice strengthening or swallow therapy, as indicated

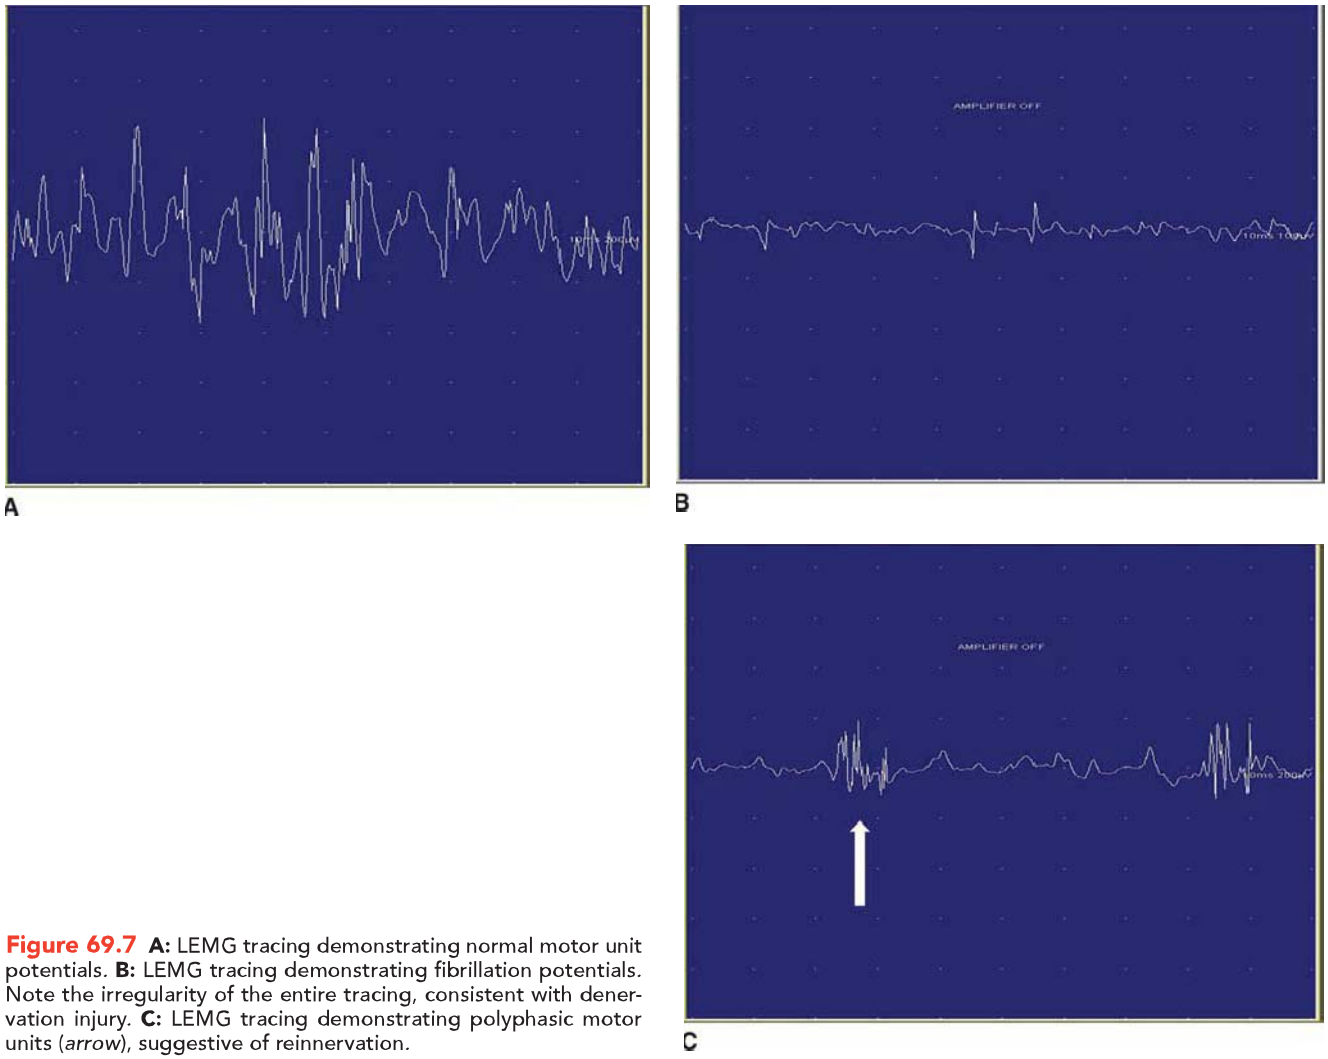

Figure 69.7 **A:** LEMG tracing demonstrating normal motor unit potentials. **B:** LEMG tracing demonstrating fibrillation potentials. Note the irregularity of the entire tracing, consistent with denervation injury. **C:** LEMG tracing demonstrating polyphasic motor units (*arrow*), suggestive of reinnervation.

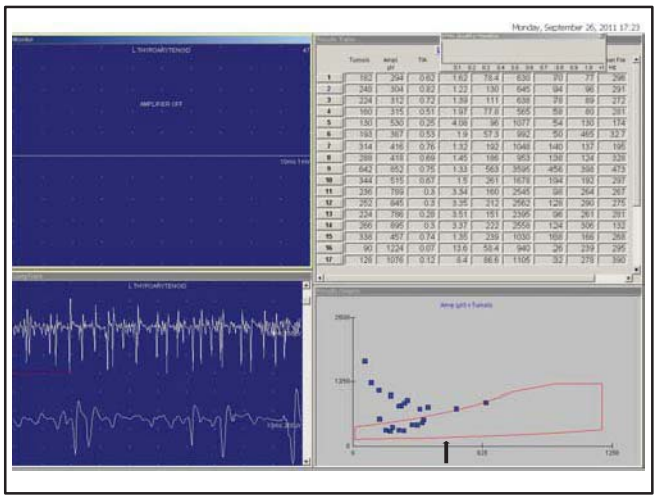

Figure 69.8 LEMG tracing depicting a graphic representation of number of "turns." Note that the majority of measurements fall below 400 (*arrow*), a finding pathognomonic for neurogenic injury.

3. Early surgical intervention:
   a. Temporary: injection augmentation of the vocal fold with temporary "filler" substance
   b. Permanent: ML (with or without AA) or injection augmentation of the vocal fold with durable substance.

Obviously, these treatment strategies can overlap or can be used simultaneously, but a management plan should be developed and followed as soon as all of the important diagnostic information is gathered. Several factors should be considered when determining the best course of action and treatment must be individualized for each patient, as shown in Table 69.3. A *treatment* algorithm is not advocated by the authors, as each patient's expectations and vocal needs are unique.

Classical teaching for the treatment of VFP advocates a watchful waiting period of 9 to 12 months before surgical intervention is considered. This management strategy was

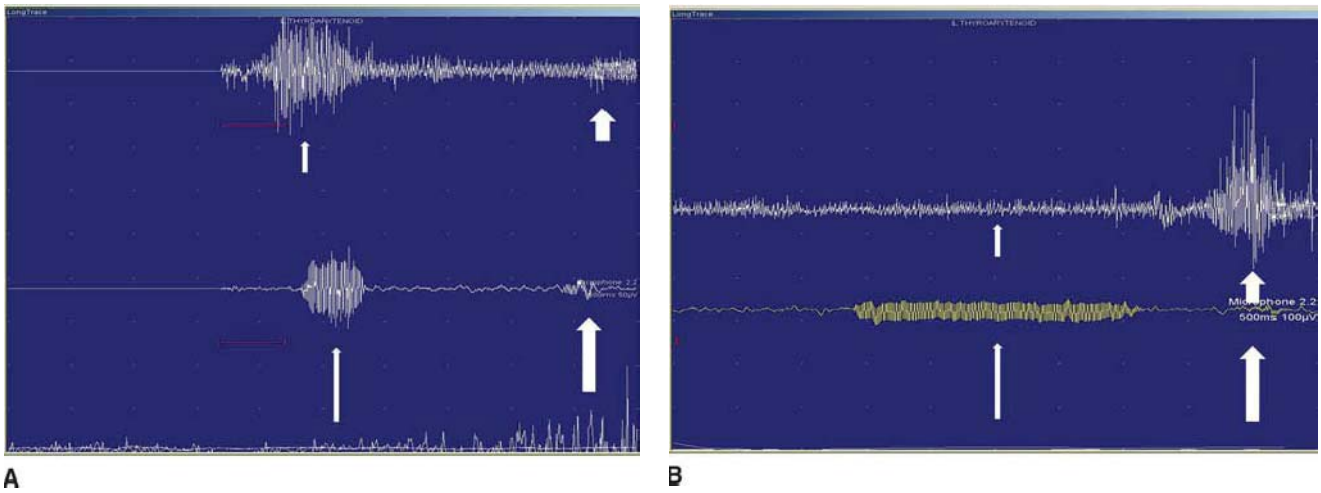

Figure 69.9 LEMG tracing demonstrating normal **(A)** and abnormal **(B)** tests for synkinesis. **A:** Activity is observed (*short narrow arrow*) in the TA/LCA muscle during phonation (*long narrow arrow*) but *not* (*short wide arrow*) during vocal fold abduction as demonstration by sniff (*long wide arrow*). **B:** In this tracing, no activity is observed (*short narrow arrow*) during phonation (*long narrow arrow*), consistent with neuropathic RLN injury. However, synkinesis is present as shown by the presence of electrical activity (*short wide arrow*) during sniff (*long wide arrow*).

TABLE 69.3 PATIENT FACTORS AFFECTING TREATMENT STRATEGY FOR VOCAL FOLD PARALYSIS

Patient Factor	Influence on Treatment (Early Surgical Intervention vs. Observation)
Presence of clinical aspiration	Favors early surgical intervention
Nature of nerve injury (transection, stretch, or unknown)	Nerve cut: favors early treatment[a]
	Nerve intact or stretch injury: favors conservative treatment (observation vs. temporizing injection laryngoplasty)
Vocal demands of patient	Nonvocal professional or limited voice use: favors observation
	Vocal professional—favors early surgical treatment
Medical comorbidity	Minimal comorbidity: all options open
	Significant comorbidity: favors local anesthetic (office-based injections vs. ML in OR)
LEMG findings	Good prognosis: favors observation or temporary injection
	Poor prognosis: favors early ML[a] or permanent injection

[a]In general, it is recommended that 2 to 3 months pass after nerve transection or injury before permanent surgery is performed to allow for muscular atrophy of the vocal fold to occur, to lessen the need for revision surgery months later.
LEMG, laryngeal electromyography; ML, medialization laryngoplasty; OR, operating room.

developed in the 1970s, when the only viable treatment option for VFP was injection augmentation with Teflon. As Teflon injection is irreversible and sometimes associated with an unfavorable vocal outcome, early surgical intervention was ill-advised during this era. Modern laryngoplastic techniques, along with an arsenal of injectable substances, have made early surgical intervention an excellent option in the treatment of VFP. Presently, 6 to 9 months following the onset of UVFP is a reasonable interval before proceeding with permanent treatment.

The decision to proceed with permanent intervention should be made on an individual, case-by-case basis and may be influenced by various considerations. The presence of unfavorable findings on serially performed LEMG (especially when performed in a quantitative manner) reflects a considerably decreased likelihood of spontaneous return of vocal fold motion. In this circumstance, awaiting the conclusion of a full 6- to 9-month observation period may be unnecessary, and it may be practical to proceed with permanent surgical treatment even as early as 4 to 5 months after onset of VFP. The nature of the VFP is also an important issue. A patient who has undergone known resection of the RLN (such as in an oncologic procedure) may be appropriate for earlier permanent intervention, particularly if unfavorable LEMG findings are found. Finally, patient factors (such as symptomatology, geographic distance, and patient preferences, age, vocal demands, and comorbidities) should also be taken into account.

The most appropriate time to pursue surgical intervention may vary considerably on an individual basis. The

authors advocate careful consideration of all pertinent factors when determining the most appropriate time to pursue both early as well as permanent surgical intervention.

Determining the Need for Early Intervention

Early surgical intervention is indicated for patients with clear-cut aspiration caused by VFP. Evidence of severe denervation injury (class V) on LEMG can also lead to early surgical intervention. Clinical experience has shown that RLN paralysis caused by pulmonary carcinoma or iatrogenic thoracic surgery injury (especially repair of aortic aneurysm) rarely recovers, and patients are counseled to consider early permanent intervention in these cases. Patients with VFP and high-level vocal demands (e.g., sales persons, clergy, teachers, attorneys) often have difficulty continuing their work-related duties. In these cases, it may be necessary to intervene early (less than 6 months) to get the patient back on the job. Temporary surgical procedures (e.g., injection augmentation of the vocal fold with temporary materials) should be considered in this population. More recent reports also suggest that early temporary injection medialization may decrease the need for permanent intervention by encouraging the vocal fold to maintain a more medialized position (41,42). Additional clinical study is needed to investigate this concept further.

The medical health of the patient should be considered. Patients with significant cardiopulmonary and other medical comorbidity may not be candidates for a general anesthetic (i.e., for microlaryngoscopy with vocal fold injection augmentation), yet may be perfectly suitable for ML or injection augmentation performed under local anesthesia. In most cases, the patient should be counseled regarding the different treatment options, including the advantages and disadvantages of the three main strategies of treatment. In this way, the patient can actively participate in the decision-making process (40). When LEMG is available, it can serve as a crucial guide to the patient and surgeon regarding (a) treatment or observation and (b) temporary versus permanent treatment (37).

Surgical Treatment

Injection Augmentation

Injection augmentation with temporary materials is an excellent means of temporizing the patient's voice for weeks to months while awaiting return of function. General characteristics of the current materials available for augmentation are listed in Table 69.4. Specific information regarding preparation of the injectables, as well as injection techniques, is contained in the references. The reader is encouraged to consult these references before using the materials for injection augmentation. Additional information is also available in Chapter 73.

Several points are worth highlighting. Gelfoam as an injected material (43) is too short-acting to justify a trip to the OR, and is rarely employed. Bovine collagen injectables (44) (Zyplast, McGhan Pharmaceuticals, Santa Barbara, CA) reliably lasted 4 to 6 months and were a good temporizing substance but were recently discontinued and are no longer available. Cymetra, or micronized AlloDerm (LifeCell Corporation, Branchburg, NJ), does not require skin testing, is immediately available for injection with a moderate degree of preparation, and lasts between 2 and 4 months. The length of effect is somewhat variable and unpredictable. Sodium carboxymethylcellulose (Radiesse Voice Gel, Merz Aesthetics Inc., San Mateo, CA) was introduced in 2005, is United Stated Food and Drug Administration (FDA) approved, lasts between

TABLE 69.4 LARYNGEAL INJECTABLES

Material	Length of Effect	Advantages	Disadvantages
Gelfoam	4–6 wk	Long track record	1. Short duration 2. Must use 18 g
Cymetra (Micronized AlloDerm)	2–4 mo	No allergy testing	1. More prep time 2. Expensive 3. Unpredictable
Fat	2 yr+ (Possibly permanent)	Autologous Forgiving	1. Time/morbidity from harvest 2. Unpredictable
Teflon	Forever	Long lasting	1. Granuloma 2. VF stiffness
Radiesse (calcium hydroxylapatite)	18 mo	1. 24 g needle 2. Long lasting	Risk of VF stiffness with superficial injection
Radiesse Voice Gel (carboxymethylcellulose)	1–3 mo	1. 24 g needle 2. Temporary/trial VFI	
Restylane (hyaluronic acid)	2–4 mo	1. 25 g needle (office) 2. Temporary/trial VFI	Few data

2 and 3 months, and has excellent safety and efficacy rates (45,46).

Calcium hydroxylapatite (Radiesse, Merz Aesthetics Inc., San Mateo, CA) was developed as a longer-lasting alternative for augmentation (47). Initially believed to last up to 2 to 5 years, more recent studies have demonstrated excellent long-term results but with an average duration of only 18 months (48–50). Hyaluronic acid (Restylane, Medicis Aesthetics Inc., Scottsdale, AZ) has potential implications for use both in vocal fold augmentation as well as in treatment of vocal fold scar but requires further study (51,52). The disadvantages of Teflon are well known (53), and most otolaryngologists have abandoned the use of this substance except in rare instances. Autologous fat (54) continues to be a relatively unpredictable substance, with some patients having complete resorption of the fat in 2 months, whereas others show persistence of the fat for years. Fat has been frequently described as a "forgiving" substance, in that less-than-perfect injection placement can still result in good voice results. Lipoinjection requires overinjection by a significant degree (sometimes as much as 100%) to correct for the expected resorption of fat in the first 4 to 6 weeks (55).

The injected material is typically delivered through a Bruening syringe (Storz Medical AG, Kreuzlingen, Switzerland), orotracheal injector (Medtronic Xomed, Jacksonville, FL), or transoral needle (Merz Aesthetics, San Mateo, CA), depending on the substance injected and the needle gauge required. Injections should be placed in the "deep" portion of the vocal fold to avoid disruption of the superficial layer of the lamina propria. The intended injection location is the medial aspect of the TA muscle (vocalis), at the midmembranous and posterior vocal fold (Fig. 69.10). Injection into the ligament has been advocated by some authors, but Courey (56) has shown that the limitations in the size of the needle gauge used make vocal ligament injection virtually impossible. Care should be taken not to inject superficially into Reinke space, because this can result in permanent loss of vibratory function.

Injection laryngoplasty can be performed under local anesthetic in clinic with flexible or rigid telescopic guidance, using either transcutaneous or peroral approach (Fig. 69.11A, B, and C). The advantages of this approach to injections include patient convenience and improved voice feedback in gauging the amount of injection needed. Alternatively, injection laryngoplasty via direct laryngoscopy can be performed under general anesthetic, with either telescopic or microscopic guidance. The advantages of the latter are improved precision and patient comfort (especially for patients with an active gag reflex). Disadvantages include lack of vocal feedback to gauge the injection. Ultimately, the technique used and material selected for injection laryngoplasty depends on the surgeon's experience and comfort level (57).

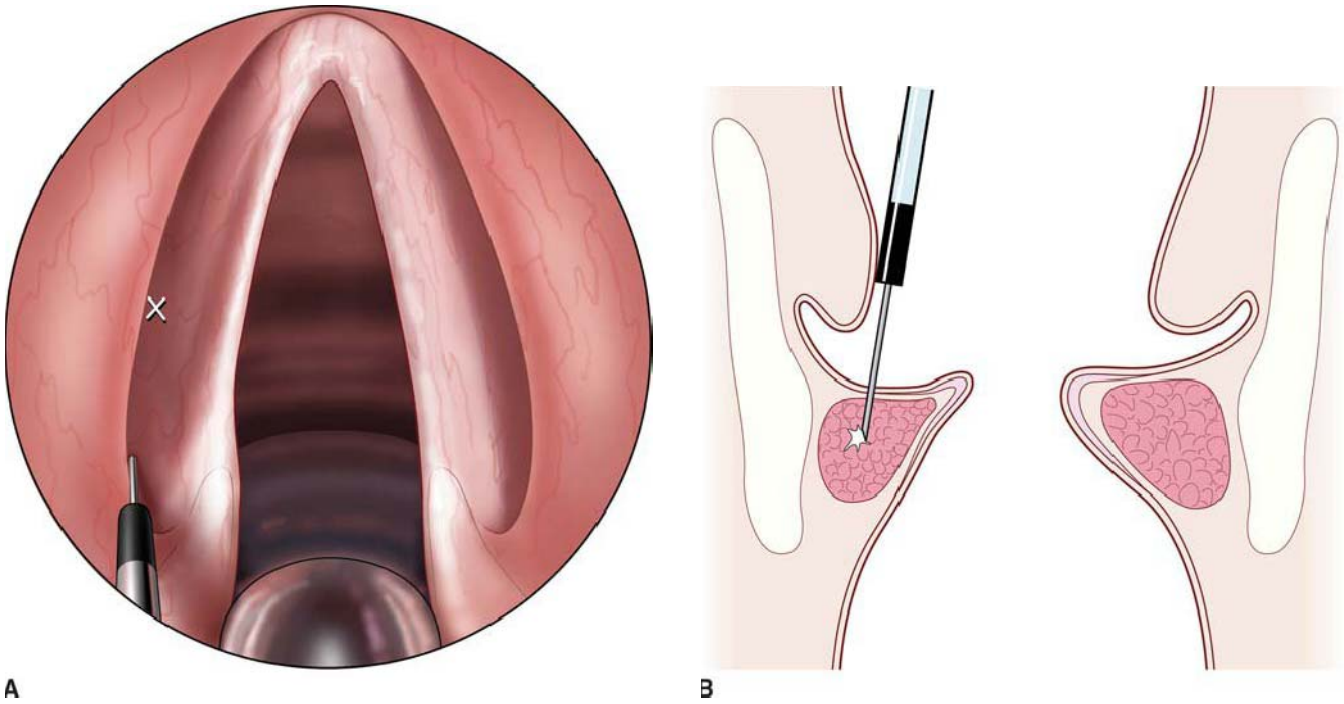

Figure 69.10 **A:** Illustration of an injection augmentation of the left vocal fold under direct laryngoscopy. "*X*" marks the injection site seen on direct visualization, at the posterior aspect of the vocal fold, lateral to the vocal process. **B:** The depth of injection into the TA muscle is depicted on coronal section. The needle tip should be deep into the vocal fold, and not superficially in Reinke space. Framework Surgery for UVFP: Medialization Laryngoplasty (ML) and Arytenoid Adduction (AA)

Laryngeal framework surgery including ML (specifically type I Isshiki thyroplasty) and AA are currently considered standard treatment for long-term treatment of unilateral VFP. Isshiki perfected the technique of thyroplasty in the early 1970s, but it was Koufman who popularized the technique in the United States and advocated the use of hand-carved silicone elastomer (Silastic) implants instead of cartilage.

The technique of ML represented a considerable departure from the traditional management of VFP. The operation is reversible (unlike Teflon injection laryngoplasty, the primary treatment for VFP in the 1970s and early 1980s), and fine-tuning of the voice result can be achieved, because the procedure is performed under local anesthesia. Multiple medialization materials have been developed and currently include Gore-Tex strips (Gore Medical, Inc., Newark, DE), the preformed silicone Montgomery system (Boston Medical Products, Inc., Westborough, MA), silastic Netterville PhonoForm block (Medtronic ENT, Inc., Jacksonville, FL), hydroxyapatite VoCoM systems (Gyrus ACMI, Inc., Bartlett, TN), and titanium Kurz implant (Heinz Kurz, Dusslingen, Germany). A recent preliminary study also evaluated an adjustable silicone balloon implant in excised canine larynges (58).

The optimal choice of medialization implant material has long been debated. However, there are few studies that directly compare medialization implants (59–61). All of these studies are limited by early postoperative assessments without long-term follow-up and do not clearly identify a superior long-term option. Future prospective studies with extended follow-up are needed to determine what differences, if any, exist in the long-term results following implantation of these various materials.

No one implant material is superior to another in performing ML. It is mostly a matter of surgeon preference. In past years, use of a custom-carved Silastic block as described by Netterville et al. (62,63) was a preferred technique by many surgeons. Proponents of this technique praised its precise medialization and superior voice results. With the introduction of other, less time-intensive materials, the use of custom-carved Silastic block has significantly decreased. Currently, the choice of implant material is mostly based on surgeon preference but appears to more often involve the use of Gore-Tex strips or prefabricated implants (64). The reader is encouraged to review appropriate references for more detailed descriptions of ML (62,63,65,66).

Most patients having ML have good to excellent voicing intraoperatively, but develop varying degrees of postoperative dysphonia as a result of paraglottic edema or submucosal hemorrhage. Within hours, a good postoperative voice will become rough and breathy. The patient should be warned of this before the surgery. In the past, all patients were kept for 23-hour observation, because of concern for airway edema. However, ML is increasingly performed as a same-day surgery, although additional caution is advised in cases of bilateral ML. In a survey of 860 otolaryngologists performing nearly 24,000 ML procedures, the rate of airway-related complications were low, including prolonged observation (greater than 24 hours) in 2%, intubation in 0.1%, and tracheostomy in 0.07% of cases (64). To decrease the risk of airway compromise secondary to edema, preoperative intravenous dexamethasone is given (10 mg), followed by two additional (8 mg) doses at 8 and 16 hours postoperatively. The period of postoperative dysphonia is variable, but can last between 2 and 6 weeks (62). Rare cases can persist up to 3 months. Voice conservation is advocated; total voice rest is unnecessary.

Both Silastic and Gore-Tex implants are reversible (67,68), if revision surgery is necessary at a later date. A thin, fibrous capsule forms around the implant, and this must be incised and released at the medial aspect to allow for medialization without tethering. Neither Gore-Tex nor Silastic implants are overly problematic in revision surgery, as long as a single strip of Gore-Tex is used (as opposed to multiple small strips), and the implant is not inadvertently placed too deep (in the substance of the TA muscle), which seems to lead to excessive fibrosis and tethering of the implant.

Patients who have had successful ML, with or without AA, often express concerns about the safety of having endotracheal intubation for surgical procedures in the future. A waiting period of 6 months post-ML (if the proposed surgery is elective) is advised. The anesthesiologist should place a 6.0 endotracheal tube (or smaller) to avoid inducing laryngeal edema from a slightly constricted glottic aperture. The risk of perioperative airway complications in this population remains low (less than 7%) but is not negligible. All health care personnel (surgeon, anesthesia, and nursing) involved in the perioperative care of these patients should be aware of this particular risk (69).

ML is an operation designed to augment or medialize the vocal fold in three dimensions: anterior-posterior, medial-lateral, and superior-inferior. During ML, the surgeon should be aware of these three dimensions and have the ability to control the implant shape in each of these dimensions. ML is an operation that has a simple premise (implant placement for vocal fold medialization) but nuances are present, which can significantly impact the success of the surgery. In general, the surgeon must avoid

placement of the implant too anterior (strained voice quality) or too superior. These are the most common mistakes made in ML surgery (70). Other revisions typically include placement of a larger implant (which may be required due to perioperative vocal fold edema obscuring accurate visualization at the time of the primary surgery) although replacement with a smaller implant or repositioning of the current implant are sometimes needed (64). Experience with ML surgery (greater than 10 and a frequency of 2 or more per year) has been shown to decrease the likelihood of postoperative complications (including lack of voice improvement) (70). Nevertheless, ML has a high success rate, with revision rates around 5% to 6% (64,70).

AA is an important adjunct in selected cases of VFP. This operation involves placement of a suture from the muscular process of the arytenoid to an anterior location on the thyroid cartilage. This simulates the action of LCA contraction. The physiologic effects of AA are not completely understood, and some debate continues. General consensus exists concerning the following basic premises (71):

Arytenoid adduction:

- Lowers the position of the vocal process
- Medializes and stabilizes the vocal process
- Rotates the arytenoid cartilage.

In patients with VFP who have a lack of vocal process contact during phonation (large posterior gap) and those with vocal folds at different levels, AA should be considered in addition to ML. Videostroboscopy often provides valuable information about vocal process contact and vocal fold height and, therefore, is useful preoperatively in assessing whether a patient needs an AA. MPT of less than 5 seconds has also been identified as a predictor of the need for AA in cases of VFP (24). The technique of AA was originally described by Isshiki, and excellent illustrations of the technique have been published by Netterville et al. (72).

Laryngeal Reinnervation

Various procedures attempting to reinnervate the larynx have been proposed. These include direct end-to-end anastomosis of the RLN, hypoglossal-to-RLN anastamosis, ansa cervicalis-to-RLN anastamosis, neuromuscular pedicle, free nerve grafting, and nerve implantation procedures. Much controversy has surrounded the utility of these procedures. In most reports, the main postoperative benefit seen was improved vocalis muscle tone, rather than purposeful vocal fold motion. More recent reports have also described LEMG findings of increased recruitment suggestive of reinnervation (73–76). In a recent multicenter randomized trial, Paniello et al. (77) directly compared ML and laryngeal reinnervation and found no difference between these procedures.

Other Therapies

Preliminary studies in a small number of animal and human subjects have shown early promise in the use of nimodipine in the treatment of acute VFP. Nimodipine may facilitate growth of the regenerating nerve via an effect on its calcium channels (78–82). Clinical trials are needed to investigate this modality further.

BILATERAL VOCAL FOLD PARALYSIS

Bilateral vocal fold immobility (BVFI) can be caused by either BVFP or posterior glottic stenosis (PGS) with or without CA joint fixation. It is important to distinguish clinically between these two entities to successfully manage BVFI.

Etiology

The etiology of BVFP is listed in Table 69.5. In most cases, BVFP is caused by iatrogenic surgical injury (55.5% to 82.8%), and most of these cases occur during thyroid surgery (3,4,83). Malignancy (esophageal or bronchogenic), neurologic, traumatic, and idiopathic causes account for the remainder of cases. In contrast to the data listed for BVFP, BVFI does not have one dominant cause (2) (*see Table 69.5*), probably because this group of patients represents a more heterogeneous population of both paralysis *and* stenosis cases.

It is clear that most patients with BVFP present a simple diagnostic picture that points to iatrogenic surgical injury involving both RLN; in these cases, little diagnostic workup

TABLE 69.5 ETIOLOGY OF BVFP AND BILATERAL VOCAL FOLD IMMOBILITY (BVFI)

Etiology	Percentage
BVFP[a]	
Iatrogenic (surgical trauma)	55.5
Thyroid surgery	48.6

[b]Adapted from Benninger MS, Gillen JB, Altman JS. Changing etiology of vocal fold immobility. *Laryngoscope* 1998;108:1346–1349, with permission.

is necessary. In some uncommon circumstances, the finding of BVFP may represent an acute unilateral VFP in the presence of a previously undiagnosed preexisting paralysis of the contralateral vocal fold, such as may occur in completion thyroidectomy procedures. These so-called "staged" BVFP can be identified by electromyographic findings and may be preventable with appropriate preoperative evaluation, including laryngoscopy. The noniatrogenic presentations of BVFP, however, often require an extensive and detailed workup to reveal the cause. So-called "idiopathic" causes of BVFP are rare, in contrast to UVFP. In addition, a substantial number of rare neurologic conditions can present with BVFP, and an extensive differential diagnostic list (Table 69.6) should be used as a guide in the workup of "unexplained" BVFP (84,85). Often, a neurology consult is needed to sort out complex presentations of BVFP.

TABLE 69.6 NONSURGICAL CAUSES OF BILATERAL VOCAL FOLD PARALYSIS

I. Neurologic

Clinical Presentation and Evaluation

The clinical presentation of BVFP is considerably different from that observed in patients who present with UVFP. The chief presenting complaint in BVFP is typically shortness of breath or stridor, often accompanied with a normal voice. The vocal folds typically drift to the midline soon after neural injury (although this can be delayed for days or weeks in some cases). This leads to a narrow 1- to 3-mm slit-like glottic inlet, which results in airway compromise (Fig. 69.12). The degree of airway compromise, which is highly variable, can range from mild stridor associated only with exertion to life-threatening airway obstruction. Voice quality can be relatively good because of the close proximity of the immobile vocal folds. It is not uncommon, however, for patients to demonstrate a monotone voice and a speech pattern characterized by short, hurried phrases followed by stridorous, inspiratory interruptions.

Clinical History

The most important part of the history when evaluating a patient with BVFP is the surgical history. Specifically, one must inquire whether the patient had any neck, chest, or neurosurgical procedures before the onset of the current condition. In general, most patients with BVFI have a straightforward history that suggests an iatrogenic cause, because the onset of breathing difficulty is temporally related to a surgical procedure that puts both RLN at risk. This is seen most commonly with thyroidectomy. In most cases, the patient develops stridor immediately on extubation or several hours after the procedure, and a prompt evaluation by an otolaryngologist reveals the typical findings of BVFI. It is important for the otolaryngologist to specifically inquire about the integrity of the nerves directly with the surgeon (if acting as a consultant): specifically, whether the nerves were identified and preserved, never identified, or a known nerve transection occurred. This information is not often very revealing, but may help determine the immediate course of action in some cases.

In cases where no clear-cut and immediate surgically induced (neck or chest) RLN trauma exists, three primary

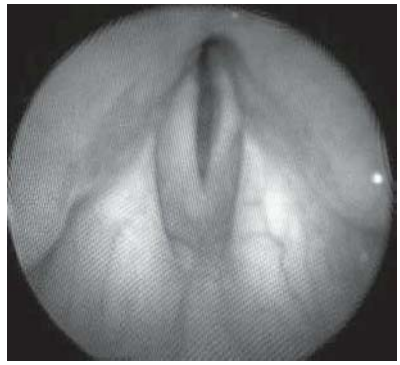

Figure 69.12 Fiberoptic laryngoscopy of the larynx in a patient with BVFP. Both vocal folds are immobile and located near the midline, resulting in airway obstruction.

questions help to sort out the direction of subsequent workup (85):

1. History of rheumatoid arthritis
2. History of blunt or penetrating neck trauma
3. Endotracheal intubation in non-neck or -chest cases, especially if a history of prolonged ventilatory dependence exists

If any of the above questions are positive, a high likelihood exists that CA fixation or PGS is the cause of the bilateral immobility, not paralysis. This necessitates a different diagnostic algorithm than that used for bilateral paralysis. On the other hand, if the answer to all three questions above is negative, then BVFP is almost certainly present, and represents a manifestation of a progressive neurologic, congenital, endocrine, metabolic, toxic, neoplastic, or inflammatory condition. These conditions are listed in Table 69.6. As can be observed, this is an extensive and exhaustive list of causes that make up a small fraction of an already rare condition, BVFP.

Because of the rarity of noniatrogenic BVFP, it is best to keep a differential diagnostic list handy for review when this scenario presents itself. Frequently, the admitting or treating physicians in these difficult cases (internal medicine, neurology) are *not* aware that BVFP can be a manifestation of the conditions listed in Table 69.6. For this reason, the otolaryngology consultant can provide valuable information to the team both by identifying the presence of BVFP and by providing a differential diagnostic list to the consulting physicians.

Physical Examination

The physical examination should consist of a complete head and neck examination (84) as well as neurologic assessment and cranial nerve examination. The most important part of the physical examination in patients presenting with BVFI, however, is a systematic and detailed flexible laryngoscopic examination.

Workup

Serology

No justification is seen for ordering routine screening laboratory serum tests in the workup of unexplained BVFI. A directed battery of tests can be used at the discretion of the medical or neurology team, based on suspected causes. In the rare case of pediatric congenital BVFP associated with other congenital abnormalities, chromosomal analysis should be performed along with evaluation by a geneticist (86).

Imaging

In unexplained cases of adult BVFI, imaging studies (generally MRI) can be ordered to evaluate for base of skull, brainstem, neck, or mediastinal pathology. In the pediatric population with BVFI, MRI is particularly valuable because 40% of cases are neurologic in origin. The common causes of BVFI in children are related to hydrocephalus and Arnold-Chiari malformation (87).

Neurology and Internal Medicine Workup

As stated, noniatrogenic cases of BVFP are rare, but an otherwise unexplained finding of BVFP in a patient should raise suspicions that an underlying global disease process is present. A thorough workup by the patient's medical team (with neurology consultation) is imperative in these rare cases.

Laryngeal Electromyography

LEMG is an important component of the evaluation for BVFI. Hillel et al. (84) advocate testing of not only both TA and CT muscles, but of the PCA muscles bilaterally as well. Evidence of PCA activity during phonation of "eee" is considered abnormal synkinetic activity. In contrast, TA activity can occur during a sniff, but it should not represent the predominant activity of the TA (i.e., more motor units should be recruited in the TA during phonation).

The utility of LEMG is as follows:

1. LEMG can differentiate between VFP, synkinetic laryngeal muscular activity, and vocal fold CA joint fixation
2. LEMG can be useful in determining the prognosis for recovery of vocal fold mobility, which can assist in treatment planning
3. LEMG can determine if the cause is peripheral or central in origin, because myopathic processes demonstrate unique EMG findings
4. LEMG can determine which vocal fold has the most robust neuromotor status. This assists in determining which vocal fold should be selected for any destructive, glottic enlargement procedure (see below).

Because of the tentative airway status in patients with BVFP, caution should be taken if LEMG is to be performed in these patients in the clinic setting.

Laryngoscopy and Palpation for Vocal Fold Mobility

Despite the expanding role of LEMG in the evaluation of BVFI, laryngoscopy with examination under anesthesia (either general or local) still provides clinically useful information. This examination should include inspection of the IA space for scarring, along with palpation of the vocal folds for passive mobility. It is important to note that IA scarring, CA joint fixation, and VFP can all coexist in the same patient. An abnormal LEMG suggests paralysis as the cause of vocal fold immobility, but it *does not* rule out PGS and/or CA joint fixation as a contributing factor. The only reliable method to evaluate for PGS and/or joint fixation is to examine the posterior commissure, and test for passive vocal fold mobility (88).

When performed in the OR, the evaluation should be carried out *without* an endotracheal tube in place and *without* the laryngoscope suspended to obtain an unobscured view of the glottis; jet ventilation can be used for patients who do not have a tracheostomy in place. In patients with PGS, the posterior glottic space is obliterated by scar tissue, giving the residual glottic airway a triangular shape (Fig. 69.13). In contrast, patients with BVFP (no stenosis) have an airway that resembles an ice cream cone, with the

Figure 69.13 Larygoscopic view of the larynx in a patient with PGS. Note the triangular appearance of the glottic aperture caused by the loss of the posterior (respiratory) glottic region.

preservation of the posterior glottic space representing the scoop of ice cream (Fig. 69.14).

Palpation of the CA joint is performed by using a sturdy instrument (e.g., a large cup forceps in the OR or an Abrams cannula in the office), placing it adjacent to the vocal process and swiftly pushing the vocal process laterally. With this maneuver, the surgeon can gauge the degree of effort required to laterally displace the vocal process as well as the speed of the recoil of the tissue in a medial direction. This same procedure should be done on the contralateral side and used to compare the degree of stiffness and range of motion of the CA joint. During this maneuver, the posterior glottis and contralateral vocal fold should be observed. In patients with PGS or IA scarring, the posterior commissure and contralateral arytenoid cartilage will be moved to the midline during the vocal process palpation because of the entire posterior glottic complex being fused with scar tissue.

Figure 69.14 Laryngoscopic view of a normal larynx. The airway has roughly the shape of an ice cream cone.

Management

Initial Management of the Airway

The management strategy for BVFP varies, depending on a variety of factors described in the treatment planning for UVFP (Table 69.3), with one key difference. The main determinant for intervention is the status of the patient's airway. A patient with BVFP who rapidly develops progressive stridor and air hunger needs immediate intervention. Generally, endotracheal intubation is preferred as the initial management. It is important to note that intubation is used to secure the airway in cases of BVFP, but *not* when PGS is present. Intubation gives the medical team valuable time to gather more data on the patient, so that an informed decision can be made regarding short- or long-term airway management strategies. Although a temptation to secure the airway with a tracheostomy exists, some cases of bilateral RLN neuropraxic injury can be managed expectantly with intubation and sedation in an Intensive Care Unit setting, IV corticosteroids, and controlled extubation in the OR several days later. This is a particularly appealing strategy when the patient has a fresh neck wound after thyroidectomy. In general, if symptomatic BVFP is still present 5 to 10 days after iatrogenic injury, securing the airway with a tracheostomy or possibly a temporizing measure (listed below) is a reasonable plan of action. LEMG can be useful to plan early treatment versus observation (in anticipation that recovery of mobility in one or both vocal folds may occur).

Temporizing (Reversible) Treatments

Tracheostomy

Tracheostomy is an excellent treatment to secure the airway until adequate time passes for spontaneous recovery to occur (6 to 12 months). In general, it is not a good long-term strategy, because most patients are unhappy with permanent tracheostomy. This is especially true in light of the many endoscopic treatments that can preserve reasonable voice quality and allow for decannulation.

Endo-Extralaryngeal Suture Lateralization

Endo-extralaryngeal suture lateralization, as popularized by Lichtenberger and Toohill (88), is a viable option for temporizing the patient's airway in select cases of BVFP. The technique uses a nonabsorbable suture placed endoscopically above and below the posterior vocal fold at the region of the vocal process. The suture can be brought out over the thyroid ala, or through the skin of the neck and secured over a button externally. Suture tension can be adjusted intraoperatively and postoperatively to fine tune the degree of vocal fold lateralization or airway aperture.

Laryngeal Botox Injection

In carefully selected cases of BVFP, where airway obstruction is not imminent and airway symptoms are principally exertional, laryngeal Botox injection into the TA–LCA muscular complex may result in minor airway improvement (89) that lasts 2 to 4 months. The symptomatic

improvement is thought to result from blocking of synkinetic TA activity during inspiration. Side effects are breathy dysphonia, aspiration of liquids, or both, which are temporary in nature. A suggested dose to achieve symptomatic improvement is 2.5 mouse units in each vocal fold (90).

Long-Term Surgical Solutions

An important concept must be brought to the attention of the patient during preoperative counseling: almost all procedures designed to treat BVFP, except tracheostomy, result in some degree of dysphonia. In general, surgical interventions cannot simultaneously result in improvement in airway without some degree of loss of vocal function; one is generally improved at the expense of the other. The vocal folds can be approximated more closely to improve the voice, but the airway narrows. Similarly, the vocal folds can be separated to open the airway, but the voice suffers. This concept must be explained to the patient, so that realistic expectations can be established preoperatively. Any discussion of surgical treatment of BVFP that does not involve the "airway for voice" equation is flawed.

Transverse Cordotomy

Endoscopic CO_2 laser transverse cordotomy (TC) is an excellent surgical option. Originally described by Kashima (91) in 1991, this technique is technically less demanding than an endoscopic laser arytenoidectomy, and appears to result in comparable airway enlargement. Vocal quality in patients who have undergone TC does worsen, becoming slightly more breathy and rough, but most patients maintain a reasonably good conversational voice (92). The procedure consists of microlaryngoscopy with a CO_2 laser TC anterior to the vocal process. The cordotomy must be extended far laterally, including division of the medial aspect of the false vocal fold. The goal is to detach as much of the TA muscle from the arytenoid cartilage as possible (Fig. 69.15). The TA muscle retracts anteriorly, and heals over several weeks, leaving a rounded tear-shaped opening anterior to the arytenoid (Fig. 69.16). Although the increase in airway diameter is only a few millimeters at best, this results in significant improvement in the patient's airway. The procedure can be repeated ipsilaterally or contralaterally if further airway opening is indicated. A tracheostomy is not often necessary perioperatively (91). Although TC has been used principally in adults, Friedman et al. (93) have reported success with a variant of TC (an additional wedge of tissue is removed) in a small number of pediatric patients.

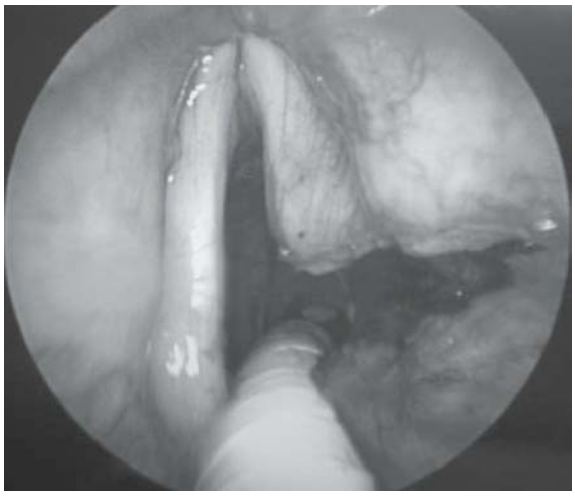

Figure 69.15 Intraoperative photo of the larynx following a right CO_2 laser posterior cordotomy. Note the cordotomy extends far laterally into the musculature of the false vocal fold.

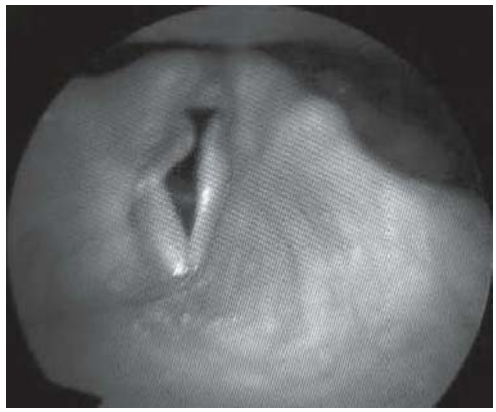

Figure 69.16 Fiberoptic laryngoscopy of patient 3 months after cordotomy for BVFP. Note the widened glottic aperture as the healed right vocal fold is in a lateralized position.

Endoscopic Laser Arytenoidectomy

Endoscopic Total Laser Arytenoidectomy. Endoscopic laser arytenoidectomy, which was introduced in 1984 by Ossoff et al. (94,95), led to a fundamental shift in the treatment paradigm of BVFP. The endoscopic arytenoidectomy shifted the treatment of BVFP from an external framework approach (Woodman procedure) to an endoscopic, laser-assisted procedure. The CO_2 laser technique provided better hemostasis than previous cold techniques, and was the catalyst that led to a resurgence of endoscopic surgical approaches for glottic stenosis and BVFP. The entire arytenoid cartilage is ablated (Fig. 69.17), and a small wedge is removed from the posterior vocal fold, along with a small cut just lateral to the wedge "to facilitate lateralization of the vocal cord during healing." The long-term success rate of this technique is 86%, and vocal quality was judged subjectively as "good." Although this technique was a mainstay in the treatment of BVFP for a decade, it has largely been replaced by the TC, or partial arytenoidectomy, since the mid-1990s.

Endoscopic Laser Partial Arytenoidectomy. The endoscopic laser partial arytenoidectomy is a variant of the technique of total endoscopic laser arytenoidectomy that preserves a portion of the arytenoid. Theoretically, this reduces the risk of aspiration, while achieving comparable voice and airway results. Originally described by Crumley (96), the "medial arytenoidectomy" preserves the lateral aspect of the arytenoid. Another modification by Remacle et al. (97) involves preserving the posterior body of the arytenoid. The results of this technique are comparable to TC in terms

Figure 69.17 Intraoperative photograph of a left CO_2 laser total arytenoidectomy.

of improvement of dyspnea without significant voice or swallowing difficulties and low complication rates (98).

Laryngeal Pacing

Perhaps the most promising treatment for BVFP is laryngeal pacing. This process involves a programmable pulse generator that is implanted beneath the skin and delivers electrical stimulation to the PCA muscle during inspiration once triggered by an electrode on the diaphragm. This resultant larger glottal airway opening allows improved ventilation without significant decrement in voice (99). Laryngeal pacing may ultimately prove to be the optimal solution for a difficult clinical problem that has frustrated otolaryngologists for decades. An initial small multi-institutional trial demonstrated that five out of six patients receiving an implantable stimulation device experienced reestablishment of normal oral airflow, allowing three of these patients to be decannulated (100). Recent small prospective canine studies report long-term complete rehabilitation of ventilation and exercise tolerance without aspiration (101,102). Technical limitations of the pacing hardware currently prevent this technique from being utilized as part of routine clinical care.

Arytenoid Abduction

In 2007, Woodson and Weiss (103) introduced the use of an arytenoid abduction suture procedure to reposition the vocal process to enlarge the glottal airway while allowing continued vocal fold adduction during phonation. In their initial study of six patients with BVFP, all patients demonstrated airway improvement, including three patients who were able to avoid tracheotomy and two of three patients with preexisting tracheotomies who were able to be decannulated (103). In her follow-up report, Woodson described continued success with this procedure in 7 of 11 additional patients and identified risk factors for poor outcome following this procedure including prolonged tracheotomy and "electromyographic evidence of inspiratory activity of adductor muscles." No patients developed aspiration or dysphagia (104).

Flap-Type Tracheostomy

It should be noted that all of the "static" laser treatments for BVFP (TC, arytenoidectomy) result in suboptimal airway caliber and worsened voice when compared with tracheostomy. It is important to remind patients that no surgery (with the possible exception of laryngeal pacing) can provide the caliber of airway and preserve the quality of voice as well as a tracheostomy. Patients should be given the option of tracheostomy when discussing the treatment options for BVFP. Clearly, most patients who seek an otolaryngology consult to discuss treatment for their BVFP consider a tracheostomy an unacceptable option. They simply need to be aware that endoscopic treatments for their condition represent a compromise in voice and airway in order to achieve successful decannulation. In those patients who are medically infirm or have significant pulmonary comorbidity (e.g., chronic obstructive pulmonary disease, obstructive sleep apnea), tracheostomy is usually the most appropriate treatment. A modified flap-type tracheostomy, as described by Miller et al.(105), with an indwelling Hood stoma stent is the ideal way to optimize patient acceptance of long-term tracheostomy in these cases.

SUMMARY

The evaluation and management of UVFP and BVFP have evolved considerably over the past decade. LEMG is an integral part of the workup in VFP, as its role in diagnosis and prognosis for recovery provides valuable insight. The surgical armamentarium for the treatment of UVFP continues to expand, with the introduction of multiple injectable substances for augmentation over the past decade. These innovations, coupled with the resurgence and refinement in office-based injection augmentation of the vocal folds, have shifted the treatment of UVFP from a "watch and wait" stance to that of early intervention. In addition, framework surgery (e.g., ML and AA) has emerged as the "gold standard" for long-term management of poorly compensated UVFP.

In the case of BVFP, TC and partial arytenoidectomy appear to be the most effective static procedures for improving airway with minimal negative impact on voice quality. Other novel treatment techniques continue to be investigated currently.

HIGHLIGHTS

- VFP most commonly occurs from an abnormality of the peripheral nervous system providing innervation to the larynx, specifically the vagus or RLN.
- UVFP and BVFP often have a shared etiology (e.g., surgical, malignancy, idiopathic). However, their

symptoms vary significantly with UVFP presenting with primary symptoms of voice and swallowing dysfunction, and BVFP presenting with symptoms related to airway restriction.

- VFP evaluation requires an exclusion of a malignancy as a causative factor. This evaluation process often requires imaging of the brain and the entire course of the vagus and RLNs.
- LEMG can provide important diagnostic and prognostic information regarding VFP with shortening the time period before proceeding with permanent treatment.
- Treatment options for UVFP include voice therapy, vocal fold injection (temporary or permanent), and laryngeal framework surgery (ML or arytenoid cartilage adduction).
- Evaluation of patients with BVFI requires a differentiation between the clinical entities of BVFP and PGS.
- Surgical enlargement of the glottic airway in cases of BVFP typically involves a trade-off of decreased voice quality for improved airway.

70 Neurologic Disorders of the Larynx

John P. Ney *Tanya K. Meyer*

The laryngopharynx coordinates the four basic physiologic functions of the upper aerodigestive tract: airway protection, breathing, swallowing, and phonation. Accurate execution of these tasks depends on proper movement and valving function of the larynx, proper contractile function of the pharynx, and intact sensation of these structures. Neurologic disorders of the laryngopharynx are largely disorders of function (and therefore movement) rather than anatomy and may result from a focal disease process or present as a local manifestation of a systemic disorder. Many diseases produce a stereotypical pattern of abnormal function in the context of historical clues that should be recognized (1).

It is important to understand as an otolaryngologist which disorders are related to end organ dysfunction and which may be due to central dysfunction. It is not unusual for a patient who cannot create normal speech due to a cortical stroke (such as apraxia or dysarthria) to be referred for "hoarseness." Such an individual may have nothing wrong with his or her larynx or with vocal fold motion or structure but is unable to produce speech output due to cortical disease.

Phonation, articulation, speech, and language are interrelated tasks that require progressively higher orders of brain function (Fig. 70.1). Phonation, defined as the production of sound by the vocal apparatus (usually but not exclusively the vocal folds), is driven by airflow from the lungs. The resultant sound is modified and amplified through resonation within the sinonaso-, oro-, and hypopharyngeal spaces. Articulation further modulates this sound with the palate, tongue, lips, and teeth to produce specific phonemes. Speech requires pronunciation of words from a collection of phonemes, and language involves meaningful groupings of words into phrases to communicate ideas. The mechanics of phonation and articulation are principally influenced by structural defects (such as surgical defects in the tongue or palate), lower motor neuron disorders (vocal fold paralysis), and brainstem function, whereas language requires control by the cerebral cortex.

NEUROANATOMY AND THE LARYNX

Understanding the implications of neurologic disease of the larynx begins with a working familiarity of the neuroanatomical structures critical to laryngeal function (Fig. 70.2).

Primary motor control of the larynx and receipt of sensory information is accomplished through descending and ascending pathways in the central and peripheral nervous system. The cerebral cortex, divided by Brodmann into a number of areas based on location and function, is the origin of motor commands. The preparatory stages of phonation involve the selection of phonemes in the superior posterior temporal and inferior parietal lobes. Grammatical speech is formulated in Broca's area (Brodmann areas 44, 45) at the inferior frontal gyrus along the sylvian fissure. This information is communicated to the supplementary motor area in the frontal cortex (Brodmann area 6), which receives inputs from the thalamus (and indirectly from the cerebellum and basal ganglia) for motor modulation, and then to the pyramidal (corticobulbar) neurons in the primary motor cortex (Brodmann area 4). These are the upper motor neurons (UMN) involved in laryngeal control. The processes of these cortical neurons descend through the subcortical white matter to the medial aspect of the anterior midbrain in an area called the cerebral peduncles. These corticobulbar fibers continue their caudal path through the anterior pons where they interact with fibers that originate in the cerebellum, and then a portion cross the midline (decussate), synapsing on the neurons in bilateral nucleus ambiguus of the posterolateral caudal medulla. It is important to repeat that the corticobulbar

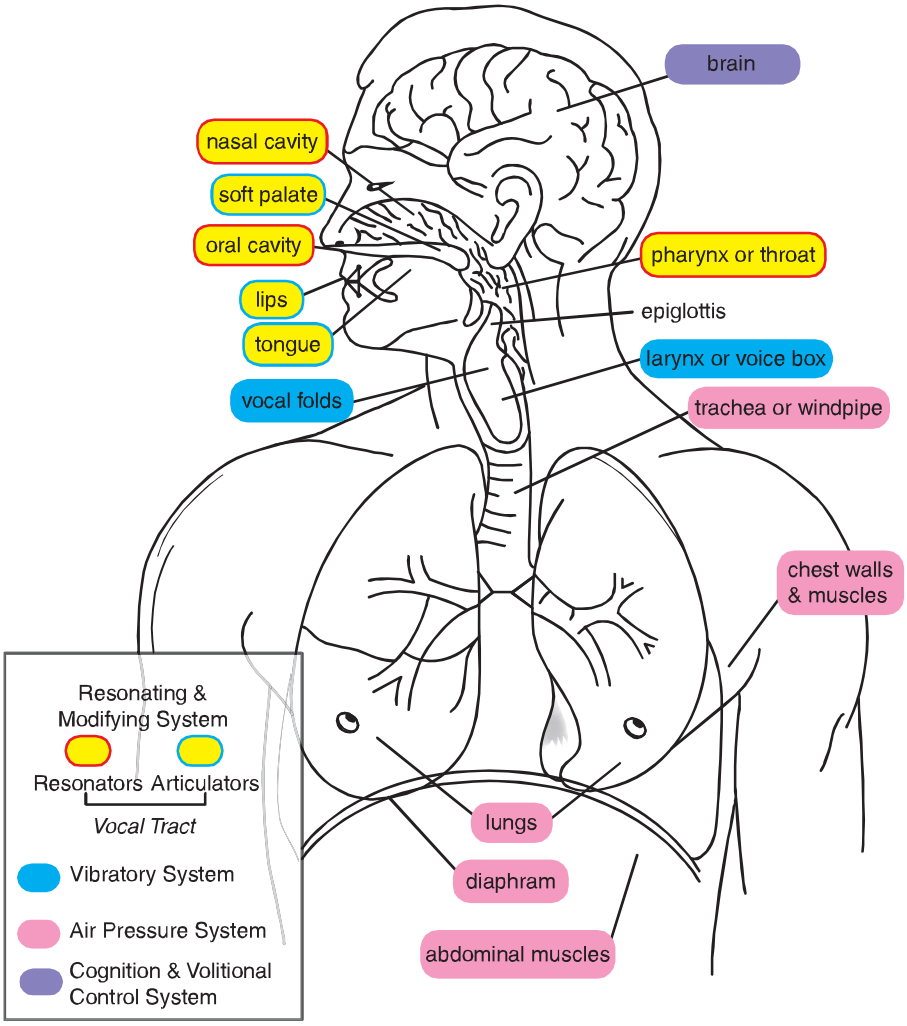

Figure 70.1 The human vocal process. Human vocal communication—effortless for a healthy adult—is the end result of a complex cognitive process leading to a highly coordinated series of motor actions of the thorax, larynx, pharynx, and mouth. The first step is volitional planning of a given vocalization in the cerebrum. The lungs, chest wall, and diaphragm then provide airflow to the vocal apparatus (usually the larynx) that provides a vibration source or a sound source. The resultant sounds are then shaped and modified by the resonating cavities of the upper airway (oral, nasal, and pharyngeal cavities) and by the articulators (palate, lips, teeth, tongue). Disease at any level can lead to a communication deficit. A stroke affects motor planning in the cerebrum, asthma or pulmonary disease can affect the air pressure system, lesions on the vocal cords will affect vibration, and disease of the upper airway or oral cavity can affect articulation or resonation (think of an individual after glossectomy, or an individual with a cleft palate, which changes vocal resonance).

fibers from one side of the cortex synapse on the neurons of both (bilateral) nucleus ambiguus in the brainstem.

Cell bodies in the nucleus ambiguus are the lower motor neurons and axons (referred to by neuroanatomists as special visceral efferents) for motor control of the larynx through the vagus nerve (cranial nerve X). The vagus exits the anterior brainstem just lateral of midline above the foramen magnum, traversing cerebrospinal fluid, and exiting the skull via the jugular foramen. The vagus travels in the carotid sheath with the carotid artery and jugular vein and gives off the superior laryngeal nerve and the recurrent laryngeal nerves. The superior laryngeal nerve branches medially off the vagus, splitting into the (sensory) internal superior laryngeal nerve, which pierces the thyrohyoid membrane, and the (motor) external superior laryngeal nerve, which descends to innervate the cricothyroideus muscle. The recurrent laryngeal nerve (RLN) branches from the vagus to loop around the arch of the aorta on the left, and around the subclavian artery on the right. The recurrent nerves then ascend in the trachea–esophageal groove posterior to the thyroid gland to innervate all the intrinsic laryngeal musculature save the cricothyroideus.

General sensory information from the larynx mimics the primary motor control pathways largely in reverse. The internal branch of the superior laryngeal nerve provides sensation above the vocal folds, and the RLN provides sensation to the subglottis and proximal trachea. These afferent impulses ascend via the vagus to the bipolar neuronal cell bodies in the inferior vagal ganglion located within the carotid sheath and the jugular foramen to enter the brainstem in the caudal medulla and synapse with neurons in the contralateral spinal trigeminal nucleus. They then ascend in the trigeminothalamic tract to the thalamus, and finally arrive at the primary sensory cortex located in the postcentral gyrus, Brodmann area 3, 1, 2.

The cerebellum and extrapyramidal systems integrate sensory and motor information to exert a modulating influence on laryngeal function. A series of inhibitory and excitatory checks and balances in the basal ganglia allows for second-to-second gradation of laryngeal motor control. The basal ganglia are located in the subcortex of the cerebrum, adjacent to the midbrain and the thalamus. The basal ganglia consist of the globus pallidus, putamen, and caudate. These have further interaction with the substantia nigra located

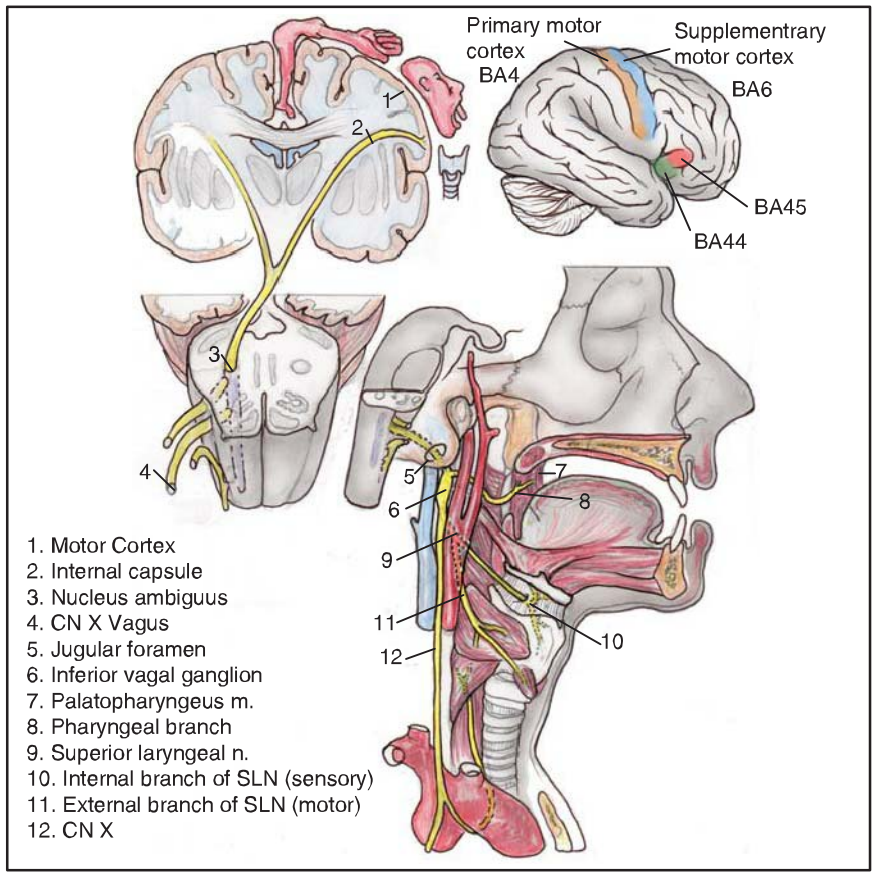

Figure 70.2 The pathway of the vagus.

in the anterior midbrain, the subthalamic nucleus, and the thalamus. In general, sensory information arrives from the cortex to the caudate and putamen, and excitatory impulses are sent to the globus pallidus with inhibitory adjustment from the substantia nigra (particularly the dopaminergic *pars compacta* region). The globus pallidus, with influence from the subthalamic nucleus, exerts a net inhibitory effect on the motor portion of the thalamus, which projects to the frontal planning regions of the cortex. For the cerebellum, sensory information is relayed through the medulla, ultimately projecting to the cerebellar hemispheres and the dentate nucleus, the most lateral deep cerebellar nucleus. Projections are also received from the parietal cortex. These, in turn, are further modulated by inputs from corticobulbar fibers in the pons, and project to the ventral lateral nucleus of the thalamus, which sends inputs back to the motor planning and primary motor areas of the cortex.

Function follows from anatomy. Motor neurons have two primary purposes, the first of which is establishing control over muscular function, and the second is providing basal tone to those muscles. UMN, originating in the cortex and terminating in the brainstem, have an inhibitory influence on lower motor neurons, acting to reduce tone in effector muscles. Lower motor neurons, in turn, provide the resting tonal stimulation to maintain muscle mass and tension. The "motor unit" consists of the total complement of axons, corresponding neuromuscular junctions, and contractile muscle fibers innervated by a single lower motor neuron. Interruption of the upper and lower motor neuron pathways creates significantly different abnormalities.

A UMN lesion to the corticobulbar tracts (at the contralateral cortex, the subcortical cerebral hemispheres, the cerebral peduncles, or the pons), would create spasticity and increased muscle tone with poor control. The voice would have a variable and unpredictable quality, which would be highly frustrating to the patient. There is not a characteristic laryngoscopic appearance—but the patient may show variable laryngeal motion depending on whether the task is a vegetative task (cough) or volitional task (speech). UMN lesions can be unilateral or bilateral, occur in combination, or in isolation, and demonstrate a wide spectrum of potential presentations depending on neurologic structures compromised.

In contrast, a lower motor neuron lesion in which any component of the motor unit is disrupted (the motor neuron, the peripheral nerve, neuromuscular junction, or effector muscle fibers) would result in atrophied, flaccid musculature devoid of tone. If skeletal muscle fibers are denervated, the motor units may depolarize spontaneously, resulting in fasciculations. Patients complain of a weak, breathy, or diplophonic voice (the voice is heard at two distinct vibratory frequencies because each cord is at a different tension), and be unable to perform a glottal stop or valsalva maneuver. Endoscopic examination of

the larynx would reveal impaired mobility of the vocal fold with possible bowing or flaccidity of the same fold and pooling of secretions in the ipsilateral pyriform sinus.

Lesions to the sensory pathways results in impaired gag, inability to clear secretions, and pooling of saliva. Patients may have gurgling speech, profound dysphagia, and absent or poorly productive cough.

The effects of lesions of the basal ganglia and cerebellum involve modulation of the frequency and smoothness of laryngeal movement. Due to the complex role of the basal ganglia, lesions involving its component structures present with laryngeal motion abnormalities that may be either hypokinetic or hyperkinetic. Hypokinetic disorders (parkinsonism) may yield a soft, breathy, monotonous voice, and difficulty initiating speech, with vocal fold bowing on phonation. Hyperkinetic disorders (e.g., dystonia, Huntington's), may manifest with rapid unexpected vocal fold spasms with poor phonatory control. Disorders involving cerebellar pathways result in ataxic speech, with a disruption in fine control of volume and pitch, and a vocal tremor.

GENERAL APPROACH TO DIAGNOSIS AND TREATMENT

The diagnosis of neurologic disease of the larynx rests largely on the traditional history and physical examination (Table 70.1). Of particular importance are changes the patient has noticed in strength and movement outside of issues with phonation, as neurologic disease is rarely limited to just the larynx. A broad neurologic assessment and consultation with a neurologist may be warranted. Beyond the history and physical (which includes endoscopy), radiologic imaging, sensory testing and laryngeal electromyography (LEMG) can add additional information. Flexible transnasal laryngoscopy is preferable to transoral rigid laryngoscopy because the former alters laryngeal mechanics the least and allows the examination to be carried out across multiple laryngeal tasks.

Neurologic diseases can be classified on the basis of the neuroanatomical structures and systems affected. Not uncommonly, disorders may span a number of neuroanatomical structures, creating a mixed picture of dysfunction.

TABLE 70.1 NEUROLARYNGOLOGY EXAMINATION

Neurologic examination

- Evaluate gait as patient walks to room
- Complete head and neck examination
- Cranial nerve examination:
  - Pay special attention to the tongue for tone and fasciculations: atrophy, flaccidity, and fasciculations indicate a LMN lesion, spasticity a UMN lesion
  - Look for twitching, dystonic posturing, or synkinesis of facial musculature
  - Pa, Pa, Pa: labial function
  - Ta, Ta, Ta/Ga, Ga, Ga: tip or posterior tongue function
  - Kitty cat: soft palate function
- Look at outstretched hands for tremor

Vocal examination

- Listen for fluidity (central), quality of articulation (central or peripheral), quality of the vocal signal (peripheral, laryngeal posturing, mucosal lesion)
- Differentiate hyperfunction, adductor spasms, abductor spasms, tremor
  - Hyperfunction will give a strained quality that does not change significantly from one word to the next
  - Tremor will be rhythmic
  - Adductor spasms are best heard during voiced sounds, such as the /ay/ in 80
  - Abductor spasms can be elicited with a vowel following a voiceless consonant. In the word taxi, there will be involuntary breathiness during the /a/ sound after the voiceless consonant t.

Fiberoptic examination

- Stop at level of the palate and evaluate for closure; have patient say "kitty cat"
- With the patient breathing quietly through the nose, evaluate the glottis at rest for tremor or paradoxical motion
- Evaluate for pooling of secretions
- Evaluate glottal closure pattern, vocal fold motion, and supraglottic hyperfunction
- Repeat vocal tasks during visualization and include
  - Glissando (sliding from low to high pitch): evaluates cricothyroid (CT) function
  - "Sniff: /i/" maneuver alternates adduction with abduction and will emphasize movement abnormalities such as a subtle paresis
  - Ask for purposeful inspiratory stridor, which may unveil lesions on the undersurface on the TVF
  - Agility and fatigability of vocal folds: alternate the sounds /pa/ - /ta/ - /ka/ past the point at which the patient is out of breath, assessing mobility, symmetry of motion, dexterity, and evidence of fatigue with repetition
- At the end of the exam, gently touch the aryepiglottic folds with the tip of the endoscope to assess for laryngeal sensation

CT, cricothyroid; LMN, lower motor neuron; TVF, true vocal fold; UMN, upper motor neuron.

The following categories focuses on disease entities most commonly associated with neurolaryngologic dysfunction, but is by no means exhaustive.

DISORDERS AFFECTING THE CENTRAL NERVOUS SYSTEM

Neurologic disorders of the central nervous system (CNS) are categorized on the basis of the systems affected. Lesions to the primary motor system (corticobulbar/corticospinal UMN, also known as pyramidal) primarily create spastic dysfunction, while lesions to the basal ganglia (extrapyramidal) result in disturbed control of function that may be hypo or hyperkinetic. (i.e., Parkinson disease would be hypokinetic, dystonia or tremor would be hyperkinetic). Disorders affecting the cerebellum and its outflow tracts in the brainstem and subcortical regions result in ataxic dysfunction. Some disorders are heterogeneous, resulting from inflammation or vascular occlusion to a number of important structures, with resulting combinations of dysfunction.

Spastic Disorders

Spastic disorders result from lesions or degeneration of UMN (pyramidal cells) and their projections in the corticobulbar pathway that extends from the cortex to the medulla. Stroke, the sudden onset of symptoms due to vascular compromise of cerebral tissue, commonly affects the motor pathways in addition to other structures and is discussed in the section under mixed CNS disorders. Amyotrophic lateral sclerosis (ALS), the most common nonvascular cause of spasticity, is a neurodegenerative disorder affecting both upper and lower motor neurons, and is discussed in detail under the section on peripheral nervous system disorders.

"Pseudobulbar palsy" refers to weakness of the bulbar musculature with hyperreflexia (hyperactive gag and brisk jaw jerk), indicating a UMN cause. This usually results from a lesion affecting the corticobulbar fibers. A true bulbar palsy would be due to compromise of lower motor neurons. Please see the explanation of bulbar palsy in the section on peripheral nervous system below.

Symptoms of pseudobulbar palsy include an exaggerated jaw jerk and gag reflex, and a spastic tongue that is contracted with a pointed tip but cannot be moved rapidly from side to side. Emotional lability (unprovoked crying or laughter), subcortical cognitive impairments, and dysarthria with thick, slurred, labored, and sometimes explosive articulation can be present. Marked hypernasality can exist, but palatal and pharyngeal reflexes are preserved. Dysphagia, dysarthria, nasal intonation, and nasal regurgitation are common.

Although often secondary to multiple bilateral vascular lesions above the brainstem, pseudobulbar palsy can also be caused by motor neuron disease. It is important to note that any disease involving the corticobulbar pathways can cause pseudobulbar palsy including multiple sclerosis (MS), neoplasm, encephalitis, and vascular disease.

Primary Lateral Sclerosis

Primary lateral sclerosis is a motor neuron disorder affecting UMN only and typically presents with spastic involvement of the lower extremities. There is often progression to spasticity of the bulbar musculature (2), giving the classic features of pseudobulbar palsy including spastic speech and dysphagia with pronounced emotional lability. The disorder is rare, accounting for a small percentage of all motor neuron disorders, and typically progresses very slowly (in contrast to ALS (3)). The cause is largely unknown. Differential diagnosis includes retroviral infection from HIV or human T-cell leukemia virus-I, MS, and adrenoleukomyelopathy. Antispasmodic pharmacotherapies such as baclofen (oral or intrathecal), or tizanidine can be helpful in ameliorating the spastic symptoms.

Hypokinetic (Parkinsonian) Disorders

Parkinsonism

Parkinsonism refers to the presentation of muscular rigidity and slowed movement (bradykinesia), with or without tremor. All forms involve damage to the pathways in the basal ganglia and brainstem, resulting in a net-inhibitory effect on movement and muscular function. Causes of secondary parkinsonism include stroke (usually accumulation of multiple basal ganglia lacunar infarcts), postencephalitic, paraneoplastic, traumatic (boxer's encephalopathy), drug-induced (phenothiazines and other antipsychotic medications), and toxic (pesticides and designer drugs such as 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine, a meperidine analog) effects. Parkinsonism also includes a number of genetic and neurodegenerative disorders referred to as Parkinson Plus syndromes. These include Shy-Drager Syndrome (multiple systems atrophy or MSA), dementia with Lewy bodies, and progressive supranuclear palsy. Parkinson disease refers to idiopathic parkinsonism and is by far the most common hypokinetic movement disorder and also the most amenable to treatment. MSA is also relevant to otolaryngologists for its association with airway difficulties.

Parkinson Disease

Parkinson disease has a prevalence of 0.3% to 0.4% of the U.S. population (4) and affects up to 2% of people over age 60 across all ethnic groups with an equal sex distribution. Up to 80% demonstrate vocal difficulties, with 30% finding it the most disabling part of the disorder. The classic symptoms include a pill rolling tremor, cog-wheel rigidity, masklike facies, small handwriting, decreased blinking, flexed posture with shuffling gait, and reduced arm swing.

Pathologically, Parkinson disease is associated with the accumulation of inclusion granules of abnormal alpha-synuclein protein in the autonomic and motor centers of the medulla oblongata. In later stages of disease, there are additional changes in the substantia nigra, basal forebrain, and ultimately, the frontal cortex (5). Autopsy examination shows loss of pigmentation of the substantia nigra, and

cellular degeneration in the globus pallidus and putamen, with prominent Lewy body formation. Parkinson disease becomes symptomatic when the loss of substantia nigra dopaminergic neurons reaches about 70%. The cause for aberrant alpha-synuclein deposition in Parkinson disease is not known, but there are rare familial forms of the disease that include an autosomal dominant mutation in the alpha-synuclein gene (4q21) and an autosomal recessive mutation of the parkin gene (6q25.2-q27).

The vocal characteristics of Parkinson disease include a soft breathy monotone voice perceived by the patient to be of normal loudness. This is caused by poor effort from a bradykinetic bellows mechanism (chest wall and diaphragm) exacerbated by an inaccurate perception of personal speech effort. Additional components include vocal tremor, poor articulation, stuttering quality, difficulty initiating speech, and swallowing difficulties.

Laryngoscopy shows vocal fold bowing with a spindle-shaped glottal gap on phonation (Fig. 70.3). Other findings include pooled hypopharyngeal secretions, decreased sensation, diminished cough reflex with aspiration, and poor coordination of the vocal folds with respiratory effort. Identification of vocal fold motion impairment suggests a parkinsonism plus syndrome, specifically MSA.

Pharmacotherapy for Parkinson disease aims to increase the amount of dopamine available in the synaptic cleft for neurotransmission to the basal ganglia. This can be accomplished by the use of the dopamine precursor levodopa (L-dopa, usually taken as an oral preparation with carbidopa, which inhibits peripheral metabolism of L-dopa), which is converted in the brain into dopamine by remaining substantia nigra cells. Other medications include dopamine agonists such as pramipexole and apomorphine (the latter available as an intravenous [IV] preparation), and therapies that prevent degradation and reuptake of dopamine once available in the synaptic cleft including the monoamine oxide type B inhibitor (selegiline) and catechol-O-methyltransferase inhibitors (entacapone). Thoughtful use of these medications is necessary, as spikes in dopamine levels can cause overflow movements including chorea and dyskinesias, while nadirs can result in ignition failure (inability to initiate movement) and freezing episodes.

L-dopa has had mixed results in dysphonia, although most studies have shown no statistical improvement (6). Vocal fold augmentation or medialization laryngoplasty (7) may improve loudness and maximal phonation time if sufficient respiratory drive for phonation exists, but in general it has demonstrated only temporary effectiveness (most likely because of progression of disease). Laryngeal surgery does not improve articulatory function or prosody. Deep brain stimulation has shown variable improvement in speech, despite significant changes in limb movements (8,9). Only behavioral therapy has shown a consistent positive effect on voice and speech function of patients with Parkinson disease.

Lee Silverman Voice Therapy (LSVT) is the most well studied of the behavioral techniques for Parkinson disease (Table 70.2). The program works both by increasing patients' physical efforts and also, theoretically, by resetting their sensory perception of their own vocal output. In the original study, 35 patients were randomized into placebo and treatment groups. At 2 years, the patients in the LSVT group sustained or improved vocal intensity over pretreatment levels, whereas the placebo group deteriorated (10). Swallowing function also appears to be improved after treatment (11).

Multiple Systems Atrophy

MSA combines parkinsonism and autonomic dysfunction. Patients with MSA suffer profound autonomic failure, usually manifesting as severe orthostatic hypotension, disturbance of sphincter control (urinary or fecal incontinence), and impotence. MSA-P (parkinsonian, previously "striatonigral degeneration") has more resting tremor and parkinsonian features, and may be difficult to distinguish from Parkinson disease, save that these patients have a poor response to dopamine-related therapies. MSA-C (cerebellar, or olivopontocerebellar atrophy), has a greater degree of cerebellar ataxia. The prevalence is up to 5/100,000

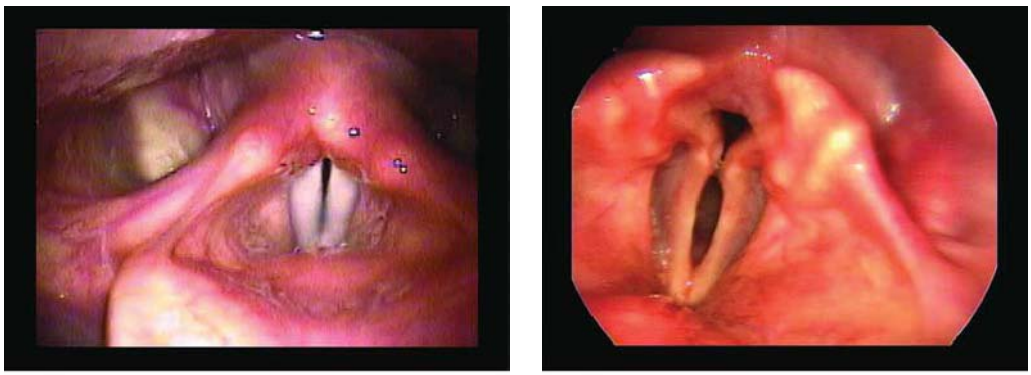

Figure 70.3 Vocal fold bowing with Parkinson disease. **A:** Normal larynx in adduction, note the near complete closure of the membranous vocal folds and also the alignment of the vocal process of the arytenoid cartilages. **B:** This individual has the characteristic vocal fold bowing of parkinsonism—there is approximation of the tip of the vocal process of the arytenoids, but a prominent glottal gap at the midmembranous vocal fold and often (as seen here) a marked posterior glottal chink.

TABLE 70.2 LEE SILVERMAN VOICE THERAPY

Three major features contribute to the voice disorder in individuals with parkinson disease:

1. Global scale-down of neural drive to the speech mechanism, resulting in a soft monotone voice (bradykinesia)
2. Inaccurate sensory perception of self-effort involved in vocalization, which prevents the individual from accurately monitoring vocal output
   "My voice is not too soft, my spouse needs a hearing aid"
3. Difficulty with independently generating the correct effort to produce adequate vocalization
   "I can't speak this loud, I feel I am shouting"

Five essential LSVT concepts:

- Increasing amplitude of phonatory output (think loud, be loud)
- Improving sensory perception of effort (think loud)
- Administering treatment in high-effort style (recalibration)
- Administering treatment intensively (four times a week for 16 sessions in 1 month)
- Quantifying all speech and voice output (sound meter)

persons (12). Like Parkinson disease, the pathogenetic mediator is the abnormal deposition of alpha-synuclein in intracellular inclusions (referred to as glial cytoplasmic inclusions, not Lewy bodies). Many patients have orofacial or craniocervical dystonia associated with a characteristic quivering, high-pitched dysarthria. Decreased sensation of the laryngopharynx and a diminished cough reflex may permit recurrent aspiration. Vocal fold immobility in a patient with parkinsonism is highly suggestive of MSA (13). Inspiratory stridor develops in about 30% of patients.

These individuals develop many sleep disorders, including obstructive and central sleep apnea, hypoxemia, phasic swings of systemic arterial pressure, reduced rapid eye movement (REM) sleep, and REM sleep behavior disorder. When obstructive sleep apnea occurs in patients with MSA, there is significant risk of sudden death (14), and tracheotomy is recommended. The disease progresses more rapidly than Parkinson disease, with average survival of less than 9 years.

Hyperkinetic Disorders

Dystonia

Dystonia is a chronic neurologic disorder of central motor processing within the basal ganglia (extrapyramidal system) characterized by involuntarily sustained muscle contractions of agonist and antagonist muscles causing twisting and repetitive movements or abnormal postures. Anxiety will aggravate the movements; sedatives may mitigate the movements; and posturing characteristically disappears during sleep. Dystonia can be focal (spasmodic dysphonia, writer's cramp), regional (cervical dystonia), or generalized, and can be idiopathic or secondary to a wide variety of causes, including hereditary syndromes (Dystonia gene [DYT1] gene locus), stroke, trauma, and drug effects.

Spasmodic Dysphonia

Spasmodic dysphonia is a focal task-specific laryngeal dystonia with involuntary contractions of the intrinsic laryngeal musculature. If the contractions in the adductor musculature predominate, it is termed "adductor spasmodic dysphonia" (AddSD) and is characterized by a harsh, strained, and strangled quality with voice breaks. If the contractions in the abductor musculature predominate, it is termed abductor spasmodic dysphonia (ABdSD), which is characterized by sustained breathiness with breathy voice breaks. The dystonic (spasmodic) muscle contractions generally do not affect nonspeech laryngeal functions such as breathing, singing, swallowing, or coughing.

AddSD was first described by Traube in 1871 in a female having a "spastic form of nervous hoarseness" (*spastiche form der nervosen helserkeit*). Spasmodic dysphonia historically has been considered to have a psychogenic cause owing to the fluctuation in symptoms and frequent coexistence of anxiety and depression. However, in 1976, Dedo described the dramatic response (although temporary) of the disease to RLN section, providing proof of an organic cause (15). In many patients, the symptoms of anxiety and depression normalize after successful treatment of their spasmodic dysphonia (16). Although the exact pathophysiology of dystonia is unknown, some autopsy studies have detected altered levels of neurotransmitters in the caudate, putamen, globus pallidus, and dentate nuclei, supporting the current theory that the site of pathology involves the basal ganglia (17,18). Furthermore, recent studies suggest that dystonias involve cerebellar pathways that modulate extrapyramidal function (19).

Spasmodic dysphonia is an adult onset disorder with a female predominance. When classified, 83% of cases are AddSD, 17% ABdSD, with rare mixed cases and rare cases of breathing dystonia. Spasmodic dysphonia is associated with essential tremor in 30% of patients and with other forms of dystonia, such as blepharospasm or writer's cramp, in 14% of patients (20). Up to 23% of patients with spasmodic dysphonia report a family history of dystonia or other movement disorders (21).

Spasmodic dysphonia affects the speaking voice but spares other vocal tasks such as singing, character speech

(e.g., speaking in falsetto like Minnie Mouse), or yelling. Patients describe more difficulty with speaking over the telephone, public speaking, and communication during stressful situations. Alcohol or sedatives can reduce voice breaks, and speech during sleep is normal. Patients describe a "strangled" feeling when trying to speak, and have great difficulty "getting the words out." Individuals with spasmodic dysphonia have a wide range of vocal patterns, depending on the severity of the spasms, compensatory vocal strategies used, and presence of overlying tremor. Some patients with AddSD use a low, breathy voice as a compensatory mechanism and sound similar to patients with ABdSD. Occasionally, it can be difficult to distinguish organic spasmodic dysphonia from psychogenic voice disorders or muscle tension dysphonia.

The vocal characteristics of AddSD include strangled breaks in connected speech, especially prominent with words that begin with vowels. Eliciting phrases would include counting from 80 to 90, and the sentence "We eat eggs every day." The vocal characteristics of ABdSD include breathy breaks in connected speech, especially for vowels following a voiceless consonant. Eliciting phrases would include "The puppy bit the tape" and "Harry had a hard head." The examiner should listen for delayed onset of phonation after the voiceless consonants p, t, and h.

Diagnosis is made by history, vocal characteristics, and flexible transnasal laryngeal examination across multiple speech tasks. Patients with AddSD demonstrate inappropriate adduction of vocal folds with hyperfunction of the supraglottis. Patients with ABdSD demonstrate inappropriate vocal fold abduction during connected speech. Some individuals are able to suppress symptoms with a sensory trick (*geste antagonist*) such as voicing while chewing, biting the tongue, or holding a finger in the corner of the mouth. Similarly, insertion of a flexible scope may diminish involuntary contractions and normalize speech. Associated neurologic disease should be excluded through neurologic consultation, preferably with a movement disorders specialist.

Botulinum toxin injection into the affected laryngeal muscles is the treatment of choice for the symptoms of spasmodic dysphonia, and results in vocal improvement in up to 90% of patients (21,22). For AddSD, the thyroarytenoid-lateral cricoarytenoid muscle complex (TA-LCA) is most commonly injected; for ABdSD, the posterior cricoarytenoid (PCA) is injected. Complications are caused by excessive glottal weakness and breathiness with TA-LCA injections, stridor with PCA injections, and dysphagia to liquids if the toxin has diffused to the adjacent constrictors. Resistance to toxin at doses used to treat spasmodic dysphonia is rare, and most treatment failures are related to technical problems (improper dosing or placement of toxin).

With a successful injection, patients can expect reduction in voice breaks, effort required for speaking, and the uncomfortable strangling sensation. The adductor or abductor muscle group can be specifically targeted, and the dose titrated to provide just enough weakness to relieve spasm without causing excessive weakness and subsequent breathiness (Add) or stridor (ABd). Results are critically dependent on achieving sufficient weakness to ameliorate spasm without causing undue side effects.

Injections are most commonly performed transcutaneously using electromyography (EMG) guidance to ensure proper placement within the correct muscle, although some groups use anatomic landmarks only (23). Although any serotype and brand of botulinum toxin can give the desired results, dosages may differ significantly. The most common brands in current clinical use are BOTOX® (Allergan, Irvine), which is botulinum toxin type A, and Myobloc® (Solstice, Louisville), which is rima botulinum toxin type B. It is important to note that, as of the writing of this chapter, although these pharmaceuticals are scientifically and clinically accepted for use in the treatment of laryngeal dystonia, they are only Food and Drug Administration (FDA) approved in the treatment of blepharospasm, cervical dystonia, and glabellar lines. For AddSD, the average dose is 1 U of botulinum toxin type A to bilateral thyroarytenoid muscles, with the range between 0.05 to 10 U (22). Most patients receive bilateral injections via the cricothyroid membrane every 3 to 4 months, although some individuals find benefit from unilateral injections at shorter intervals. Side effects include breathiness and difficulty swallowing liquids, which emerge in 1 to 3 days and can last up to 2 weeks. For ABdSD, the average dose is 2 to 5 U unilaterally into the PCA (22). (See the LEMG section for a detailed explanation of injection techniques.) The side effects are stridor with airway compromise (from weakening the sole abductor musculature) and dysphagia. For this reason, unilateral injections are usually given to reduce the chance of airway compromise until the patient's reaction to injections are better known to the treating clinician (24). All patients must be evaluated by transnasal laryngoscopy to assess glottal adequacy before injection of the PCA.

There are several surgical therapies for spasmodic dysphonia that prevent glottal closure through destruction of branches of the RLN (25), resection and thinning of the dystonic musculature (26), altering the laryngeal framework (27) (type II thyroplasty), or reinnervation of the dystonic musculature with a branch of the ansa cervicalis (28). These therapies have been reported to provide good symptomatic relief in carefully selected patients. Unfortunately, to date, all successful treatments for spasmodic dysphonia have focused on symptomatic amelioration of the laryngeal end organ, and have not been effective in correcting the underlying disease process in the brain. Botulinum toxin injections remain the gold standard treatment for this group of patients and the only treatment for AddSD demonstrated to be effective by a controlled clinical trial (29).

Essential Tremor

Essential tremor is a common, benign, and likely inherited movement disorder with a female predominance (30). Oscillatory 4 to 8 Hz shaking of the hands and rhythmic head titubation are the most commonly affected areas. Thirty percent of afflicted persons will have symptomatic vocal involvement. Vocal symptoms are related to tremor

in the muscles in the larynx, pharynx, soft palate, and the strap muscles of the neck. Although aggravated by anxiety, public speaking, telephone use, and mitigated by alcohol and benzodiazepines, tremor differs from spasmodic dysphonia by its rhythmicity and presence across all speech tasks. Most patients with essential tremor are treated with systemic agents (propranolol and primidone); however, in our experience vocal tremor does not respond as well as head or hand tremor to medical management. Injections of botulinum toxin may be useful to "dampen" the tremor by weakening the affected musculature, but oscillatory movements will persist at diminished amplitude.

Tic Disorders

Tics are sudden, recurrent, quick, abnormal movements or vocalizations that abruptly interrupt normal (31) activity. Largely thought of as a phenomenon of childhood with male predominance, upwards of 30% of children may have transient tics. Many adults have unrecognized simple tics, making the prevalence difficult to characterize. Simple phonic tics include throat clearing, snores, squeals, coughs, and belching noises. There is a compulsion to perform a movement, which is relieved once the movement is completed. Tics can be temporarily suppressed, although doing so will cause anxiety. They are usually aggravated by stress, anger, and excitement, and can decrease with relaxation and sleep. Tic disorder, a clinical diagnosis, often exhibits a good response to medical therapies including tetrabenazine, clonazepam, and botulinum toxin.

Gilles de la Tourette syndrome is a tic disorder with associated behavioral abnormalities (96% by age 11). Tourette's generally emerges in early childhood, peaks by age 10, and regresses in about half of patients by adulthood. Compulsive personality disorder, attention deficit disorder, and anxiety disorders are present in most of these individuals. Complex phonic tics may be present, including palilalia (repetition of one's last word or syllable), echolalia (repetition of someone else's last words) and coprolalia (obscenities), although coprolalia is likely present in less than 20%.

Myoclonus

Oculopalatolaryngopharyngeal myoclonus is an uncommon disorder consisting of twitch-like, rhythmic contractions of the soft palate, pharynx, and larynx at a rate of one or two contractions per second. This condition may affect only the palate, or all of the laryngopharynx. This condition can be part of a seizure disorder, be posttraumatic, or be caused by a viral, toxic, or metabolic encephalopathy, where a lesion interrupts the pathways between the olivary nuclei in the medulla, the dentate nucleus in the cerebellum, and the red nucleus in the midbrain (Mollaret triangle). Speech may be choppy with intermittent hypernasality from palatal dysfunction. Often, the chief complaint will be persistent clicking in the ear. The palate and vocal folds can be treated with injections of botulinum toxin to decrease the severity of the contractions, but Eustachian tube dysfunction and velopharyngeal insufficiency are important limitations. Systemic medications can be helpful.

Ataxic Disorders

Disorders of the cerebellum and its outflow tracts create ataxic laryngeal dysfunction, usually through the influence of toxins (alcohol), the presence of tumors of the posterior fossa, genetic conditions, or stroke. The clinical picture is one of poor control of speech volume and pitch, with uncoordinated laryngeal muscle contractions.

Friedreich Ataxia

Friedreich ataxia (FA) is an autosomal recessive congenital disorder caused by a mutation in the gene *FXN* (32) that codes for a protein essential for proper functioning of mitochondria. FA is the most common inherited ataxia. Prevalence is 1 to 2/100,000, and age of onset is generally in mid to late childhood. Although the target of the dysfunctional protein is unknown, the dentate nucleus of the cerebellum and the dorsal root ganglia outside the spinal cord are most affected, causing severe difficulties with proprioception (awareness of body in space) and limb, girdle, and vocal ataxia. Treatment is supportive.

Arnold-Chiari Malformations

Arnold-Chiari malformations are the most important of the posterior fossa deformities, and of the four types, Chiari I and II are encountered most commonly. Individuals with Chiari I have cerebellar tonsillar herniation 5 mm below the foramen magnum without other brain malformation. This occurs with an incidence of 1% (33) and can cause brainstem and vagal compression.

Symptoms, which often do not develop until adult life, include tussive head pain (increased intracranial pressure), visual changes, syncope, dizziness, dysphagia and hoarseness (cranial nerve X), absent gag reflex (cranial nerve IX), and ataxia. There is a high incidence of associated syringomyelia (cavitation of the central parts of the spinal cord usually in the cervical region) (Fig. 70.4).

In Chiari II, the posterior fossa is small and the cerebellum, pons, and medulla are displaced to varying degrees into the cervical canal. Infants present with brainstem dysfunction, including swallowing difficulties, slow feeding, repeated aspirations, and breathing difficulties (e.g., apnea and stridor) from vocal fold paresis. Older children and adults may have extremity weakness, sensory changes, and swallowing difficulties. In selected patients, surgical decompression of the posterior fossa will allow neurologic recovery.

Mixed Disorders

Stroke

A stroke refers to a sudden interruption of blood flow to a portion of the brain causing neurologic deficits that become maximal within seconds to minutes. Stroke is the

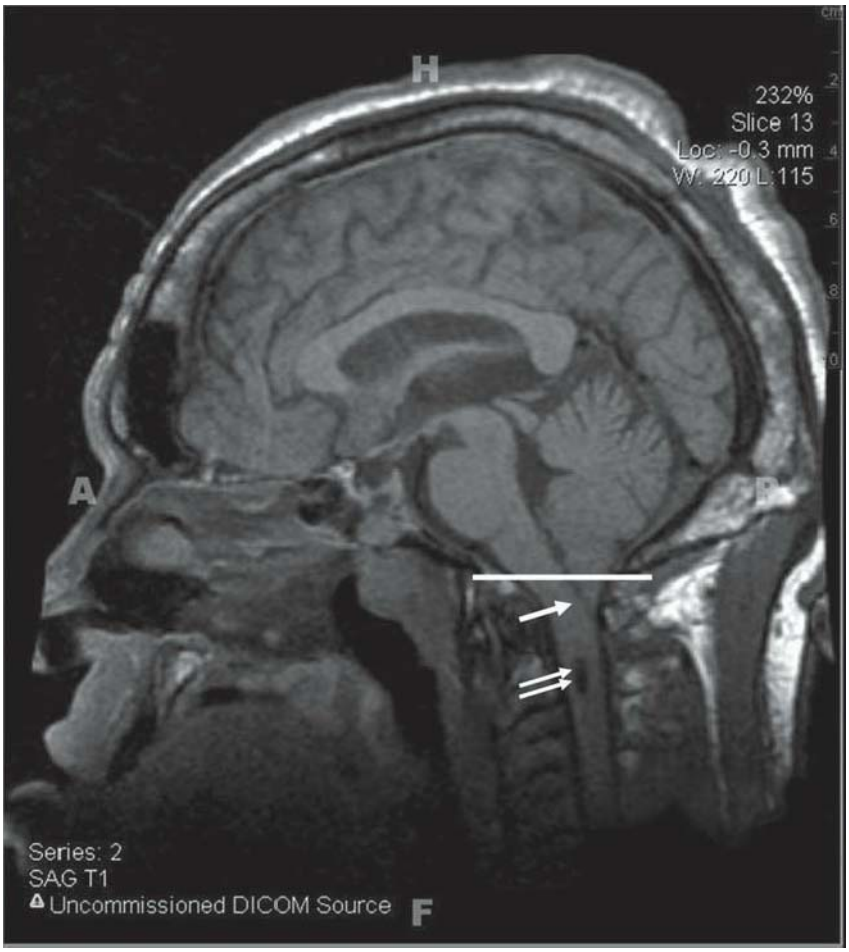

Figure 70.4 Sagittal T1-weighted MRI showing the presence of a Chiari type I malformation associated with a cervical syrinx (*double arrow*) and herniated cerebellar tonsils (*single arrow*) through the level of the foramen magnum (*white line*). (Courtesy of M. Michel and M. Kocak. Medical College of Wisconsin, Milwaukee.)

third leading cause of death in the United States and affects more than half a million persons per year. Eighty-five percent of strokes are ischemic, from reduction or absence in blood flow to one of the arteries supplying the cerebrum, cerebellum, or brainstem. The remaining 15% of strokes are hemorrhagic, either from overt hemorrhage or conversion of a prior infarct after reperfusion. Ischemic strokes are generally further divided into large vessel (affecting an arterial distribution) or lacunar (affecting small penetrating arteries). The etiologies of large vessel and lacunar infarcts differ. Large vessel infarcts are generally embolic, referring to a clot or occlusion that travels from another source—typically atheromas in the carotid arteries or cardioembolism due to atrial fibrillation. Lacunar infarctions are typically *in situ* thromboses caused by gradual arterial sclerosis from chronic hypertension.

The neurologic deficits of strokes arise from the location of brain tissue affected. Large-vessel infarctions, particularly of the middle cerebral artery (MCA), can have a devastating effect on language comprehension and formulation, as well as speech production affecting Broca or Wernicke areas and the connections between them. MCA distribution infarcts may result in hemiparalysis as they affect the primary motor cortex and the descending corticobulbar tracts. Lacunar infarctions, on the other hand, generally affect the deeper structures at the base of the brain, particularly the basal ganglia, and often have a better prognosis for recovery. Although a single lacunar infarction in the basal ganglia is unlikely to cause a movement disorder, the accumulation of multiple lacunes may result in a "vascular parkinsonism," which responds poorly to L-dopa. Lacunar infarctions may also affect the corticobulbar pathways in an area that runs near the basal ganglia, called the internal capsule, causing contralateral weakness of the hemibody, face, tongue, or vocal fold paresis.

Infarctions of the vertebrobasilar circulation involve the brainstem, which can have particular implications for laryngeal function. In particular, a posterior–inferior cerebellar artery (PICA) infarction affects the lateral medulla (Wallenberg syndrome), lesioning the nucleus ambiguus, nucleus solitarius, and the tracts providing sensory information. This can cause a severe unilateral vocal fold paralysis, as well as other features such as chronic hiccups. PICA infarctions often occur in association with vertebral artery dissections, and dissection should be looked for, particularly in younger patients. Hemorrhagic infarctions have a similar etiology to lacunar infarcts, and most often occur in the basal ganglia, followed by the thalamus, and the cerebellum in frequency of location. Because they may introduce a large volume of blood to a limited space, hemorrhages may increase intracranial pressure and compress nearby structures such as the brainstem, impairing

consciousness and vital functions. Decompressive surgery for acute hemorrhages to prevent brainstem herniation can be life-saving.

Diagnosis of stroke is initially clinical and then confirmed with computed tomography (CT) or magnetic resonance imaging (MRI). Although MRI is the more sensitive of the two modalities, CT is invaluable in the acute diagnosis of hemorrhage. Ischemic infarcts should be followed up with imaging of carotid arteries to rule out atherosclerotic plaques, and further evaluation for cardiac lesions responsible for embolism such as atrial fibrillation.

Acutely embolic ischemic infarctions can be treated with IV or intra-arterial (IA) thrombolytic agents such as tissue-plasminogen activator (TPA) or streptokinase, although both of these treatments are time sensitive (usually less than 4 hours for IV-TPA, less than 6 hours for IA-TPA). Subacute and chronic treatment is geared toward prevention of further strokes, and mostly involves platelet inhibition with aspirin, clopidogrel, or aspirin-dipyridamole in combination. Carotid end-arterectomy and stenting may prevent further embolism from carotid atheromas, and warfarin, heparinoid, or direct thrombin inhibitor-based anticoagulation is indicated for prevention of cardioembolism (usually from atrial fibrillation). In the chronic phase, the role of the otolaryngologist is to ameliorate symptoms of spasticity, movement abnormalities, and paralysis, described elsewhere in this chapter.

Multiple Sclerosis and other Demyelinating Disorders

MS is defined by the presence of at least two neurologic deficits, separated by time and space. The disorder preferentially affects the oligodendroglia responsible for CNS myelin, but severe and chronic lesions may cause axonal damage. MS is the most common autoimmune disorder of the CNS, with a prevalence of 91/100,000 persons in the United States. Like many autoimmune disorders, the disease has a bimodal distribution, with the first incident peak in women in their 20s and 30s, and a second, smaller peak in men in their 40s and 50s. MS has a predilection for persons who grew up in northern climates (before age 15). Etiology of the autoimmune dysfunction is unknown, but may be related to human leukocyte antigen haplotype and viral exposures, and most recent research has found an association with vitamin D deficiency (34). Unlike stroke, the onset of neural dysfunction is more gradual, usually occurring over hours to days. Early in the course of MS, the deficits may improve over time, return the patient to baseline or at least remaining stable thereafter, creating a pattern of relapse and remission. The overall trajectory of neurologic dysfunction is usually progressive, and many patients ultimately experience a steady downward course (secondary progressive course). However, like stroke, the location of the lesion is responsible for the neurologic deficit. Typical locations for demyelinating lesions include the deep white matter, including corticospinal and corticobulbar tracts, the middle cerebellar peduncle (extending from the pons), the corpus callosum, and the optic nerves (which have oligodendroglia). Brainstem involvement is common, and may be responsible for extraocular motion abnormalities, tremor, spasticity, and weakness, depending on the exact location of the lesions. Demyelinating events that may serve as precursors to MS include optic neuritis (optic nerve inflammation with blurred vision and loss of intensity of color), internuclear ophthalmoplegia (double vision with ocular misalignment secondary to upper brainstem lesions), and transverse myelitis (sensory loss, weakness, and /or bowel or bladder dysfunction from spinal cord involvement). Most initial demyelinating events herald ultimate progression to MS.

A number of options exist for confirming MS diagnosis. MRI (Fig. 70.5) is the most used modality for diagnosis

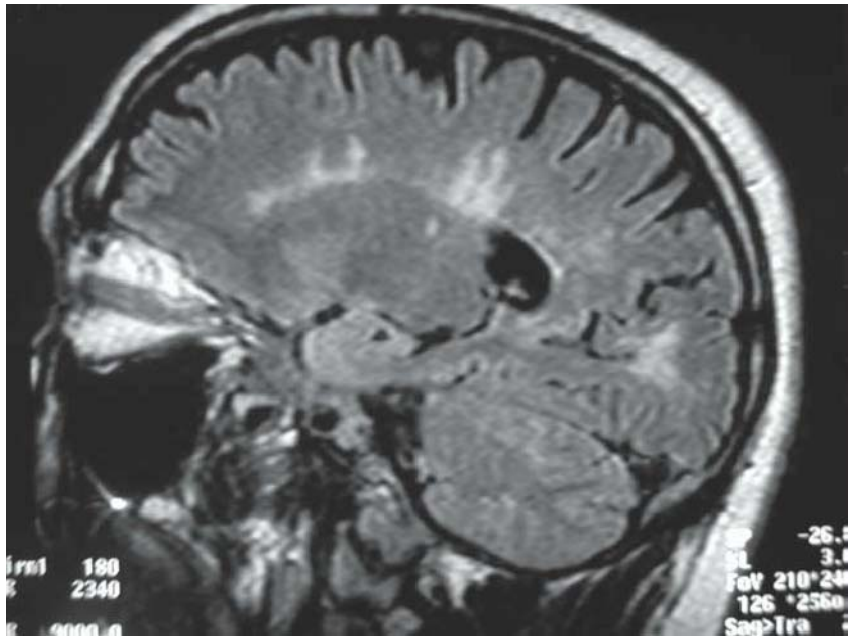

Figure 70.5 Sagittal Fluid Attenuated Inversion Recovery (FLAIR) image near midline, demonstrating signal abnormalities in the periventricular white matter oriented perpendicularly to the ventricular surface, typical for multiple sclerosis. An additional area of abnormality is also seen in the occipital white matter. (Courtesy of M. Kocak. Medical College of Wisconsin, Milwaukee.)

and staging of MS, and the Mcdonald criteria can categorize the probability of MS diagnosis based on the type, number, and location of active and chronic demyelinating lesions. With inconclusive MRI results, other testing may be indicated. Visual evoked potentials can confirm demyelinating damage from a prior optic neuritis by detecting a delay of the P100 waveform and examination of cerebrospinal fluid obtained from lumbar puncture may show biomarkers such as elevated immunoglobulin G levels and oligoclonal banding.

An acute exacerbation of MS may respond to 3 to 5 days of IV methylprednisolone, 1,000 mg, which will speed recovery from the exacerbation but not affect overall disease course. Disease-modifying therapies for chronic disease, including subcutaneous and intramuscular formulations of interferon-beta and glatiramer acetate, a copolymer, reduce the frequency and intensity of exacerbations, and diminish the number of demyelinating lesions on MRI. The monoclonal antibody natalizumab has been FDA-approved for the treatment of MS, and has shown a powerful effect in reduction of demyelinating lesions and altering the clinical course of MS. Natalizumab treatment is associated with activation of the parvovirus responsible for Progressive Multifocal Leukoencephalopathy, a potentially lethal condition. Therefore, natalizumab treatment should not be undertaken lightly.

Due to the frequent involvement of the brainstem and motor tracts in patients with MS, otolaryngologists have a crucial role in the evaluation of MS-related dysphagia and dysphonia. Pseudobulbar palsy and spasticity are common, as is an ataxic pattern of laryngeal function. Lower motor neuron-related paralysis may occur with lesions that affect the nucleus ambiguus, and sensory dysfunction with poor clearing of secretions, impaired cough and gag reflexes may occur.

Laryngeal Dysfunction Following Closed Head Injury

Traumatic brain injury produces diffuse damage to the neuronal connections among interactive brain structures. Some individuals may suffer laryngeal spasticity and hyperfunction (35), whereas others experience glottal incompetence caused by paresis or vocal fold atrophy often compounded by poor effort. Hypernasality caused by velopharyngeal insufficiency is also common.

DISORDERS AFFECTING THE PERIPHERAL NERVOUS SYSTEM

Peripheral nervous system disorders induce laryngeal dysfunction largely through their effect on the motor unit. Because the motor unit comprises the lower motor neuron in the brainstem, the peripheral nerve, the neuromuscular junction, and the sum of muscle fibers which it innervates, disturbance to any one of these structures can create vocal fold weakness or paralysis.

Bulbar Palsy

The term *"bulbar palsy"* refers specifically to paresis of cranial nerves IX–XII associated with the "bulb," which is a historical term for the medulla. The trigeminal and facial nerves can be involved but these are not strictly within the medulla. Weakness of the jaw, face, sternocleidomastoid, trapezius, tongue, pharynx, and larynx is prominent. Symptoms include dysphagia, dysarthria, nasal intonation with drooping of the palate, nasal regurgitation, absent jaw and gag reflex, pooling of saliva in the pharynx, a weak cough, and a wasted, fasciculating tongue with a rounded tip. This can occur in many disorders, including diphtheria, poliomyelitis, myasthenia gravis (MG), myotonic dystrophy, botulism, and Chiari malformation.

Motor Neuron Disorders

Amyotrophic Lateral Sclerosis

Amyotrophic lateral sclerosis (ALS), also known as Lou Gehrig disease, is a progressive neurodegenerative disorder involving both the lower motor neuron cell bodies (anterior horn cells in the spinal cord, motor nuclei of the lower cranial nerves in the brainstem) and the UMN in the corticospinal or corticobulbar pathways. Because of the involvement of both upper and lower motor neurons, the picture can be a mixed one of both flaccid atrophy and spasticity. Disease onset is usually after the age of 50 and the process is usually fatal within 3 to 6 years (36). The annual incidence is 2/100,000, with a male predominance, 10% is inherited, and 1% of the total number affected is attributable to a mutation in the superoxide dismutase gene.

Weakness of the bulbar muscles is seen as the initial symptom in 20% of patients. Poor tongue function is common, manifesting as slurred speech, dysphagia, or drooling. Patients may have difficulty coughing and breathing, with weakness and eventual paralysis of respiratory function. Other symptoms include progressive weakness, atrophy, fasciculation, and hyperreflexia of limb musculature. Extraocular movements and bowel and bladder function are typically spared.

Riluzole, a sodium channel blocker, is currently the only medication approved for treatment of ALS, giving a 9% advantage in 1-year survival (37), but can have side effects including nausea and liver dysfunction. Most interventions are supportive such as anticholinergics for drooling, percutaneous endoscopic gastrostomy tube, and finally tracheotomy with ventilation. Motor neuron disease is progressive and usually has a fatal outcome within 3 to 5 years, most commonly from pulmonary infections.

Progressive Bulbar Palsy

Progressive bulbar palsy is a distinct type of adult onset motor neuron disease caused by lesions affecting the motor nuclei of the cranial nerves. Typically, the patient is spared UMN symptoms, such as spasticity and jaw hyperreflexia. Kennedy syndrome, or bulbospinal muscular atrophy is

an inherited motor neuron disease, associated with gynecomastia and primarily lower motor neuron degeneration. The disorder is X-linked, and is based on an accumulation of trinucleotide repeats.

Spinal Muscular Atrophy

Spinal muscular atrophy (SMA) is a group of genetic disorders from deletions in the survival motor neuron gene on chromosome 5, and is classified largely by time of presentation. SMA-I, Werdnig-Hoffman syndrome, is evident sometimes even in utero from decreased fetal movements, and is characterized by a "floppy," severely hypotonic infant with poor suck and weak cry. Bulbar muscle weakness is prominent, affecting feeding and causing continuous gurgling, ultimately placing the infant at high risk for aspiration pneumonia. Tongue fasciculations are common. Most infants with SMA-1 do not live beyond age 2. In SMA-II (arrested or intermediate) and III (Kugelberg-Welander), onset is later, from 18 months to 15 years of age, limb weakness and contractures is most prominent, although aspiration and respiratory compromise (usually involvement of intercostals rather than diaphragm) can occur.

Poliomyelitis

Poliomyelitis, now rare in developed countries since vaccination, is caused by a ribonucleic acid virus of the picornavirus group. After a flu-like prodromal phase, asymmetric weakness develops in the bulbar and respiratory muscles, with or without associated limb weakness. There is no sensory deficit. Management is supportive.

Postpolio Syndrome

Postpolio syndrome is characterized by recurrence some years later of the original illness, with increasing weakness of previously involved or seemingly uninvolved muscles. Treatment is supportive. The likely cause is further loss of anterior horn cells caused by aging from a pool that was depleted by the original infection.

Peripheral Neuropathies

Peripheral neuropathies affect the peripheral nerve distal to the neuronal cell bodies in the anterior horn cells and the dorsal root ganglia. The major etiologies of neuropathies are hereditary, toxic and metabolic (particularly diabetes), trauma, and infectious/immune-mediated (38).

Neuropathies typically fall into one of two categories: those that primarily affect the axon and those where damage is primarily to the myelin layer (myelinopathy). Axonal neuropathies exhibit length dependency, where the most distal portions of nerve are preferentially affected, often due to disruption of microtubular transport mechanisms that prevent the sustainment of the distal axon from the neuronal cell body. Antimitotic agents such as colchicine and vinca alkaloids particularly can cause this variety of damage, as can alcohol and diabetes. The length-dependency of many axonal neuropathies usually means that most axonal polyneuropathies will spare proximal nerves.

Myelinopathies, by contrast, often affect more proximal segments of nerve. Hereditary myelinopathies, such as Charcot-Marie Tooth type I, also called hereditary motor sensory neuropathy, are the result of dysfunctional peripheral myelin proteins, and affect myelin throughout the nerve. Acquired myelinopathy, such as Guillain-Barré syndrome (GBS)/acute demyelinating inflammatory polyneuropathy cause damage to some (often proximal) segments of myelin, sparing others.

Mononeuropathies, typically due to entrapment of the nerve in a bony canal or fibrous tunnel, or acutely from trauma in penetrating injury or nerve stretch injury, initially causes damage to the outer myelin (neurapraxia), but can result in injury to the axon as well. Following onset of acute nerve damage, evidence of electrophysiologic abnormalities in nerve conductions and EMG may require up to 3 weeks to occur.

Vocal Fold Paresis and Paralysis

The strict definition of vocal fold paresis and paralysis is motion impairment or complete lack of motion caused by damage or loss of *innervation* to muscle. In general use, these terms describe the *symptom* of motion impairment, which can be caused by nerve injury or mechanical fixation. More precise terminology would use the descriptor vocal fold motion impairment or vocal fold immobility until the etiology has been ascertained. Because it can be difficult to distinguish between paralysis and fixation by laryngoscopy alone, additional diagnostic measures may be necessary. LEMG may suggest paralysis (Fig. 70.6), fixation, or synkinesis. Direct laryngoscopy under anesthesia will permit evaluation for posterior glottic stenosis and palpation of the cricoarytenoid joint for ankylosis. If the cause is not obvious (trauma or iatrogenic), a typical workup would include a thorough history and imaging of the course of the vagus and RLN from skull base to mediastinum to search for possible lesions along the course of the nerve.

The clinical presentation of vocal fold paralysis varies from asymptomatic to severe laryngeal dysfunction. Patients may complain of an asthenic (weak), breathy, and diplophonic voice (the voice is heard at two distinct vibratory frequencies because each cord is at a different tension). Because the patients cannot approximate the vocal folds tightly (glottal incompetence) they will suffer phonatory shortness of breath due to rapid air escape and have a weak and incompetent cough. Because the RLN also contributes to innervation of the pharyngeal musculature and the cricopharyngeus muscle, dysphagia may be prominent. Additionally, loss of sensation in the hypopharynx secondary to superior laryngeal nerve compromise can result in pooling of secretions in the pyriforms and contribute to dysphagia and aspiration risk. Laryngoscopy reveals decreased mobility of the affected vocal cord, a glottal

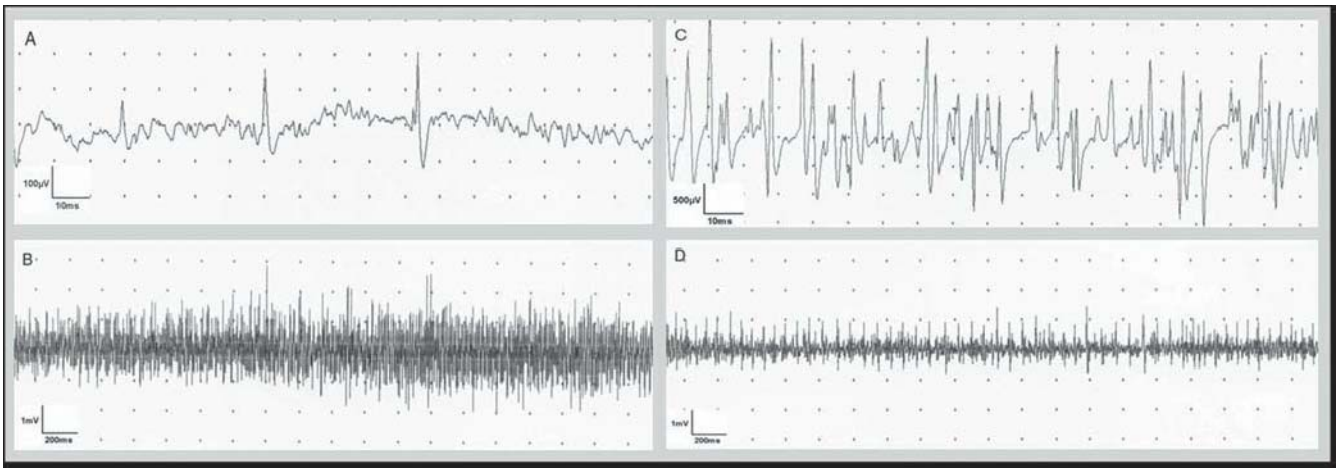

Figure 70.6 LEMG sequence of a patient with a left vocal fold paralysis caused by injury of the recurrent laryngeal nerve. **A:** Tracing of the electrical activity of the right thyroarytenoid muscle taken during quiet respiration, showing isolated firing of MUP of normal morphology. **B:** The normal, full interference pattern for the right thyroarytenoid, obliterating the baseline. **C:** Tracing of the electrical activity of the left thyroarytenoid muscle taken during phonatory effort shows multiple polyphasic giant waves indicative of reinnervation. **D:** A decreased interference pattern for the left thyroarytenoid, demonstrating the picket-fence pattern characteristic of neuropathy.

gap, pooling of secretions in the ipsilateral pyriform sinus, abnormalities in position of the arytenoid tower, and occasionally decreased sensation.

Because vocal fold paresis or paralysis often recovers spontaneously or patients develop satisfactory compensation, a logical treatment plan must be formulated to account for the natural progression of the injury. If potential for spontaneous recovery exists, a temporary augmentation procedure can provide immediate airway stabilization and restore glottal competence. This will improve vocalization, cough, swallow, and help prevent aspiration. If laryngeal EMG or the clinical scenario (such as latrogenic nerve transection) imply a poor chance of recovery, the patient would be a candidate for a more permanent rehabilitation procedure (see Chapter 69).

Bilateral vocal fold paralysis most often results from a surgical misadventure (thyroidectomy, esophagectomy). The voice may be close to normal, but patients can develop significant airway compromise from inability to abduct the vocal folds. Interestingly, even after bilateral injury, patients may tolerate the restricted airway for days to years before developing symptoms, which may then be misdiagnosed as asthma or bronchitis until laryngeal examination. Thus, it is always important to inquire about previous surgery—especially thyroidectomy, esophageal, or spine surgery—and examine the patient for revealing scars. If the airway compromise is severe, a tracheotomy may be required. This is sometimes done awake because it may not be absolutely evident if the embarrassment is caused by nerve injury, posterior glottic stenosis, or other laryngeal fixation. After the patient's airway has been secured, a direct laryngoscopy with evaluation of the cricoarytenoid joint should be performed. In less emergent circumstances, other vocal fold lateralization procedures can be considered (e.g., partial or total arytenoid ablative procedures, posterior cordotomy, an external lateralization stitch, or selective chemical neuromuscular denervation [39]) (see Chapter 62). These procedures are generally designed to maintain approximation of the anterior membranous vocal fold for phonation but increase the respiratory glottis.

Superior Laryngeal Nerve Paresis

Superior laryngeal nerve paresis manifests as sensory loss from the internal branch with motor weakness of the cricothyroideus muscle from the external branch of the RLN (Fig. 70.7). This can occur independently of recurrent nerve injury, and can be iatrogenic (thyroidectomy, neck dissection) or idiopathic. A unilateral sensory loss can cause throat clearing, coughing, and a globus sensation. A bilateral sensory loss can lead to severe, life-threatening aspiration. The vocal characteristics are caused by asymmetric cricothyroideus muscle function. Although individuals without complicated vocal demands may not notice any vocal defect, singers will complain of a ceiling effect (i.e., inability to reach their highest registers). Additionally, individuals may complain of vocal fatigue and diplophonia. On examination, pooling of secretions in the pyriform on the affected side reflects the sensory defect (40) The diagnosis can be confirmed by LEMG. Although some advocate voice therapy for unilateral loss and cricothyroid approximation for bilateral loss, no proven, useful medical or surgical interventions are available.

Acute Immune-Mediated Polyneuropathy—Guillain-Barré Syndrome

GBS is a heterogeneous grouping of immune-mediated inflammatory polyneuropathies generally characterized by motor, sensory, and autonomic dysfunction. In its most

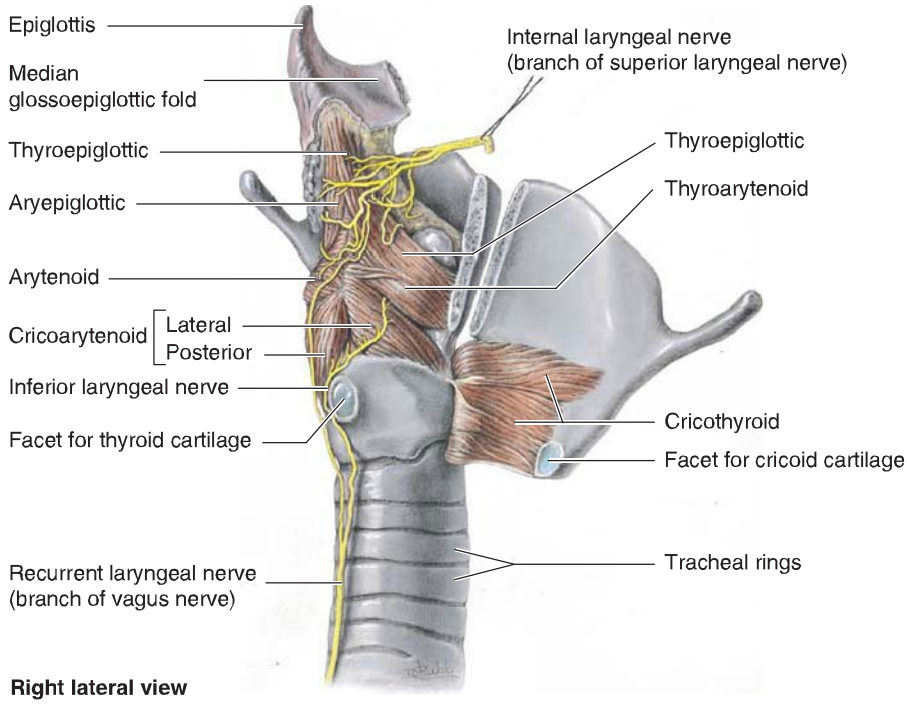

Figure 70.7 Details of the superior and recurrent laryngeal nerves. (From Moore KL, Dalley AF II. *Clinical oriented anatomy*, 4th ed. Baltimore, MD: Lippincott Williams & Wilkins, 1999.)

common form, GBS is characterized by progressive symmetric ascending muscle weakness, paralysis, and hyporeflexia with or without sensory or autonomic symptoms. In severe cases, muscle weakness may lead to respiratory failure.

GBS is a sporadic disorder with an incidence of 1 to 2 cases per 100,000 in North America and Europe and a 2:1 male predominance (41). In 60% of cases, acute inflammatory demyelinating polyneuropathy is preceded by a respiratory tract infection (e.g., cytomegalovirus, Epstein-Barr virus) or gastroenteritis (*Campylobacter jejuni*). The pathobiology of the disease is felt to result from postinfectious molecular mimicry in which nerve antigens are attacked by the immune system because they resemble antigens presented by microbes.

Miller Fisher syndrome is a variant of GBS that presents with the triad of ophthalmoplegia, ataxia, and areflexia. This form manifests as a descending paralysis, proceeding in the reverse order of the more common form of GBS and usually affects the eye muscles first. Up to 50% of patients will have bulbar palsy with prominent dysarthria and dysphagia (42).

The diagnosis is usually made by nerve conduction studies. With prompt treatment by IV immunoglobulins or plasmapheresis, together with supportive care, the majority of patients will recover completely. In the modern setting, acute mortality is about 2%. In general, slow spontaneous recovery occurs over a period of weeks or months. Most patients can expect complete recovery or minor sequelae; about 20% have a persistent disability. Individuals with Miller Fisher variant have an excellent prognosis.

Neuromuscular Junction

Myasthenia Gravis

MG has distinct implications for neurolaryngology, beginning with the first description in the 17th century by the English physician Thomas Willis, who described a woman who had transiently lost speech and was rendered "as mute as a fish." The disease has a prevalence of 14 to 20/100,000, and like many other autoimmune disorders, has a female predilection, with a bimodal incident distribution of young women in their 20s and 30s, and older men in their 40s and 50s. MG is associated with other autoimmune disorders, including Graves hyperthyroidism in about 10% of MG patients. Antibodies in MG are directed against the postsynaptic acetylcholine receptors, competitively inhibiting acetylcholine binding. These antibodies are produced from T cells that have their origin in the thymus.

MG patients complain of weakness that worsens toward the end of the day and with repeated activity or movement. Myasthenia affects proximal muscles more than distal muscles, and may involve extraocular muscles exclusively (ocular myasthenia), causing diplopia or ptosis. Patients with ocular myasthenia frequently progress to generalized muscle involvement.

If disease is localized to the throat, patients can have difficulty speaking, breathing, or swallowing, and examination of larynx and palate will reveal fatigue with repetitive movements. Because of the sustained contraction of the vocalis and cricothyroideus muscles required to maintain a high musical pitch, individuals with myasthenic involvement of these muscles fatigue quickly with a lowering of the pitch over a few seconds (43). Rhinolalia (hypernasal

voice) and nasal regurgitation of food are manifestations of myasthenic involvement of palatal musculature.

Diagnostic testing for MG include serologic, provocative, and electrophysiologic testing (44). Binding acetylcholine receptor antibodies (AchRAbs) can be detected in serum, and are positive in 85% of generalized myasthenics and 50% of patients with ocular MG. Blocking antibodies to the acetylcholine receptor are positive in approximately 1% of patients with negative binding AchRAbs. Antibodies to muscle-specific kinase may be positive in up to 40% of myasthenics with negative AchRAbs. The edrophonium (Tensilon) stimulation test involves injection of a small amount of a short-acting acetylcholine esterase inhibitor (edrophonium 0.05 to 0.1 mg/kg, slow push over 1 minute), which is deemed positive if the patient's weakness, ptosis, ocular misalignment, or vocal cord paresis transiently resolves or improves. Because edrophonium acts at both nicotinic and muscarinic acetylcholine receptors, premedication with atropine may be performed to prevent symptomatic bradycardia.

Additional electrophysiologic testing that aids in diagnosis includes repetitive nerve stimulation and single fiber EMG. These tests can be positive in many diseases of the peripheral nervous system, so is not specific for MG.

Early detection is invaluable because medical treatment is effective and potentially lifesaving. Exacerbations may result in respiratory compromise and require intensive care unit stay. Medications either act to increase the amount of acetylcholine in the synaptic cleft by inhibiting the breakdown enzyme acetylcholine esterase (pyridostigmine) or modifying immune response (steroids, steroid-sparing agents including mycophenolate and azathioprine, and intravenous immunoglobulin [IVIG] and plasma exchange for acute exacerbation). Thymectomy for thymic hyperplasia or thymoma may ameliorate the condition, or even be curative, in some cases.

Myasthenic Syndrome or Lambert-Eaton Syndrome

Lambert-Eaton Myasthenic Syndrome is a paraneoplastic condition primarily associated with small cell lung and other cancers (45). Antibodies against tumor antigens cross-react with epitopes on voltage-gated calcium channels and prevent transmission presynaptically. The patient presents with weakness that improves with exertion and repetitive movement, in contrast to MG. Treatment is 3,4 diaminopyridine to aid in acetylcholine release from the synaptic terminal. Steroids, IVIG, and plasmapheresis may be of some benefit in immune modulation. The syndrome may precede discovery of actual cancer by up to several years, and its presence warrants a search for a primary neoplasia.

Botulism

Botulism is the paralytic disease caused by poisoning with the toxin of the anaerobic, spore-forming, gram-positive rod *Clostridium botulinum*. Botulism most commonly occurs following ingestion of improperly home-canned food. Fulminating weakness, which begins 12 to 72 hours after ingestion of the toxin, is manifested initially by diplopia, ptosis, facial weakness, dysphagia, and rhinolalia, then progressing to respiratory failure. Weakness usually appears last in the limbs. Also present may be the anticholinergic symptoms of blurry vision, dry mouth, paralytic ileus, and postural hypotension. Symptoms can progress for several days. Antitoxin is available, although the effect on the disease course is unclear. Guanidine hydrochloride (facilitates release of acetylcholine from nerve endings) can improve muscle strength. Supportive care is the mainstay of treatment.

Botulinum Toxin Mechanism

The bacteria *C. botulinum* is an anaerobic, spore-forming, gram-positive rod that is a soil organism. Disease is caused by (a) inoculation of a wound with local proliferation of the bacterium and systemic spread of the toxin; (b) ingestion of the spores in improperly cooked food, with germination and growth in the gut and absorption of the toxin; or (c) ingestion of preformed toxin in improperly cooked foods with systemic absorption. The toxin is heat labile and can be inactivated by boiling for several minutes.

Seven serotypes (A–G) exist, which exert their paralytic effect by inhibiting the exocytotic release of acetylcholine at the neuromuscular junction, and may have inhibitory activity in the afferent transmission of pain by preventing the release of pain mediators such as substance P, calcitonin gene-related peptide, glutamate, or neurokinin A. The toxins are composed of a heavy and light chain. The heavy chain is responsible for neuron-specific binding and internalization, and the light chain is a protease that cleaves one of the fusion proteins responsible for vesicle docking, thus preventing neurotransmitter exocytosis. Specific serotypes target different docking proteins, botulinum toxin A and E target synaptosomal-associated protein 25 (SNAP-25), and botulinum toxin B, D, F, and G target synaptobrevin, and type C targets syntaxin. It takes approximately 3 months for the Snap-25 to become functional again, and 2 months for synaptobrevin to be regenerated, which correlates to the duration of muscular weakness seen clinically.

When neuromuscular transmission is initially interrupted, the axon responds by creating sprouts to establish new junctions. These new junctions allow weak stimulation at about 1 month. At approximately 90 days, the original terminals regain activity, resulting in regression of the sprouts.

The potency of the toxin is determined by *in vivo* mouse assays. One unit of the brand name BOTOX® (botulinum toxin A—Allergan) is defined as the amount of toxin required to kill 50% of a batch of female Swiss-Webster mice. The lethal dose in humans is estimated to be approximately 3,500 U of BOTOX®. Dysport (Ipsen Pharmaceuticals, Berkshire, England) is also botulinum toxin type A, but 1 U of BOTOX® is felt to be equivalent to 3 to 4 U of Dysport. Myobloc (Elan), which is botulinum toxin type B, has slightly different characteristics. It has a faster onset (24 hours vs. 1 to 3 days) and a shorter duration (2 months vs. 3 months). One unit of BOTOX® is felt to be equivalent to 54 U of Myobloc.

Individuals can form antibodies to the toxin, which appear to cause no harm in terms of anaphylactic reactivity, but do render the patients resistant to the paralytic effect of the toxin. Individuals immunoresistant to one serotype of toxin usually receive benefit from switching to another serotype.

Aminoglycoside Antibiotics

Large doses of aminoglycoside antibiotics can produce a clinical syndrome like botulism owing to prevention of acetylcholine release from nerve endings. This is likely related to calcium channel blockade. Symptoms resolve if the drug is discontinued. These antibiotics are best avoided in patients with disturbances of neuromuscular transmission and should be avoided in patients with MG.

Myopathic Disorders

Myopathies

Myopathies, primary disorders of muscle, are diseases that can be classified as muscular dystrophies, genetic disorders resulting in aberrant microcellular structure, or myositides, inflammatory muscle diseases. Myopathies generally affect more proximal muscles than distal muscles, and result in muscle weakness and atrophy. Diagnostic modalities include needle electromyography (nEMG), serum creatine kinase, myoglobin levels, and muscle biopsy.

Muscular Dystrophies

Muscular dystrophies are inherited myopathies that affect muscle membrane and cytoskeletal elements (46). They may have associated cardiomyopathies and other organ system dysfunction. They may be accompanied by mild to moderate elevations of serum creatine kinase. Examples of muscular dystrophies include X-linked *Duchenne* and *Becker* diseases that come from production of an abnormal dystrophin membrane protein. They affect boys in childhood and their teens. *Limb-girdle* and *facio-scapular-humeral muscular dystrophies* are inherited in various patterns, affect a variety of muscle proteins, including calpain, caveolin, and lamin, and affect people in the later teens and adulthood. The pattern of weakness and atrophy is evident in the named disorder.

Oculopharyngeal muscular dystrophy is a rare muscular dystrophy of variable inheritance pattern causing ptosis and ocular misalignment, as well as dysphagia and tongue weakness. Symptom onset is in the late teens to forties. Expansion of the trinucleotide repeat GCG on chromosome 14 encoding the protein polyalanine is implicated in the pathogenetic mechanism. *Myotonic dystrophies*, so named because of the presence of clinical and electrical myotonia due to muscle membrane abnormalities that create abnormal patterns of contraction and relaxation, may affect distal or proximal musculature. *Myotonic dystrophy type I* (DM1) affects distal hand muscles, neck flexors, and tongue and palate, beginning in early childhood. DM1 is caused by a trinucleotide repeat expansion on chromosome 19 affecting the myotonin kinase enzyme, while *myotonic dystrophy type 2* (DM2) also called proximal myotonic myopathy, is caused by an expansion of a tetranucleotide repeat affecting the zinc finger 9 membrane protein. DM2 has an onset in later childhood and has less face, tongue, and palate involvement.

Inflammatory Myopathies

Polymyositis and *dermatomyositis* are inflammatory myopathies often associated with lung carcinoma, autoimmune disorders, or polio. These myopathies are often associated with muscle pain, tenderness, dysphagia, and respiratory difficulties. Dermatomyositis is clinically distinguished from polymyositis by the presence of skin findings including a heliotrope rash and Gottron papules on the extensor surfaces of the hands but has a distinct pathophysiology. Dysphagia can be a presenting symptom (47), but most patients will often also have proximal muscle weakness as evidenced by difficulty in standing up from a seated position without using their arms to assist, or difficulty in sitting up from a supine position. Patients may have serum creatine kinase elevation several hundred times the normal indicative of the degree of muscle breakdown from the disorder; EMG shows evidence of myonecrosis and muscle biopsy will show inflammatory cells. The course can progress rapidly, and treatment with steroids and other immune modulators is indicated.

Inclusion body myositis (IBM), has an unusual distribution insofar as it has preference for the anterior thigh muscles and the finger flexors of the hands. Dysphagia, affecting the upper one-third of the esophagus is present in half of patients with IBM. Age of onset is usually after 50 years, and is slowly progressive over one to two decades. Muscle biopsy is distinct in showing the presence of rimmed vacuoles. IBM generally responds poorly to immune modulatory treatment (48).

ELECTROMYOGRAPHY OF LARYNGEAL AND PHARYNGEAL MUSCLES

nEMG is a valuable tool in the evaluation of laryngeal and pharyngeal musculature function. The nEMG evaluation has two primary functions: (a) evaluation of the stability of the muscle membrane and (b) evaluating changes to the motor unit. Remember that the motor unit is the summation of the motor neuron (from the nucleus ambiguus), the axon, and all the muscle fibers it supplies. Therefore, characterizing any alterations to the motor unit waveforms may be diagnostic of a motor neuron disorder, damage to the peripheral nerve axon, or an intrinsic muscle lesion.

nEMG detects electrical potentials at the recording electrode, relative to the potentials at the reference electrode, and the difference between potentials at these two sites is displayed. This effectively cancels out any ambient electrical activity not specific to the reference site. The output is digitally processed for presentation on a computer screen and loudspeaker for both visual and audio interpretation.

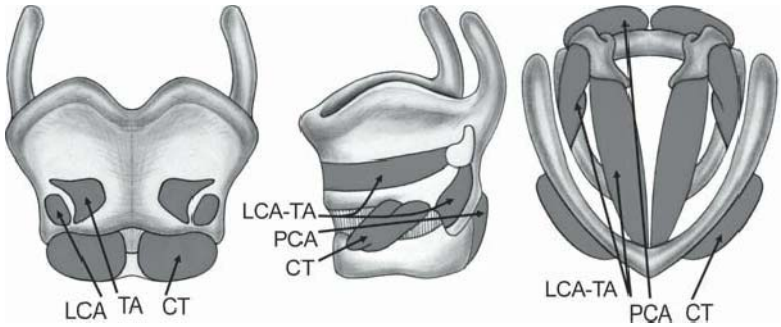

Figure 70.8 Needle electrode placement for the thyroarytenoid (*TA*), cricothyroid (*CT*), lateral cricoarytenoid (*LCA*), and posterior cricoarytenoid (*PCA*).

Laryngeal nEMG (LEMG) is performed using a 25 to 27 gauge monopolar needle recording electrode with a surface reference electrode or a concentric needle (with its own reference). Both require a surface ground electrode. The monopolar needle is Teflon-coated, glides through muscle with greater ease, and also has a greater recording volume. The concentric needle has both recording and reference electrodes contained in the needle, is not coated in Teflon, and has a recording volume of roughly half the size of the monopolar needle. A 37-mm length needle is sufficient for most patients. Electrical waveforms recorded from a monopolar needle are wider and larger than those from a concentric needle, but a concentric generally yields a more precise recording for evaluation of waveforms, particularly for concerns of myopathy.

For LEMG, a needle electrode is inserted through the skin and into the muscle of interest. Proper insertion is verified by asking the patient to perform appropriate verification tasks such as vocalization (for the thyroarytenoid) or sniffing (for the PCA). EMG evaluation consists of sampling electrical activity during three events: needle insertion into the selected muscle, spontaneous electrical activity when the muscle is at rest, and volitional electrical activity during muscle contraction.

Technique

In general, three muscle groups are sampled during routine LEMG: the cricothyroid reflects superior laryngeal nerve function, and the TA-LCA and PCA reflect RLN function.

The cricothyroid muscle is accessed by inserting the needle electrode 5 mm lateral to midline at the lower edge of the cricoid cartilage and directing the tip of the needle toward the inferior tuberculum of the thyroid cartilage. Correct placement is verified by increased activity with glissando. The TA-LCA muscle is accessed by inserting the needle through the cricothyroid membrane at the midline and directing the tip submucosally and laterally toward the superior thyroid corneau. Correct placement is verified by increased activity with phonation. The PCA can be accessed laterally by laryngeal rotation or transglottically by piercing the posterior lamina of the cricoid cartilage. Correct placement is verified by increased activity during sniffing but not during phonation (Fig. 70.8).

When the needle is felt to be in the muscle of interest, the patient is asked to rest and breathe quietly to evaluate for spontaneous activity. In general, complete relaxation of a healthy striated muscle gives no EMG activity, or only minimal nonpropagated depolarizations owing to proximity to the motor endplate. Muscles that have had neuropathic damage with denervation will develop abnormal spontaneous activity such as fibrillation potentials and positive sharp waves approximately 2 to 3 weeks after injury, which will persist until reinnervation occurs or until the motor endplates of the muscle degenerate (Fig. 70.9).

Volitional activity is measured by asking the patient to perform selected vocal tasks. The resultant motor unit potentials (MUPs) are evaluated for phase, duration, amplitude, and the interference or recruitment pattern.

A normal MUP is bi- or triphasic (phases are counted by noting the number of times the potential crosses the baseline). Greater than four phases is abnormal and termed polyphasic. Polyphasia occurs when the single muscle fibers are not well synchronized. Although this can occur for many different reasons, it most often occurs following denervation of muscle fibers, as adjacent axons sprout to reinnervate the orphaned muscle fibers after a neuropathic injury. Over time, the polyphrasia resolves as the motor

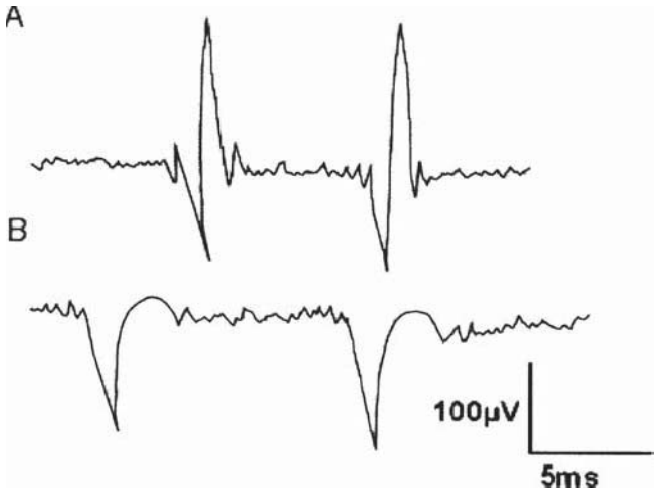

Figure 70.9 Diagrams of abnormal spontaneous activity suggestive of denervation. **A:** Fibrillation potential. **B:** Positive sharp wave.

unit consolidates into a unit of wider duration and greater amplitude than what existed prior to the injury. Thus "polys" and "giant MUPs" characterize neuropathic injury.

In myopathic conditions, the number of functioning muscle fibers in a motor unit decreases and the amplitude of the associated MUP also decreases. Myopathic MUPs, therefore, are often polyphasic, but have decreased amplitude and duration (brief, small amplitude polyphasic potentials [BSAPs]; Fig. 70.10).

Finally, the recruitment pattern is determined. As a muscle is contracted intensely, the frequency of motor unit firing will increase, filling the display screen with MUPs such that individual patterns are not discernible and the baseline is obliterated. A *full recruitment* pattern is normal. In a neuropathic process, there is loss of motor units and despite full firing of all available units, the baseline will not be obliterated yielding a *reduced recruitment* pattern. This pattern visually appears as a picket fence on the EMG screen, and the auditory signal sounds like the dragging of a stick along a picket fence or the monotonous firing of a machine gun. In this case, a single motor unit may have to fire at a greater rate to produce the same muscle power that several normally recruited units would create. So, reduced recruitment indicates a decrease in functioning motor units. With a myopathic process, there is no loss of motor units, but the power of an individual motor unit is less than normal. Therefore, more motor units are more quickly engaged to produce the same amount of power as a normal motor unit, hence termed *early recruitment*. This produces an interference pattern that is reduced in amplitude but still able to obliterate the baseline (Fig. 70.11).

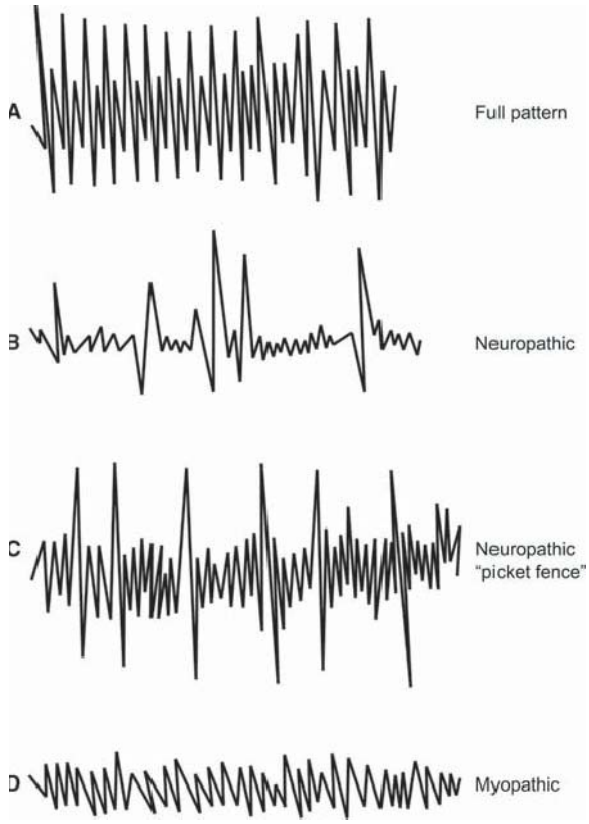

Figure 70.11 Examples of recruitment patterns. **A:** Normal pattern with a full interference pattern obliterating the baseline. **B:** Reduced recruitment seen with a neuropathic process. Note that the baseline is not obliterated. **C:** "Picket-fence" pattern characteristic of a neuropathic process. **D:** Early recruitment pattern seen with a myopathic process. The baseline is obliterated quickly with an overall lower amplitude.

Uses in Laryngology

1. Paralysis versus fixation: Vocal fold paralysis should have the EMG findings of neuropathy, whereas cricoarytenoid arthritis, dislocation, and posterior glottic scarring should yield a normal EMG pattern (49,50).
2. Prognosis of paralysis (51): In general, laryngeal EMG better predicts which patients will NOT recover vocal fold motion and are thus candidates for early rehabilitation. Presence of spontaneous activity (fibrillations and positive sharp waves), polyphasic potentials, absence of normal MUPs, synkinesis (52), and a decreased recruit-

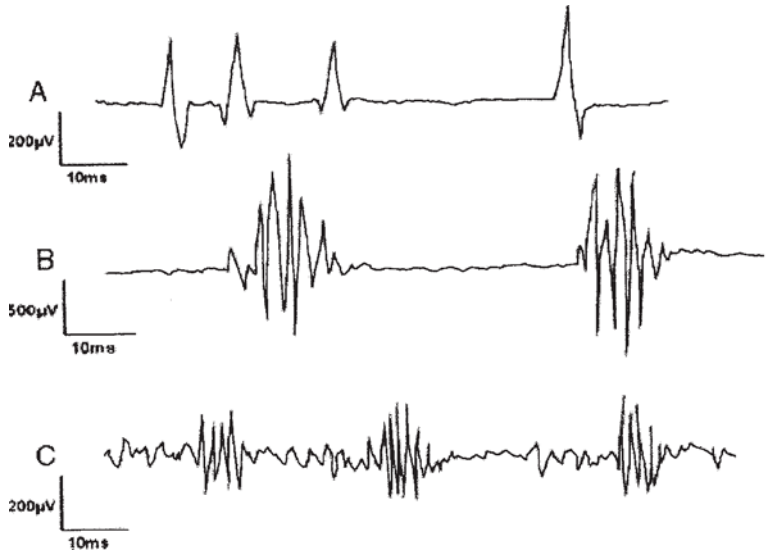

Figure 70.10 Examples of MUP. **A:** Normal units. **B:** Neuropathic units. **C:** Myopathic units.

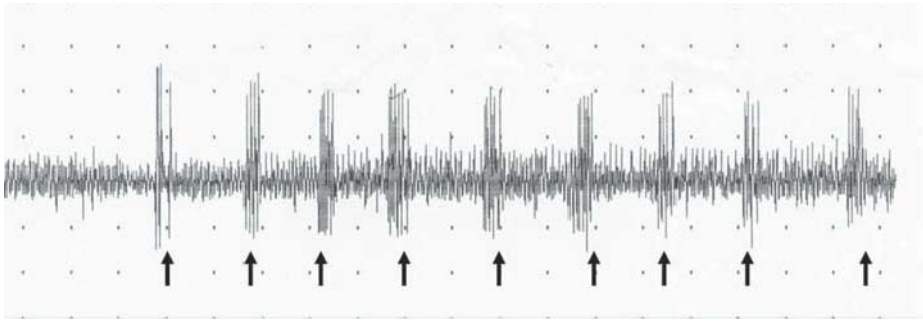

Figure 70.12 Synkinesis. A recording from the thyroarytenoid muscle of a patient with long-standing vocal fold immobility, demonstrating inappropriate activation when the patient is asked to sniff (*arrows*), an abductory task during which the thyroarytenoid muscle is normally not active.

ment pattern are indications that the nerve damage is severe and may not recover. Presence of normal MUPs, a normal recruitment pattern, and absence of spontaneous activity indicate a good chance of return of function. A mixed pattern gives an intermediate prognosis. This information must be interpreted in light of the clinical history and time course (53). Recent advances in quantitative laryngeal EMG demonstrate significant improvements in ability to prognosticate return of function (54).

3. Site of lesion localization: EMG testing of the cricothyroid muscle compared with the thyroarytenoid muscle allows isolation of the two components of vagal innervation to the larynx. A high injury will show abnormalities in the EMG pattern of both muscles, and an isolated superior or recurrent injury will show an abnormal pattern in one muscle only.
4. Synkinesis: EMG testing of the TA-LCA muscle and the PCA muscle will show inappropriate activation of muscle groups with certain laryngeal gestures. So, the TA-LCA will be activated with sniffing, or the PCA will be activated with voicing. This is felt to be caused by misdirected regeneration of nerve fibers between abductor and adductor muscle groups (52) (Fig. 70.12).
5. Identification of appropriate muscles for BOTOX injection.
6. EMG can be used to determine a neurologic diagnosis (MG, ALS, myopathy).
7. Intraoperative nerve monitoring.
8. Biofeedback in speech and swallowing disorders.
9. EMG can determine the relative levels of functional neuromuscular innervation of each vocal fold. This information can influence surgical and procedural decision making for laryngeal reinnervation, vocal fold augmentation, arytenoid adduction, or a destructive glottic enlargement procedure.

TABLE 70.3 NEUROLARYNGEAL DISORDERS, BY LARYNGEAL PRESENTATION

Presentation	Spastic	Hypokinetic	Hyperkinetic	Ataxic	Paresis/Paralysis
Vocal Fold Appearance	Variable	Rigid/bowing on phonation	Hyperabducted	Uncoordinated, decreased mobility	Atrophied, flaccid, fasciculating
Anatomical Structures Involved	UMN/corticobulbar tracts	Basal ganglia	Basal ganglia	Cerebellum	Brainstem—nucleus ambiguus; peripheral nerve; neuromuscular junction; muscle
Example Disorders	PLS, ALS, stroke, MS	Parkinson disease, MSA	Dystonia, tremor, myoclonus	Friedreich ataxia, stroke, MS	ALS, brainstem stroke, GBS, superior laryngeal nerve injury, MG, polymyositis
Treatment	Botulinum toxin, voice and swallowing therapy vocal fold medialization	Voice and swallowing therapy, vocal fold medialization	Botulinum toxin, voice and swallowing therapy	Voice and swallowing therapy, vocal fold medialization	Tracheostomy(severe), vocal fold medialization or lateralization, voice and swallowing therapy

UMN, Upper Motor Neuron; PLS, Primary Lateral Sclerosis; ALS, Amyotrophic Lateral Sclerosis; MS, Multiple Sclerosis; MSA, Multiple Systems Atrophy; GBS, Guillian-Barre Syndrome; LSVT, Lee Silverman Vocal Therapy.

HIGHLIGHTS

- The accurate diagnosis of neurologic disease of the larynx relies on both history and physical examination, with adjunctive testing, LEMG, and neurology consultation.
- Flexible transnasal laryngoscopy is the preferred method of laryngeal evaluation for neurologic disease. Transoral rigid laryngoscopy or mirror examination significantly alters laryngeal mechanics owing to tongue traction and inability of the patient to perform normal speech and vocal tasks.
- Neurologic disorders of the larynx are, for the most part, disorders of function as determined by the structure disrupted (Table 70.3).
- Behavioral therapy (LSVT) is the only treatment modality that has shown a consistently positive and lasting effect on the vocal function in many parkinsonian patients.
- An individual with parkinsonian features and vocal fold immobility should be evaluated for multisystem atrophy. If these individuals develop sleep disorders, they are at risk for sudden death.
- Vocal fold paralysis can be diagnosed in an individual with vocal fold immobility when it can be shown by history or examination that there has been damage to the RLN, EMG evidence indicates denervation, or palpation of the cricoarytenoid joint confirms lack of fixation.
- Spasmodic dysphonia is a focal laryngeal dystonia. Botulinum toxin injections into the laryngeal musculature are the treatment of choice, and have both peripheral and central neurologic effects. Vocal spasms are ameliorated by weakening the dystonic musculature, and CNS function is modulated through changes in peripheral feedback. Surgical therapy yields transient results and speech and medical therapy are useful only as an adjunct to toxin injection.
- LEMG is a useful adjunct in the diagnosis of neurologic disease of the larynx and is critical to guide medical and surgical treatments. LEMG is especially helpful in the prognostication of recovery from vocal fold paralysis.

71 Voice Therapy for the Treatment of Voice Disorders

Jackie Gartner-Schmidt

The otolaryngologist and speech–language pathologist are critical members of the voice care team (1). The role of each, however, is different. Patients enter the medical setting with the medical intervention model in mind; namely, is there a medicine or surgery that will fix their voice problem? Whereas otolaryngologists take responsibility for effecting change either medically or surgically, a speech–language pathologist teaches patients to adopt responsibility for behavioral change because, in its most basic sense, voice therapy teaches patients to modify faulty or compensatory vocal behavior. Persuading patients to become responsible for their vocal behaviors may be difficult, but it is paramount to successful voice therapy (2–4). Otolaryngologists are the first people to impress this message to their patients: voice therapy is often successful but requires active participation from the patient. Unfortunately, there are high rates of attrition in voice therapy (5–7). It is important for otolaryngologists to refrain from saying "I want you to *try* voice therapy" as often this verbiage can plant the seeds of noncompliance and attrition. In addition, because most patients assume the medical model of rehabilitation, a rapid restoration (i.e., "quick fix") of voice is expected. Behavioral modification is not a "quick fix" and patients need to understand this basic premise.

A common question posed by otolaryngologists to speech–language pathologists is, "What do you do in voice therapy?" In this chapter, a model of the component parts of voice therapy will first be illustrated followed by a condensed description of some of the most commonly used voice therapies and their applications to specific voice disorders. In addition, approximate treatment durations, reference to appropriate referrals, and limitations to therapeutic success will be discussed.

The Venn diagram in Figure 71.1 illustrates the key categories of any voice therapy program: increase vocal hygiene, decrease phonotrauma, and increase coordinated voice production. Although the circles delineate separate entities, they are not mutually exclusive. This model is very similar to the component parts (i.e., categories) of voice therapy. The speech–language pathologist determines which category (i.e., circle) to work with the patient, so modification of the appropriate maladaptive behaviors can be emphasized. The speech–language pathologist must also realize that patients may be in more than one circle. The first two circles, increase vocal hygiene and decrease phonotrauma, represent indirect approaches to voice therapy, whereby the speech–language pathologist essentially educates the patient concerning how his or her laryngeal mechanism works and what may cause harm. The third circle, increase coordinated vocal production, represents a direct approach to voice therapy; here, the speech–language pathologist directly alters the patient's speaking technique in an attempt to increase vocal quality and efficiency. Indirect voice therapy usually requires 1 to 2 weekly sessions, whereas direct voice therapy usually requires 4 to 6 sessions (e.g., weekly sessions are ideal but not mandatory). This therapy schedule mirrors preoperative and postoperative therapy, in that patients generally receive 1 to 2 sessions of preoperative voice therapy and 4 to 6 sessions of postoperative therapy. Patients may also benefit from a subsequent series of voice therapy (1 to 3 sessions) months after the initial voice therapy to evaluate transfer and retention of the new vocal behaviors.

VOCAL HYGIENE

Vocal hygiene is the foundation of voice therapy. Patients are taught to take care of their vocal fold tissues by keeping hydrated and limiting laryngeal irritants. The best voice therapy starts with the patient taking active control of his or her vocal health. In addition, good vocal hygiene may decrease susceptibility to postoperative scarring (8). Two general topics are included in this circle: hydration and laryngopharyngeal reflux (LPR).

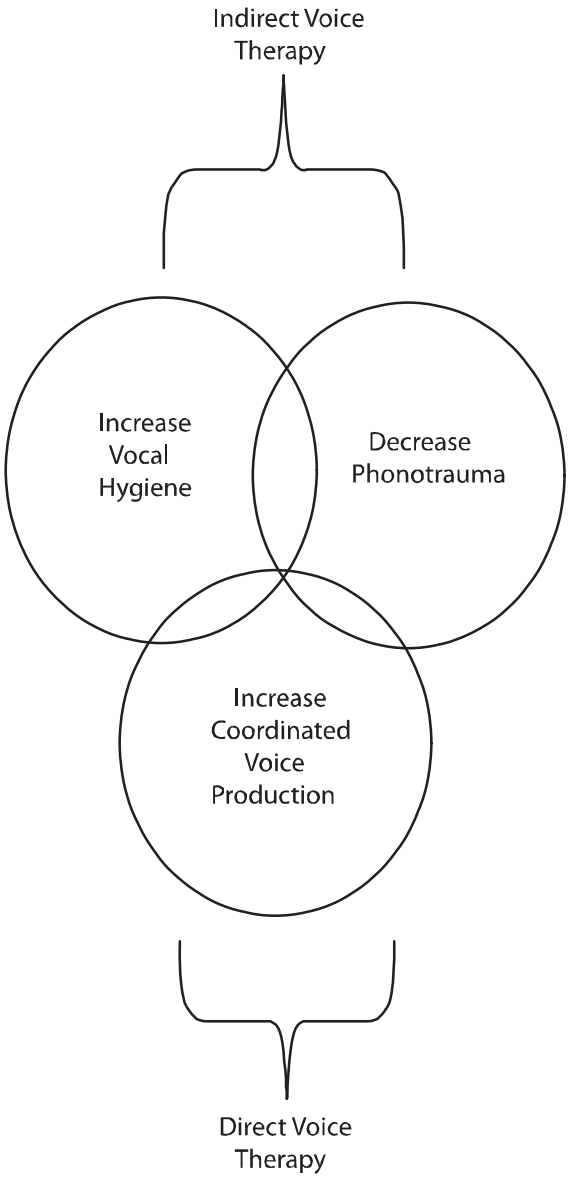

Figure 71.1 Model for voice therapy: three categories.

Hydration

Laryngeal sicca is increased viscosity of laryngeal secretions and is a result of the reduction of water in the body. Patients should be educated concerning why drinking water is important to the physiology of vocal production; they should not simply be told "to drink 8 glasses of water a day." Increased viscosity of secretions may cause increased viscosity of vocal fold surfaces and, in turn, cause increased heat, friction, and edema of the vocal folds, which may increase the risk of phonotrauma (9). Research has shown that hydrated vocal folds vibrate with less subglottic pressure than do nonhydrated vocal folds, especially at high pitches (10–14). Hydrated vocal folds are less predisposed to trauma than dry vocal folds and show more resilience from trauma (i.e., phonotrauma) than dry vocal folds (9,12–15). Interested readers are referred to a review article by Leydon et al. (16). Patients may hydrate internally (i.e., drink water), externally (i.e., steam shower, steam inhaler, and/or hot water vaporizer), or both, based on medical history and individual need. Hygiene programs should be individualized for each patient. For example, if a patient is diagnosed with congestive heart failure, they may not be able to drink large quantities of water. In addition, smoking cigarettes or other substances should be eliminated. Engaging in voice therapy when patients continue to use laryngeal irritants (e.g., smoking) is obviously counterproductive to therapeutic success.

Laryngopharyngeal Reflux

Patients diagnosed with LPR should be medicated (e.g., proton pump inhibitors, H_2 blockers, antacids) for this disease and engage in behavioral LPR treatment if needed (see Chapter 59). LPR may inflame the vocal folds, change the biomechanics of phonation, and potentially influence vocal fold pathologies (17). Initiating voice therapy with the healthiest vocal folds possible is the launch pad of therapy. Voice therapy is often used in conjunction with medical intervention in this circle.

DECREASE PHONOTRAUMA

The second circle is entitled decrease phonotrauma (vocal abuse/overuse) and is defined as a voice produced with too much effort for increased durations of time or at an inordinately high volume, often resulting in organically based vocal fold pathology. Phonotraumatic vocal behaviors may result in benign vocal fold lesions (e.g., nodules, cysts, fibrous mass, polyps) and scar. Such vocal behaviors as screaming, yelling, throat clearing, continued voicing while sick, vocalization during vigorous exercising, vocal overuse, and speaking over background noise are examples. Although modern-day voice therapy is much more than a "do/don't" list, the prevailing "don't" recommendation in voice therapy is "don't scream." High-pitched screaming may result in vocal fold hemorrhage. Vocal overuse may also cause vascular changes (i.e., vascular permeability) in the vocal folds, which may predispose patients to have small and large hemorrhages, often recurrent in nature. Cumulative microtrauma to the vocal fold tissues may result in scarring, sulcus vocalis, or both. Voice therapy is often used in conjunction with surgical intervention for phonotraumatic lesions in this circle.

Patients should be educated concerning the first two circles (increase vocal hygiene and decrease phonotrauma) in the first and second sessions of voice therapy. If patients show difficulty with compliance to increasing vocal hygiene and decreasing phonotrauma, prognosis for improvement in voice therapy is guarded.

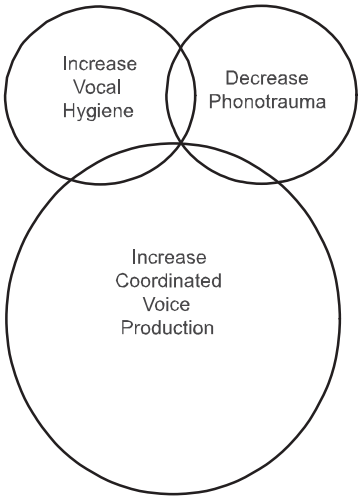

Figure 71.2 Interaction between the three categories of voice therapy.

INCREASE COORDINATED VOICE PRODUCTION

The third circle, increase coordinated vocal production (vocal misuse), is the crux of voice therapy. Uncoordinated vocal production is defined as an abnormal-sounding voice production resulting from the imbalance of respiration, phonation, and resonation. As illustrated in Figure 71.2, patients may have initially engaged in phonotraumatic behaviors and developed benign vocal fold lesions only to perpetuate their problems by producing voice in an unbalanced manner. Although faulty hygienic and phonotraumatic behaviors may have decreased, the patient now uses maladaptive compensatory voicing techniques, which places them in the third circle. Alternatively, patients may have a normal larynx but produce voice in an unbalanced manner. Examples of this include primary muscle tension dysphonia (MTD) and, the most extreme case, functional aphonia. Examples of poor balance between respiration, phonation, and resonation include "holding breath back" at the level of the vocal folds and respiratory mechanism (e.g., faulty airflow management), extra intrinsic and extrinsic laryngeal muscular tension (e.g., high larynx and glottal/supraglottic constriction), and abnormal pitch and intensity. These examples frequently define MTD. Often patients will complain of vocal fatigue and general tightness/constriction in the neck region. It is important not only to ask patients about the sound of their voice production but also about the "feel" of their voice production. Some patients are not so bothered by the sound of their voice but rather the feel.

VOICE THERAPY APPROACHES

The following is a brief synopsis of a variety of different voice therapy approaches that "rebalance" the voice production system. The types of therapies listed in the following are not intended to be comprehensive nor instructive in nature; instead, they are a description of the most commonly used voice therapies. "Typical" voice disorders may be paired with specific voice therapies; however, there is no general agreement among speech–language pathologists about which voice therapies to use with specific voice disorders. In part, this is because the medical disorder (e.g., nodules or vocal fold paralysis) does not necessarily determine how the patient uses his or her mechanism. Thus, it is much more important to treat the vocal behavior versus the voice disorder. Most speech–language pathologists use a combination of the therapies listed and do not use one therapy in particular. Although the following list defines each specific therapy, voice therapy is not "cookbook care." Each patient presents with individual needs, and some therapies work better with some patients than others.

Accent Method

The accent method, originally developed by Smith and Thyme (18), focuses on rhythmic breathing as the primary control mechanism and pairs body movement with respiration and phonation to rebalance the system. The method trains patients to produce easy voicing, abdominal breathing movements (by alternating contraction and release), and open throat postures. These productions are achieved by using rhythmic vocalizations of consonant sounds (called accents), in combination with body movements (e.g., swaying arms or rocking back and forth), while stressing respiratory support for each accent. Proponents of this method report that patients acquire optimal respiratory support, coordination of exhalation and phonatory onset, and phonatory effort (19). Research investigating the efficacy of the accent method shows good outcomes (19,20).

Anatomic/Physiologic Explanation

The rhythmic pairing of timing with respiration and phonation may promote motor learning of new phonatory behaviors (21).

Application

The accent method may be used to treat benign lesions, MTD, vocal fatigue, paradoxical vocal fold motion, and mild glottal incompetence.

Confidential Voice

Confidential voice therapy is used to reduce the force of vocal fold collision and excessive laryngeal hyperfunction during phonation. A breathy voice produced with slightly abducted vocal folds (22) is the therapeutic goal. The slight abduction of the vocal folds results in increased airflow, decreased loudness, and decreased collision force. Although a breathy voice is not the final goal of therapy, it is encouraged for a prescribed period to promote mucosal healing. Confidential voice therapy allows surgical

sites to heal without strong collision forces/stress impact, decreases lesion size, eliminates excessive muscular activity, and increases awareness of habitual loudness levels.

Anatomic/Physiologic Explanation

Producing a breathy voice results in slightly abducted vocal folds, which results in smaller amplitudes of vibration and decreased collision force/stress impact. As a result, the vocal folds should be protected from further injury and allowed to heal.

Application

Confidential voice therapy may be used to treat benign lesions, MTD, and it can be used during the postoperative period of voice reinstatement. It is not appropriate for patients with voice problems related to glottal incompetence. Also, confidential voice is only used for a period of time to promote vocal fold healing; once that period is finished, the voice production is shaped into a healthy vocal production by other therapies mentioned in this chapter. A soft, breathy voice is not an appropriate goal of any voice therapy technique.

Lee Silverman Voice Treatment

Lee Silverman voice treatment (LSVT) is the most researched voice therapy protocol to date. LSVT was developed to address the hypokinetic dysphonia most frequently associated with Parkinson disease. LSVT is a systematic voice therapy approach that focuses on increasing loudness during four sessions per week for 4 weeks (23–25). Patients are trained to "recalibrate" their habitual speaking volume to one louder because the loudness that they think is normal is, in reality, too quiet. Having patients use a very loud voice also improves their articulatory precision and inflection. Treatment and home practice are intensive, and a high degree of independent compliance is required by the patient. The efficacy of this treatment has been well researched (23–27). It should be mentioned that there is a modified version of LSVT called Pitch Limiting Voice Treatment, which requires patients to voice in a low and loud pitch to increase loudness and speech intelligibility (28). Two other therapy programs designed from the LSVT theoretical framework are LSVT (LOUD) and LSVT (BIG) that may be used with patients with Parkinson disease, the aging voice, and other conditions including stroke, multiple sclerosis, cerebral palsy, and Down syndrome (29).

Anatomic/Physiologic Explanation

Loud speech tends not only to be more intense but also more intelligible. Many of the characteristics of speech produced in noise (i.e., loud speech) are perceptually more intelligible than conversational speech produced in quiet (29). When patients are asked to speak loudly, not only does vocal fold closure increase but articulatory precision also improves.

Applications

LSVT has been most researched on patients with Parkinson disease; however, LSVT may be useful for patients with atypical Parkinson disease and other types of neurologic disorders.

Manual Circumlaryngeal Techniques

Manual circumlaryngeal techniques (30) are direct hands-on approaches in which the larynx is repositioned during phonation while observing changes in voice. These techniques are used when extrinsic and intrinsic laryngeal muscle dysregulation (imbalance) contribute to an abnormal-sounding voice. When muscle tension pulls the larynx out of the neutral position, the larynx is suspended high in the neck and the hyoid–laryngeal sling is tight. Symptoms of excessive laryngeal muscle tension are usually neck tenderness, soreness, and tightness. Unilateral symptoms are common. On palpation, focal areas of tenderness may be felt in the thyrohyoid musculature, along the superior horns of the thyroid cartilage and the inferior border of the hyoid bone. The thyrohyoid space is often narrowed as a result of laryngeal elevation. There are three laryngeal reposturing maneuvers: (a) "push-back" maneuver, (b) "pull-down" maneuver, and (c) "medial compression and downward traction." Brief manual laryngeal reposturing, sustained pressure, or downward traction while the patient phonates interferes with habituated patterns of muscle imbalance. Moments of voice improvement are identified, shaped, and reinforced with manual laryngeal manipulations (i.e., digital cueing). Then the digital cues are faded while the patient learns to rely on vibrotactile, kinesthetic, and auditory feedback to maintain improved voice, muscle balance, and laryngeal positioning.

Speech–language pathologists may also use manual laryngeal tension reduction (i.e., circumlaryngeal massage) (31) which differs from manual circumlaryngeal techniques because rather than reposturing the laryngeal mechanisms, direct massage to the laryngeal area is done. This is elaborated by Morrison and Rammage (32). Circumlaryngeal massage is achieved by placing the thumb and forefinger over the tips of the hyoid bone while using circular motion to massage inferiorly to the thyrohyoid space and posterior borders of the thyroid cartilage. Roy and Leeper (33) showed almost normal return of voice following a single session in 93% of 17 participants with hyperfunctional dysphonia. Further, Roy et al. (34) reported significant value in both short- and long-term gains using manual circumlaryngeal therapy for functional dysphonia, with brief episodes of relapse in 68% of the participants.

Anatomic/Physiologic Explanation

The "push-back" maneuver uses digital compression in the posterior direction within the region of the hyoid bone. The "pull-down" maneuver impedes laryngeal elevation

by applying downward traction over the superior border of the thyroid cartilage. The medial compression and downward traction maneuver puts pressure directly over the posterior aspect of the thyroid cartilage and thyrohyoid space. Circumlaryngeal massage may directly stretch the laryngeal muscles and effect relaxation.

Applications

Manual circumlaryngeal techniques and circumlaryngeal massage were originated for patients with MTD and muscle tension aphonia, but they may also be effective in patients with organic lesions who have developed maladaptive compensatory excessive muscle tension.

Resonant Voice

Several speech–language pathologists and voice trainers have used some form of resonant/frontal focus voice therapy (i.e., general class of resonant voice therapies), which is initiated by having patients hum on nasal sounds (m, n, ng) and prolong voiced fricatives (z, v). Resonant voice or "voice with forward focus" usually refers to an easy voice production that is associated with vibratory sensations in the anterior facial bones (35). The Lessac-Madsen Resonant Voice Therapy (LMRVT) (36) is probably most well known. The therapy program was developed through a convergence of basic science and performing arts traditions and consists of three critical issues: (a) physiology (biomechanics), (b) learning, and (c) patient compliance. The target in LMRVT is "barely adducted" or "barely abducted" vocal fold configuration, facilitated by the use of "resonant voice," which is defined as "easy" voice production with perceptible anterior oral vibrations (36). This glottal configuration produces the greatest amount of acoustic output with the least amount of intravocal fold impact stress associated with phonation (37,38). In LMRVT, emphasis is placed on experiential learning using sensory awareness and principles of motor learning (39–41). Formal written instructions for patients and patient self-monitoring devices are used to increase compliance. Eight weekly therapy sessions are prescribed. Verdolini-Marston et al. (42) investigated the effectiveness of confidential voice therapy and resonant voice therapy in patients with vocal fold nodules. Phonatory effort, auditory-perceptual analysis, and laryngeal appearance on stroboscopy all improved regardless of the type of treatment.

Anatomic/Physiologic Explanation

Several studies show that easy, resonant voice is produced with vocal folds that are barely touching or barely separated vocal folds, which tend to optimize the relation between voice output intensity and vocal fold impact intensity (38). This glottal configuration appears to produce the strongest, clearest voice with the least amount of effort. Thus, resonant voice may be defined as having large-amplitude vocal fold oscillations with decreased vocal fold impact stress.

Application

Resonant voice may be used with patients who have benign vocal fold lesions, mild glottal incompetence, and hyperfunctional (e.g., MTD) voice disorders.

Respiratory Retraining

Relaxed "open-throat breathing" was described by Florence Blager (43) for patients diagnosed with paradoxical vocal fold motion disorder (PVFMD). Christopher et al. (44) also described a form of speech therapy that focused on breathing with the abdominal muscles during inspiration and reduction of the muscular effort of the oropharyngeal muscle groups. Later, Martin et al. (43) elaborated this therapy into a multistepped therapy program focusing on exhalation. The keys to therapy include muscle relaxation; open-throat breathing, retraining the breathing cycle to increase the patient's awareness of relaxed rhythmic inhalation/exhalation and to reduce the laryngeal and respiratory effort associated with breathing. Open-throat breathing can be achieved by inhaling through the nose with a relaxed tongue posture or inhaling with pursed lips (e.g., like sucking a thick milk shake up through a straw) and prolonging audible exhalation through pursed lips on an unvoiced /u/ or by producing a voiceless fricative like /s/, /f/ or "sh." Patients are taught both "rescue breathing techniques" when in an attack, as well as rhythmic breathing to "prevent" an attack. Emphasis is also placed on gentle movement of the abdomen in breathing and extra attention is paid to exhalation. Often, videonasoendoscopic biofeedback is used with this patient population to show them that they are in control of their vocal folds.

Anatomic/Physiologic Explanation

The activities in respiratory retraining focus the patient's attention on the rhythm of respiration. Nasal inhalation and pursed mouth breathing encourage wider glottal abduction than oral inhalation and a more open-throat posture. Attention to the exhalation phase of breathing focuses attention away from dyspnea on inhalation and primes the parasympathetic nervous system for relaxation.

Application

Respiratory retraining is mostly used with patients diagnosed with PVFMD.

Flow Phonation

Flow phonation (45) was adapted from a therapy called Stretch and Flow Phonation developed by Stone and Casteel (46). Flow phonation is a model of intervention that focuses on airflow management. Many patients present with breath-holding tendencies that are either the cause of their voice problems (e.g., MTD or functional aphonia), in conjunction with another diagnosis (e.g., benign midmembranous lesions), and/or maladaptive

compensatory responses to physiologic limitations of their laryngeal mechanism. The model incorporates four simple skills that increase awareness of "breath-holding" habits.

Skill One: Airflow Release—encouraging patients to let unvoiced airflow through the glottis in a consistent steady manner (i.e., "let go").There are many ways to accomplish this task (e.g., sustaining a voiceless /u/, sighing, gargling, sustaining voiceless fricatives [e.g., /s/, /f/], etc.). Attention to the effects of the airflow at the mouth via sensation of flow at the lips, a piece of tissue or finger at the lips is encouraged.

Skill Two: Breathy Phonation—the parameter of voicing is added and the result is breathy phonation. Having patients recognize that they are not holding their breath is the key.

Skill Three: Flow Phonation—fading the breathy voice quality is accomplished by simply asking the patient to produce a louder voice without increasing effort while continuing to feel airflow at the lips. This last skill level results in a balanced "normal" voice production. Discriminating between breathy phonation and flow phonation is important in this step.

Skill Four: Articulatory Precision—asking patients to concentrate on articulatory precision seems to facilitate the sensation of airflow energy at the front of the mouth while maintaining decreased throat constriction. If patients can *feel* the airflow energies of most consonants and not feel throat tightness, transfer of flow phonation to conversational speech occurs.

Anatomic/Physiologic Explanation

By focusing on egressive airflow, patients learn not to hold their breath while they speak. This model elicits laryngeal function with an absence of excessive laryngeal and respiratory muscle activity that has become associated with habitual phonation and shapes the relaxed laryngeal function into behavior that results in coordinated vocal production.

Application

Flow phonation may be used with patients with functional aphonia, MTD, and mild atrophy and it also may be effective in patients with benign vocal fold lesions.

Vocal Function Exercises

In the 1950s, Briess (47,48) developed voice therapy techniques based on specific laryngeal muscles. The most recent publication on vocal function exercises demonstrates how Stemple et al. (49) adapted this therapy program into a series of vocal function exercises (VFEs). These VFEs are a series of systematic vocal manipulations, similar in theory to physical therapy for the vocal folds, intended to strengthen and balance the laryngeal musculature and to improve the efficiency between the interaction of airflow, vocal fold vibration, and resonance. There are four steps to the program: (a) vocal warm-up by sustaining the vowel "ee" for as long as possible, (b) stretching of the laryngeal muscles by gliding from the lowest note to the highest note on the word "knoll," (c) contracting of the laryngeal muscles by gliding from the highest note to the lowest note on the word "knoll," and (d) building muscular power by sustaining musical notes for as long as possible on the word "knoll" minus the "kn." The exercises are performed two times each and are repeated twice a day. The exercises are to be done softly without excess strain. Stemple et al. (50) investigated the efficacy of VFEs on young adult females with no vocal fold pathology or voice complaint and proposed that VFEs, based on significant improvement in measures, may improve laryngeal muscle and respiratory effort and supraglottic placement of tone. Another study (51) suggested a beneficial role for VFE for singers.

Anatomic/Physiologic Explanation

Practice on maximal prolongations should improve strength and endurance of vocal fold muscles and the coordination of respiration and phonation. By performing pitch glides to high and low pitches, the cricothyroid and thyroarytenoid muscles should be lengthened and shortened, inducing flexibility and strength.

Application

VFEs may be used on patients with benign vocal fold lesions, mild glottal incompetence, and MTD.

Semioccluded Vocal Tract Therapies

Semioccluded vocal tract (SOVT) therapies can be described as an umbrella term for vocal exercises that employ a semiocclusion in the vocal tract either in the front (i.e., lips/tongue) or the back (i.e., epilarynx tube). Examples of common SOVT exercises are humming, lip bubbles, tongue trills, straw phonation, sustained fricatives (/z/, /v/), etc.

Anatomic/Physiologic Explanation

A semiocclusion heightens the sound source (vocal folds) and vocal tract interaction in that these semiocclusions (front or back) dictate vocal fold oscillation in which the vocal folds are slightly abducted by back pressure caused behind the semiocclusion. Thus, positive pressure above the true vocal folds lower the pressures needed to start and sustain phonation (52).

Application

Almost all voice disorders can be helped by this general grouping of therapies, as well as the nonspecific complaint of vocal fatigue.

APPROPRIATE REFERRALS FOR VOICE THERAPY

Not all patients are appropriate patients for voice therapy. A proper referral is the key to successful therapy. Voice therapy begins with an accurate diagnosis and referral from an otolaryngologist. The otolaryngologist diagnoses the voice disorder, and the speech–language pathologist evaluates the vocal behavior while determining stimulability for improvement. Just as an otolaryngologist may "think twice" about doing laryngeal surgery on certain patients, speech–language pathologists also "think twice" about voice therapy for certain voice disorders. Although most patients benefit from a brief session (1 to 2) of indirect voice therapy (increase vocal hygiene and decrease phonotrauma), multiple voice therapy sessions are often misguided for certain voice disorders. Referrals that may result in limited voice therapy success may be categorized under the following two headings: patient factors and laryngeal status. *Patient factors* refer to such things as motivation for change, positive attitude, compliance to behavioral modification, adherence to homework, hearing loss, and accepting responsibility for change. *Laryngeal status* refers to the physiologic integrity of the laryngeal mechanism. Table 71.1 compares voice disorders that typically get better from voice therapy and do not need surgical management with voice disorders that typically require surgical management with or without voice therapy. The following voice disorders represent organic problems that are less amenable to voice therapy as a result of physiologic limits of the larynx.

Chronic Vocal Fold Scar/Sulcus Vocalis

Although some speech–language pathologists offer such voice therapy exercises as trills and pitch extension glides as possible strategies to loosen scarred mucosa by creating greater force for vocal fold oscillation and actively stretching the scarred mucosa, anecdotal results of such exercises show limited success. In addition, there are no articles published on this topic. Whether phonation affects the biologic process of vocal fold wound healing is a question still unanswered, although basic science studies may be laying groundwork for future investigations into this area, namely, how phonation effects the tissue biology of vocal folds (53).

Papilloma

As a result of the multiple surgeries and subsequent increase in scar tissue, therapy is limited in success, as discussed above.

Severe Reinke Edema

Reinke edema is often found in patients who smoke, have LPR, or engage in phonotrauma (i.e., vocal abuse). Whereas voice therapy may be helpful in reducing phonotrauma, patients with severe (extensive) Reinke edema have significant anatomic abnormalities of the vocal folds that limit the success of voice therapy.

Cysts, Fibrous Masses, and Polyps

Typically, a specific diagnosis of what type of vocal fold lesion is present is not made until after voice therapy and sometimes not until surgery (see Chapter 68). Thus, the indication for a full course of therapeutic voice therapy is not made on the specific diagnosis. Most patients with benign, midmembranous vocal fold lesion(s) should be treated with voice therapy prior to being considered for surgery. Often the lesion(s) will not substantively change in size but therapy results in improved voice function and thus surgery is not indicated. In contrast, some lesions are "unfavorable" sole voice therapy candidates; these are lesions that very large and exophytic or cause a severe

TABLE 71.1 COMPARISONS OF WHICH VOICE DISORDERS ARE MORE OR LESS AMENABLE TO VOICE THERAPY

Voice Disorders Amenable to Voice Therapy (Infrequent Surgical Management)	Voice Disorders Less Amenable to Voice Therapy (Frequent Surgical Management Required)[a]
Nodules	Cysts, polyps, fibrous masses, pseudocyst
Primary muscle tension dysphonia	Scar/sulcus
Functional aphonia (muscle tension aphonia)	Papilloma
Mild vocal fold atrophy	Moderate-to-severe atrophy
Paradoxical vocal fold motion disorder	Reinke edema
Parkinson disease	Paralysis/dense paresis
	Spasmodic dysphonia/vocal essential tremor

[a]Although patients may require a brief session of voice therapy, to be educated about their current laryngeal mechanism and engaged in indirect voice therapy, possibly reduce edema around the lesions for better surgical success, and to be instructed in ways to reduce compensatory extralaryngeal tensions, voice therapy most likely will not resolve the problem.

amount of mucosal stiffness (most likely due to their involvement with the vocal ligament). These patient are best approached with a short course of voice therapy (1 to 3 sessions) followed by a reevaluation prior to proceeding with additional voice therapy or progressing to phonomicrosurgery (see Chapter 68).

Spasmodic Dysphonia/Essential Tremor

In general, voice therapy does not work well for this patient population. However, diagnostic voice therapy is often needed to disentangle MTD from spasmodic dysphonia (SD). A novel approach to helping a client with vocal essential tremor (54) is discussed in this case report.

Vocal Fold Paralysis in a Paramedian Position

Controversy continues to surround the role of voice therapy for unilateral vocal fold paralysis (55). Success in voice therapy seems to be based on the position of the paralyzed vocal fold (median, paramedian, intermediate, and level mismatch), differing bulk/mass of the vocal folds, and vocal fold tension of the paralyzed fold. A well-positioned paralyzed fold in the median position is most prognostic for therapeutic success. Even after surgery for vocal fold paralysis via laryngeal framework surgery (e.g., thyroplasty type I) or injectable augmentation, therapy may remain problematic. Complete glottal closure resulting from surgery does not address the dynamic nature of vocal fold vibration (e.g., issues of tissue bulk/mass, tension, and glottal plane differences between the vocal folds).

Moderate-to-Severe Vocal Fold Atrophy Associated with Aging

Biologic aging of the vocal folds may be seen in the elderly population with glottal incompetence as the prevailing laryngeal finding. If the vocal folds are severely affected by a glottal gap, surgical augmentation is often needed before starting voice therapy. However, decreased muscle tone is often the more perplexing of problems because surgical augmentation may decrease a glottal gap but decreased tonicity is hard to help both surgically and behaviorally. Sadly, sometimes neither treatment works (56).

Primary versus Secondary Muscle Tension Dysphonia

Primary MTD is seen in patients with an otherwise normal larynx. Primary MTD responds extremely well to voice therapy. However, secondary MTD (57) is an adaptive compensatory response to an underlying glottal incompetence. Voice therapy is often limited in success. For example, if a patient shows supraglottal medial and anterior/posterior constriction as a result of vocal fold atrophy, scarring, or vocal fold paralysis, voice therapy may be limited until the underlying primary laryngeal disorder is surgically altered.

A caveat to the applicability of voice therapy to the previously mentioned voice disorders is that sometimes patients need a brief session of voice therapy to be educated about their current laryngeal mechanism and its limitations—in particular, the tradeoff between sound versus feel of voice production. For example, in many of the voice disorders, patients will use extralaryngeal tension/constriction to compensate for their glottal sound source limitations. These extralaryngeal compensations usually come with a price tag of vocal fatigue/pain. Thus, patients may be able to sound louder and clearer with vocal effort, but it will cost them in vocal fatigue. Alternatively, patients may be taught to relax their extralaryngeal tension but may pay a price by having a significantly softer voice with less clarity. It is important for patients to understand this tradeoff.

LIMITATIONS TO VOICE THERAPY SUCCESS

Assuming an appropriate referral, the following list of prognostic considerations is offered. First, the patient must be stimulable for behavioral change. Can the speech–language pathologist elicit a better-sounding and healthier voice production from the patient? Second, the patient must be motivated for behavioral change and accept responsibility for the same. The patient is in control of his or her own laryngeal mechanism and does the majority of "work" in voice therapy. Unless this is understood at the beginning of voice therapy, success may be limited. Third, the patient must be compliant with voice exercise homework. Voice therapy requires behavioral modification. In turn, it is only by practice that the new vocal behaviors are entrained. Fourth, appropriate goals for voice therapy should be established immediately. Unfortunately, the physiologic limitations of the patient's laryngeal mechanism may preclude a return of the patient's premorbid voice. In other words, the vocal folds may be damaged to the extent that "normal" or premorbid voice characteristics will never occur. The patient should be instructed as to any limitations to success. Fifth, emotion, personality, stress, and anxiety may be component parts of many voice disorders (58), both as an etiology and consequence. Acceptance of this reality and concomitant therapy with a trained psychological counselor may be necessary. Sixth, although voice therapy can be very effective, there are speech–language pathologists who are better at voice therapy than others. A certified, licensed speech–language pathologist who specializes in voice should perform voice therapy. Referring patients to speech–language pathologists with little training or interest in voice wastes the patient's time and health care funds and inevitably fails. Table 71.2 summarizes these points.

TABLE 71.2 VOICE THERAPY: REASONS FOR SUCCESS OF FAILURE

Success	Failure
Appropriate referral • Stimulable for a better voice • Wants to avoid surgery—motivated to change voice production • Compliant to vocal hygiene, LPR treatment, decreasing phonotrauma, and daily homework • Takes responsibility for change	*Inappropriate referral* • Not stimulable for a better voice • Decreased motivation for change (i.e., wants a "quick fix") • Noncompliant to vocal hygiene, LPR, treatment, decreasing phonotrauma, and homework • Will not accept responsibility • Hearing loss • Possible concomitant emotional/psychological problems • Accurate referral to an inexperienced speech–language pathologist • Medical–legal issues not resolved (e.g., secondary gain)

WHAT CONNOTES SUCCESS IN VOICE THERAPY?

The answer to the question "What connotes success in voice therapy?" is riddled with unknowns. Because there is a paucity of prospective, randomized clinical trials concerning voice therapy efficacy, the answer to this question seems to be driven by expert opinion rather than data. Anecdotally, most professionals believe that success in voice therapy is defined as a return to a functional level of voicing rather than a change of the laryngeal mechanism. For example, a patient may get functionally better without a reduction in lesion size.

SUMMARY

Otolaryngologists, speech–language pathologists, and patients are witness to the success of voice therapy. However, the success is limited by a lack of data to support positive outcomes. Much-needed efficacy studies are under way to verify the anecdotal success of voice therapy. This chapter is not intended to be an all-inclusive list of all voice therapies; it is a synthesis of some of the most commonly used therapies and prerequisites for success. In general, when an otolaryngologist makes an appropriate voice therapy referral to a speech–language pathologist who specializes in voice, behavioral voice therapy is highly effective in treating patients with voice disorders.

HIGHLIGHTS

- Voice therapy teaches patients to modify phonotraumatic/inefficient vocal behavior and requires compliance to daily exercises; voice therapy is not a "quick fix."
- Voice therapy requires that patients assume responsibility for their vocal behavior.
- The three key categories of any voice therapy program include the following: increasing vocal hygiene, decreasing phonotrauma, and increasing coordinated voice production.
- Indirect voice therapy includes educating the patient about how his or her laryngeal mechanism functions, identifying what may cause them harm (e.g., dehydration, smoking, LPR), and establishing realistic therapeutic goals; it usually lasts 1 to 2 weekly sessions.
- Direct voice therapy includes actively altering the patient's speaking technique through various exercises and manipulations to increase vocal quality and efficiency; it usually lasts 4 to 6 weekly sessions.
- There are many different voice therapies, and most speech–language pathologists use a combination of same; voice therapy techniques should be chosen for the patient's voicing *behavior* and not the laryngeal disorder.
- Not all patients are appropriate referrals for voice therapy. Although most patients benefit from a short course of voice therapy, multiple direct voice therapy sessions for such voice disorders as vocal fold scar/sulcus vocalis, recurrent respiratory papillomatosis, severe Reinke edema, fibrous masses, spasmodic dysphonia, vocal fold paralysis with severe glottal incompetence, severe atrophy, and secondary MTD are limited in success.
- Successful voice therapy involves the following: an appropriate referral to a speech–language pathologist specializing in voice, a patient stimulable for a better sounding and/or feeling voice, and a motivated patient who takes responsibility for behavioral change.

Care of the Professional Voice

72

Julina Ongkasuwan *Mark S. Courey*

A thorough understanding of the principles of laryngeal anatomy, physiology, and sound production provides an excellent background on which to build diagnostic and therapeutic strategies for all types of laryngeal disorders. In the 21st century, it is no longer adequate for otolaryngologists to treat voice complaints differently in different types of voice users. Rather, the appropriate management for all voice disorders is based on a thorough understanding of voice-production principles. The otolaryngologist/laryngologist must have a basic understanding of voice requirements and physiologic demands for all patients from the child to the opera singer. With this knowledge, the otolaryngologist can make correct decisions in the management of all voice problems from transient edema secondary to overuse to the management of vocal fold lesions.

ANATOMY AND PHYSIOLOGY OF VOICE PRODUCTION

While details of laryngeal anatomy, development, and physiology have been previously presented, it is helpful to reemphasize certain concepts.

Extrinsic Laryngeal Musculature

The series of strap muscles attaching to the outside of the laryngeal framework are referred to as the extrinsic laryngeal musculature. These are paired and consist of the sternohyoid, sternothyroid, and thyrohyoid muscles (Fig. 72.1). They are innervated by the ansa cervicalis, which arises as a branch from cranial nerve (CN) XII. For the purposes of voice production, these muscles are believed to influence laryngeal position within the neck. Laryngeal position affects the length of the vocal tract, which in turn alters the resonance characteristics of the voice. It also should be noted that the tongue and floor of mouth musculature, including the paired digastric muscles, geniohyoid, genioglossus, hyoglossus, and mylohyoid, all attach to the top the external laryngeal framework on the hyoid bone. Although these are not part of the extrinsic laryngeal musculature, they influence the laryngeal position within the neck because of their attachment on the hyoid bone. These muscles also receive a portion of their motor innervation through branches of CN XII, and they function primarily to move the tongue for articulation of speech. Because both muscle groups controlling laryngeal height and articulation are innervated by the same motor system, overlap or stimulus generalization may occur during speech production. To produce a balanced or pleasing sound, the professional voice user must learn to control laryngeal height for resonance separately from the tongue movement for speech articulation (1).

It also is important to consider the pharyngeal musculature. The inferior constrictor attaches to the posterior aspect of the thyroid framework. This muscle plays a role in shaping the pharynx during speech production and, along with the middle and superior constrictor, also alters laryngeal height and closure patterns. The constrictors receive motor innervation from branches of CN X, which also controls the intrinsic laryngeal musculature. Therefore, stimulus generalization also may occur as the professional voice user attempts to separate intrinsic laryngeal function from pharyngeal shape and laryngeal height for resonation characteristics.

Intrinsic Laryngeal Musculature

The paired intrinsic muscles attach to the arytenoids and the cricoid and thyroid cartilages. As are most muscles, they are named for the origins and insertions. First, the thyroarytenoid (TA) muscles originate near the most anterior portion of the thyroid cartilage and insert on the side of the vocal process of the arytenoid and the middle and upper body (Fig. 72.2). This muscle is innervated by CN X.

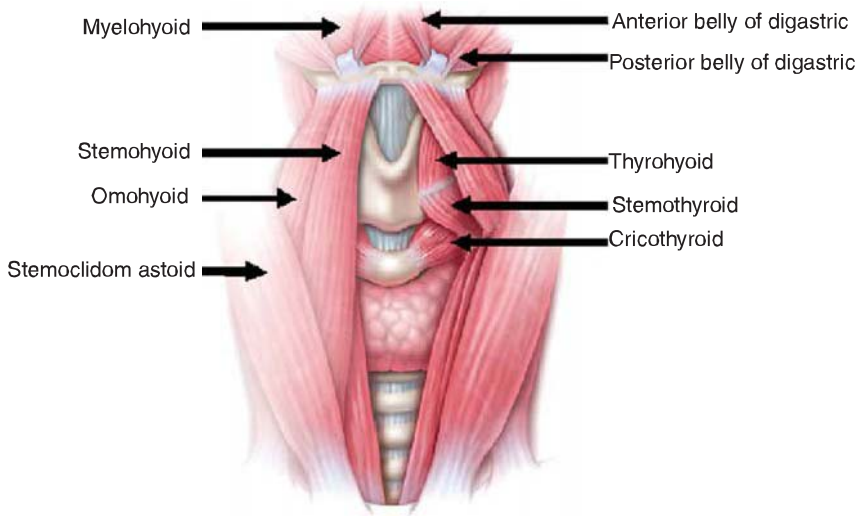

Figure 72.1 Extrinsic laryngeal musculature.

Through muscular activation, the distance between the arytenoid and thyroid cartilages is shortened. This occurs primarily by pulling the arytenoid forward on the cricoid ring. As the distance shortens, the mucosal membrane overlying the muscle is thickened, and the extracellular matrix proteins are brought into the closer approximation with each other. The thickening of the tissue will affect its characteristics of vibration.

The lateral cricoarytenoid (LCA) muscle originates on the lateral aspect of the cricoid ring and the inserts onto the muscular process of the arytenoid (Fig. 72.2). These paired muscles receive motor innervation through CN X. As the muscle contracts, the muscular process is pulled laterally and inferiorly. This action displaces the vocal process medially and inferiorly because of the angle of the cricoarytenoid joint. As the vocal fold adducts, the anterior aspect remains fixed at the anterior portion of the thyroid cartilage, but the posterior aspect moves inward and inferiorly.

The interarytenoid (IA) muscle is also innervated by CN X and attaches to the upper bodies of the arytenoid on the posterior and medial surfaces (Fig. 72.2). The muscle fibers run both obliquely and transversely. As the IA contracts, the upper portions of the arytenoid bodies tilt toward the midline. This action approximates the tissue slightly above the plane of the vocal process. In men, with thick mucosa and large cartilaginous structures secondary to the androgenic effects of testosterone, the entire space between the vocal processes is obliterated. In women, with more delicate structures, because of the relatively limited androgen effects of estrogen, the space is not filled or obliterated completely and is often viewed as an opening behind the vocal process or is referred to as an "open posterior chink." This phenomenon has been reported in up to 76% of middle aged women (Fig. 72.3) (2).

The posterior cricoarytenoid is the only abductor of the vocal fold. It originates on the posterior aspect of the cricoid

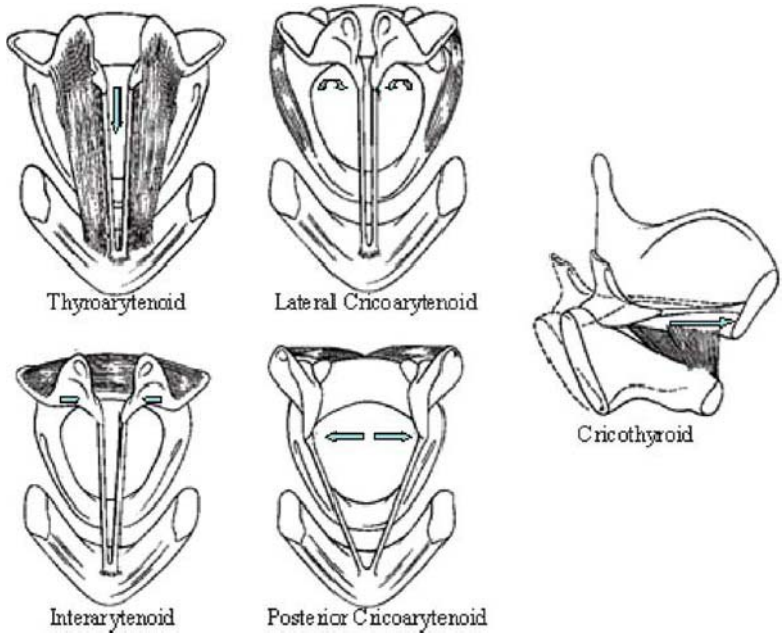

Figure 72.2 Intrinsic laryngeal muscles.

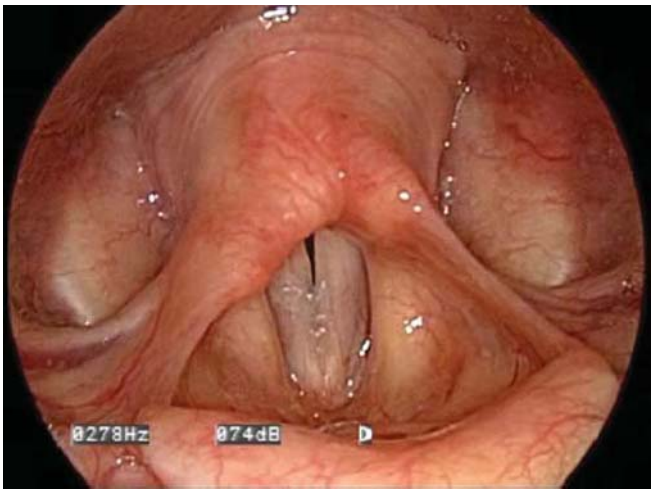

Figure 72.3 Posterior glottic chink.

ring and attaches to the muscular process on the posterior aspect of the arytenoid (Fig. 72.2). Contraction, stimulated by the recurrent laryngeal nerve from CN X, results in medial and inferior displacement of the muscular process. This results in lateral and upward displacement of the vocal process and, with it, the posterior aspect of the vocal fold.

Finally, the cricothyroid (CT) muscle originates on the anterior aspect of the cricoid ring and attaches at the anterior aspect of the thyroid cartilage at the inferior tubercle (Fig. 72.2). Contraction is regulated by the external branch of the superior laryngeal nerve, which is a branch of CN X. As the CT muscle contracts, the thyroid lamina is pulled closer to the cricoid ring. The cricoid ring sits anterior to the thyroid lamina. As the thyroid lamina is displaced forward, the vocal fold is stretched. The action tenses the vocal fold and thins the mucosal cover, decreasing the mass of the vocal fold available to participate in the vibration. This is analogous to the action of a rubber band. As the rubber band is stretched, it becomes tenser, and its thickness or lateral dimension, and width or vertical dimension, are reduced.

Minor Intrinsic Laryngeal Cartilages

The minor intrinsic laryngeal cartilages, which include the corniculate, cuneiform, and epiglottis, do not function directly in voice production. Their presence most likely results in alteration of the configuration and stiffness of the vocal tract, which ultimately affects the shape and therefore the resonance quality of the vocal tract (1).

PRINCIPLES OF SOUND PRODUCTION

Sound production of all types requires three basic components: a power source, a vibratory source, and a resonator (Fig. 72.4). In human voice production, the exhaled air from the lungs serves as the power source that drives vocal fold vibration, the vibratory source. The true vocal folds produce a faint primary sounds source, which is then

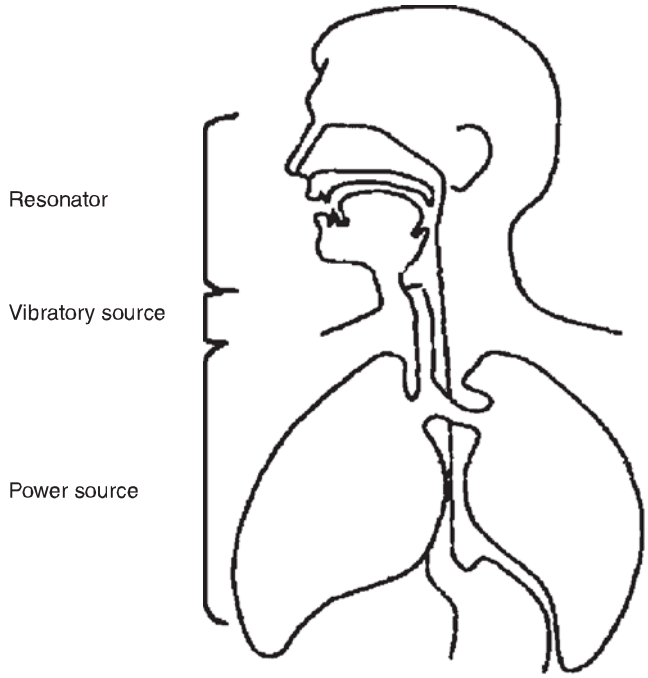

Figure 72.4 Vocal tract.

modulated by the third component, the resonating chamber or the supraglottic vocal tract. The supraglottic vocal tract is formed by the supraglottic larynx, the pharynx, and the oral cavity. If no resonating chamber were present, the primary sound source would produce a buzzing-type sound similar to a faint duck call.

Human communication can be divided into language, speech, and voice. Specifically, language production requires cognitive skills regulated by the cerebral cortex. Patients integrate higher cortical functions to express themselves through words and actions familiar to a certain region in which they were educated. Speech production refers to the articulation of words to produce language. It involves the supraglottic vocal tract for resonation and articulation of sounds produced at the glottis level. It is under the control of the cerebral cortex but is regulated by the coordinating centers in the basal ganglia and brain stem (3). Voice is produced through vocal fold vibration and specifically refers to the sound that emanates from the vocal folds as they are held in approximation and passively vibrated by the air that flows between them. Sounds produced by vocal fold vibration are termed *voiced sounds*. Commonly these are the vowels and voice consonants that require vocal fold adduction. Adduction and tension are regulated by cerebral cortical activity and are coordinated through the basal ganglia as well.

Harmonic Sound Source

Patients can present with problems of language, speech, voice, or a combination of these. In the professional voice user, we are most often concerned with problems of voice

TABLE 72.1 EXAMPLE OF FUNDAMENTAL FREQUENCY, OVERTONES, AND HARMONICS

Frequency (Hz)	Order	Overtones	Harmonic Numbering
440	$n = 1$	Fundamental	First Harmonic (H1) or F_0
880	$n = 2$	First overtone	Second Harmonic (H2)
1320	$n = 3$	Second overtone	Third Harmonic (H3)
1760	$n = 4$	Third overtone	Fourth Harmonic (H4)

production. Vocal fold vibratory activity is critical for voice production, as it provides the primary sound source, which is modulated by actions of the vocal tract (4). Vocal fold vibrations produce a complex tone. That is, they vibrate at a set of frequencies that have a whole-number mathematic relation between them. The primary frequency of vibration is termed the *fundamental frequency* (F_0), and is closely related to the perceived pitch of the voice. Each whole-number multiple of the F_0 is called an overtone. The terminology is such that the F_0 is labeled the first harmonic (H_1), and each multiple of that frequency is the second, third, fourth, fifth harmonic (H_2, H_3, H_4, H_5, etc.), and so on to infinity (Table 72.1).

Formant Frequencies

The harmonic spectrum is presented to the vocal tract. Because of the length, shape, and distal opening of the vocal tract, certain of these harmonics are amplified or resonated, and others are dampened or attenuated (4). This pattern, known as the *spectral envelope*, creates the sounds that we hear in speech production. The amplified or resonated harmonic regions of the spectral envelope are called the *formant* regions. The first two formant regions are responsible for vowel differentiation, whereas the third through the fifth regions are responsible for the quality of the sounds (timbre). The different sounds of speech are produced by alterations in the length, shape, and mouth opening of the vocal tract. This is under voluntary control. The vocal professional learns to alter the shape of the vocal tract to produce the target sound quality.

The formant regions can be evaluated through spectral analysis of the vocal signal. The spectrogram is a visual representation of the audible sounds. It is a plot of frequency and intensity changes of sound over time (5). To produce a spectrogram, the sound emanating from the vocal tract is broken into various frequency regions as it is passed through a variable bandpass filter. The filter identifies the audible frequency regions between 0 and 8,000 Hz. The harmonic frequencies within this region are represented on the *y*-axis and time is represented on the *x*-axis. Intensity of the various harmonics is represented by darker frequency bands on the graph. The darker bands represent the amplified harmonics and are called the formant regions.

Vowels have characteristic first- and second-formant frequencies. These are represented as F1 and F2. The vowel is determined by the absolute F1 and F2 as well as the relative distance between them (Fig. 72.5). Harmonics are selectively amplified by changes in the length, shape, and distal opening characteristics of the vocal tract. The higher formants (F3 to F5) are responsible for the timbre of the sounds and differences in the sound characteristics between speakers. Classically trained singers learn to cluster the third, fourth, and fifth formant regions to amplify the harmonic sounds frequencies between 2,800 and 3,500 Hz (6). Amplified sound in this frequency range is preferentially detected by the human ear over other sounds. It is known as the *singer's formant*, and is produced by learned behavior through which the classically trained singer, through movements in the tongue, pharynx, and lips, manipulates the vocal tract into a certain shape to amplify selectively the harmonics in the desired regions (7).

Although the quality of the spectral envelope is largely influenced by the shape, length, and distal opening of the vocal tract, it also is affected by the richness and quality of the harmonic spectrum presented to it as the sound source. Therefore, the vocal professional must be able to regulate

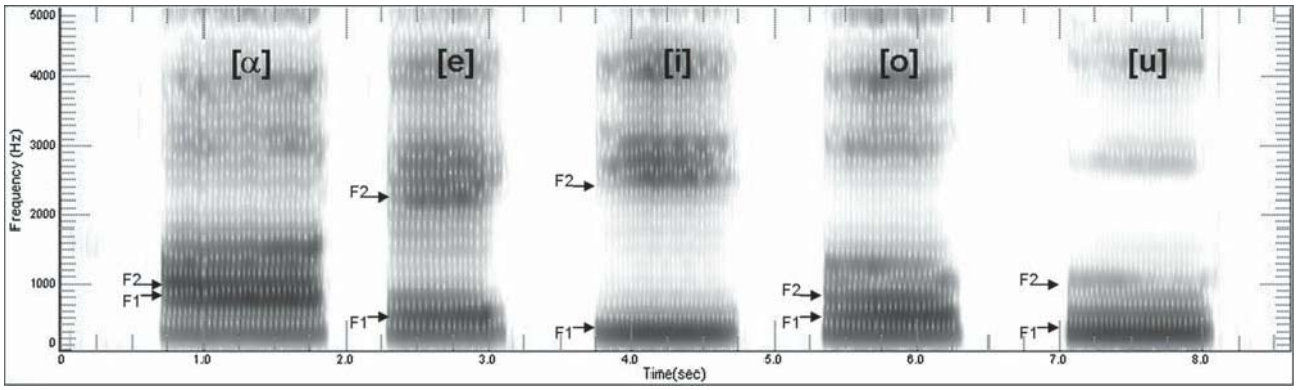

Figure 72.5 Spectrogram.

the harmonic source spectrum from the larynx, as well as the shape of the supraglottal vocal tract. Through manipulations of these two organ systems, all human speech sounds for professional and nonprofessional voice are produced (8).

MECHANISM OF VOICE PRODUCTION

We previously discussed the actions of the supraglottic vocal tract. Specifically, in speech production, the speaker moves the tongue, pharynx, and lips to alter the shape, length, and distal opening of the vocal tract. In this manner, the formant regions are manipulated to amplify the desired harmonics produced by the sound source. The speaker also manipulates the sound source to enhance the harmonic spectrum presented to the vocal tract (9). Manipulation of the vibratory source is accomplished in all styles of voice production with the same basic mechanisms. These mechanisms include control of subglottic pressure, control of vocal fold approximation, and control of vocal fold tension (Table 72.2).

Subglottic Pressure

Subglottic pressure is the pressure immediately below the vocal folds during vocal fold vibration. It is generated by a combination of the force of the expelled air and by the force of vocal fold closure used to resist the outflow of the air (Fig. 72.6). Subglottic pressure correlates directly with the volume of the sound that is produced by the sound source (10). Sound is a disturbance in the pressure–density equilibrium of the atmosphere. Greater disturbances result in louder sounds. During the closed phase of vocal fold vibration, as the mucosal surfaces are approximated, the disturbance in the pressure–density equilibrium is minimal. As the air explodes through the glottis, the pressure–density disturbance is maximized. Higher subglottic pressures built up through prolonged closure explodes through the glottis and result in a more rapid change and a greater disturbance in the pressure–density equilibrium. Both the absolute degree of change and the rate of change are important. A louder sound source presents more intense harmonics to the resonating chamber. The spectral envelop is altered because the more intense harmonics are better amplified. In this manner, all of the formants, including those in the 2,800 to 3,500 Hz range, which are preferentially identified by the human ear, are amplified. Thus, all of the formants are boosted by a loud sound source (6).

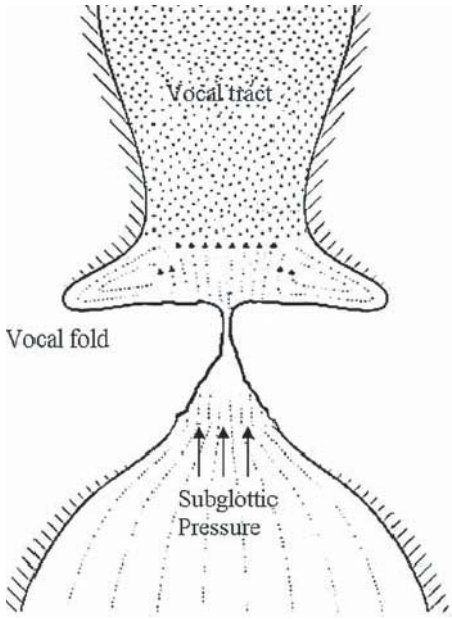

Figure 72.6 Subglottic pressure.

TABLE 72.2 MANIPULATION OF THE VIBRATORY SOURCE

Subglottic pressure
Respiratory support
Vocal fold contraction
Vocal fold approximation
Vocal fold tension

Control of Subglottic Pressure with Respiratory Support

Singers can create more volume and therefore more amplification of the harmonics by increasing the subglottic pressure. Professional voice users, and all voice producers for that matter, control the rate of exhalation during voice production by allowing incremental relaxation of the muscles that expand the thorax. The diaphragm is the primary muscle used to expand the thorax. It is assisted by the actions of the intercostal muscles, which spread the ribs, and the spinal accessory muscles, which elevate the clavicles and first and second ribs. During inspiration, the thorax is expanded beyond its resting volume. Air is drawn into the lungs by the negative pressure created through expansion. As the diaphragm and intercostal muscles are relaxed, the thorax passively recoils to its resting size. During voice production, the rate of recoil is resisted through incremental relaxation of the muscles of inspiration and through contracting the muscles of the abdominal cavity. This phenomenon is referred to as *respiratory support* and is believed to be the most efficient mechanism for the regulation of subglottic pressure.

Control of Subglottic Pressure with Vocal Fold Contraction

However, during all types of voice production, increases in forces of vocal fold adduction, which resist air escape and overclose the larynx, can also be used to increase subglottic

pressure, and with it, the volume of the sound source. This mechanism for increasing subglottic pressure is believed to be inefficient and may result in excess muscular fatigue through hypercontraction of the TA muscles, LCA muscles, or both, which most often relax during phonation.

Vocal Fold Approximation

Overclosure states, through a combination of hypercontraction of the intrinsic and extrinsic laryngeal musculature, can be used to augment the degree of laryngeal closure, affect the length of the closure phase during vibration, and alter the shape of the resonating vocal tract. Thus they affect the sounds spectrum through altering the sound source as well as the shape of the vocal tract.

Vocal Fold Tension

Finally, laryngeal tension for frequency of vibration and pitch control is under voluntary regulation. Tension is adjusted primarily by contraction of the CT muscle, which results in anterior displacement of the anterior commissure and elongating or stretching the vocal fold. In addition, CT contraction causes a reduction in vocal fold mass available to participate in vibration through thinning of the vocal cover as it is elongated. Both these actions result in pitch elevation.

The coordinated vocal user and particularly the vocal professional learn to control their vocal mechanism efficiently so that excess TA muscle contraction is not used to affect pitch. The vocal folds are set into a position for vibration. The relative tension for the desired frequency of vibration is set by tone in the CT muscle, which is termed *prephonatory tuning*, and then air is passed through the vocal folds, and vibration begins. During the sound-production phase, the TA muscle relaxes, and the vocal folds are held in nearly approximated position by the activity of the IA muscle. This activation pattern has been studied and documented through laryngeal electromyography (11).

Vocal fold approximation, by the IA muscle, however, is opposed by activity of the CT muscle. As the CT contracts and the anterior portion of the TA is stretched forward, the posterior attachment to the arytenoids remains relatively fixed. Because the posterior border of the cricoid ring and the cricoarytenoid joint are angulated superiorly to inferiorly, continued unopposed contraction of the CT will lead to lateral displacement of the arytenoids and the posterior aspect of the vocal fold. As the vocal folds are spread apart by this action, the glottis width increases and vibration will stop unless the glottic distance is decreased through coordinated action of the intrinsic laryngeal musculature (LCA, TA) or the airflow from the lungs is increased (Fig. 72.7). Thus to maintain a continuum of pitches without allowing for a break in phonation, the coordinated vocal user balances the desired vocal fold tension against the abductory forces, so that the vocal folds maintain a nearly approximated aerodynamic position. In addition, the trained vocal professional is probably altering the speed of the air flow as well to help merge these vibratory ranges.

The vocal folds can be tensed and maintained in an artificially thick state. This will result in alterations of the vibratory patterns with prolonged closure. This prolonged closure phase will alter the sound source and may produce desirable harmonic characteristics. These intensified harmonics are more easily amplified by the vocal tract, and the singer's formant region is boosted. Because of the boost in this region, the sound is preferentially distinguished as human and is enjoyable. This phenomenon is frequently used by female commercial vocalists as they attempt to sing in a relatively high-pitched, robust voice. It is referred to as "belting." During belt voice production, a bright brassy sound is produced at the expense of laryngeal and cervical muscle hypercontraction. If the TA muscle is held overly tense during voicing, it may affect the vibratory characteristics of the

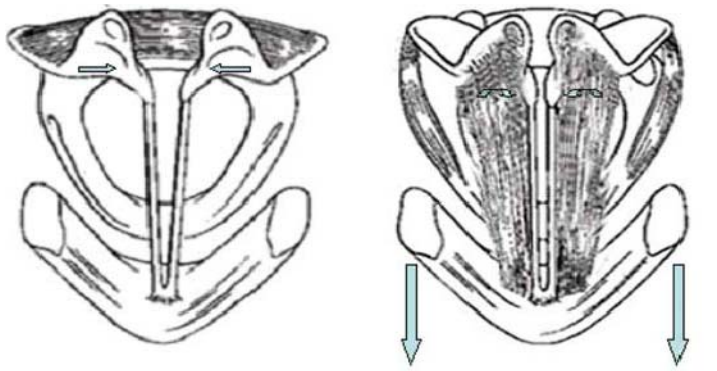

Figure 72.7 Using vocal fold tension to help control pitch.

overlying vocal ligament and cover by not passively cushioning the vibratory forces. A stiff underlying TA may increase the shear or compressive stress placed on the overlying ligament and cover, thus increasing the likelihood of injury.

VOCAL PERFORMANCE STYLES

People perform by using both the speaking and singing voice. As covered in the last section, these sounds are produced by using the same anatomic and physiologic principles. The successful performer must be able to manipulate both the sound source and the resonating vocal-tract characteristics to produce sound of the desired style.

Voice Classification

Regardless of style, voices can be categorized by the range of pitches they can produce. The average person can produce pitches over a 12- to 30-muscial note range. For the male voice, the average speaking vocal pitch hovers around 120 Hz, and for the female, approximately 200 Hz. The lowest note that a person can produce is frequently four to five notes below this average pitch range. Within individual people, however, significant variations are found in average pitch, their highest and lower pitch capability, and their overall pitch range. In total, these characteristics of voice, average pitch, and pitch range are described as the vocal profile. Men and women usually exhibit vocal profiles either higher or lower than the average pitch for their gender. For men, the lowest voices in classical singing are termed bass voices, the medium pitched voices are termed baritone voices, and the higher voices are termed tenor voices. In women, the lower voices are termed contralto or alto voices, whereas the higher voices are termed soprano voices (Fig. 72.8) (1).

Voice classifications are determined by several factors. These factors include the absolute pitch range, timbre characteristics, and vocal of vibratory break points within the voice. As stated previously, vibratory frequency or pitch of voice is proportional to the tension within the vibratory vocal fold and the mass of the vocal fold available to participate in vibration. The mass of our vocal folds is a physical characteristic within each of us. We then manipulate pitch (frequency of vibration) by adjusting tension with the vocal fold.

In singing terminology, the *chest voice* roughly correlates to the range in which the TA muscle relaxes, and the vocal folds are held in nearly approximated position by the IA. The *head voice* roughly correlated to the range in which the LCA and TA are employed to decrease the glottal distance as the CT lengthens the vocal folds (1). The area between these two ranges is termed the *mixed voice range*. At the beginning and the end of the mixed range, the notes involved are termed the *passaggio* or passage. These characteristic points help to determine the voice user's range and quality. In general, male voices have a smaller mixed voice range than do female voices, and females are asked/required to sing in their mixed voice range more commonly than are males. Male basses are usually required to sing below their mixed voice range, whereas tenors are required to sing above theirs. These passaggio points occur at relatively consistent frequency and are used along with the absolute high and low range to determine the voice class or type on the bass-to-soprano continuum (1).

Male baritone and bass voices have an additional register on top of the head voice referred to the as the falsetto voice. It is often described as breathy and less brilliant or full in sound. The majority of the vocal fold remains long

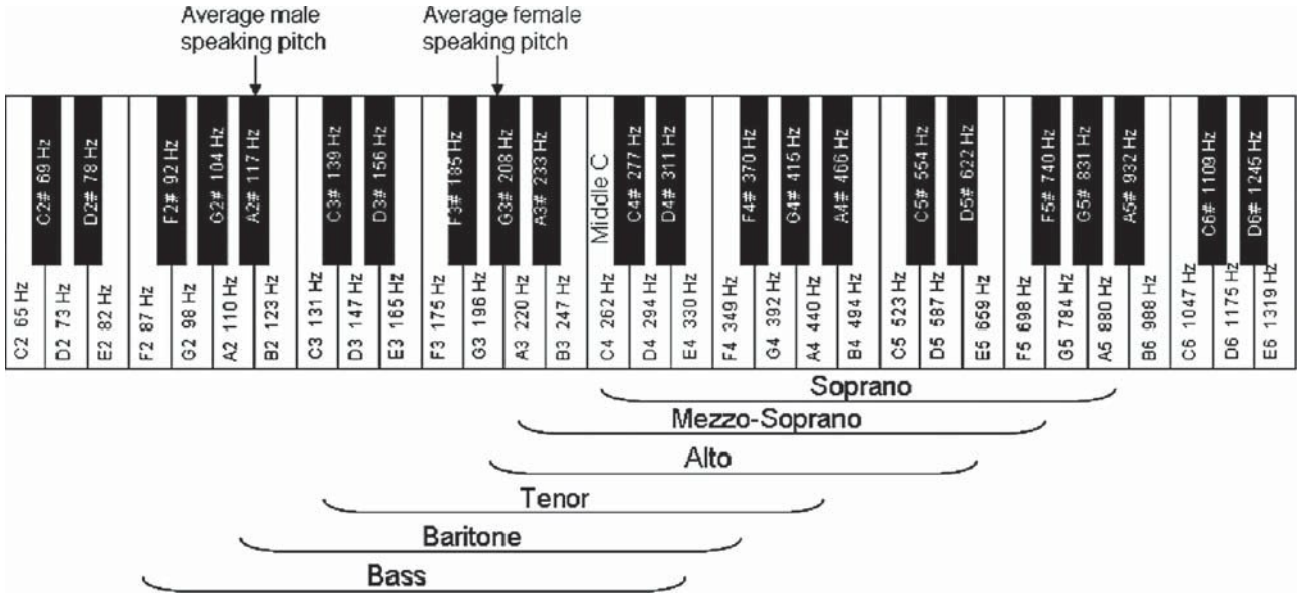

Figure 72.8 Voice classification by average pitch range.

TABLE 72.3 VOCAL REGISTERS

Chest voice	Lower register	TA muscle relaxes IA holds vocal fold approximated
Head voice	Higher register	CT lengthens the vocal folds LCA and TA hold vocal folds approximated
Mixed voice	Register between chest and head voice	
Passaggio	The beginning and end of mixed voice	
Falsetto (male)	Breathy, flute-like sound relatively free of overtones	Only the medial edges of the vocal folds vibrate
Whistle register (female)	Distant high-pitched bell-like sound	Vibration occurs only at the anterior portion of the vocal folds

and stiff with vibration occurring only at a thin medial edge with less complete vocal fold approximation compared to head voice. It is frequently used to imitate the female voice (1).

The male falsetto should not be confused with a female register above the upper voice often referred to as the flageolet register or whistle register. This also has a distinct timbre that is sometimes referred to as a distant high-pitched bell. When producing these pitches, the vocal folds lengthen and the posterior portion of the vocal folds are dampened. This register has been used by some commercial singers (Table 72.3) (1).

PERFORMANCE STYLES

In general, singing performers can be broken down into two basic types. These are classical styles and commercial styles of performance. Within the classical and commercial styles, many subtypes exist.

Historical Evolution of Performance Styles

The evolution of music performance demonstrates how these two styles of voice production developed. As human civilizations grew, history and daily events were often told through music. The original musicians, therefore, were traveling bards who would entertain and tell their stories to small groups of people. They would be rewarded through charitable contributions from the crowd and learned to tell their stories to music that the local population enjoyed. This was the original form of folk music and persists today through many styles.

During the Middle Ages, humans began to live more commonly in towns and cities. In addition, musical instruments where being developed. As such, musical composers began to develop music for many instruments to perform simultaneously. These pieces were often combined with human voices. As the number of musical instruments increased and the performance halls enlarged to accommodate larger audiences, the vocal performers needed to develop a technique that would allow their voices to carry to the back of the performance hall and be heard above the musical accompaniment. The call voice or the singer's formant was a natural way to accomplish this requirement. Within Europe, during the Middle Ages, many different schools of musical education developed in the various regions to train performers in distinct ways of producing and using the singer's formant (1). The common goal among these schools was the production of a voice that would rise above the musical instruments because electrical amplification had not yet been developed.

In folk music, these performers did well as long as they kept their performance venues small. However, with the birth of the recording industry in the early to middle portion of the 20th century and continued urbanization, the performance venues for this type of music grew. In addition, electrical amplification was developed. These amplification devices were built into the musical instruments but not into the vocal instrument. Therefore, performers had to learn how to amplify their voices or to produce a loud voice to be heard over the accompaniment. Successful performers learned how to do this efficiently by controlling the volume of voice use and applying appropriate electrical amplification to preserve their voices.

Performance Style—Classical

Opera, art song, and legitimate musical theater are generally considered within the classical styles of vocal production. These performers have usually had significant amounts of vocal training and attempt to take advantage of the singer's formant resonatory characteristics to have their voices heard above the accompanying musical instruments. Within these styles, however, are many different schools of training techniques, each of which is probably

best suited for different anatomic vocal tract characteristics. Successful performers will have found a style of training that is relatively atraumatic for their vocal mechanisms. In addition, within each of their styles, they will have identified a particular number of vocal roles that they can learn and perform well. They become known for performing these roles and are sought out to appear in each one. The unsuccessful performer will often attempt to perform a role for which he or she is not anatomically or physiologically well suited. This will often lead to inefficient vocal behaviors and excess vocal trauma.

Performance Style—Commercial

Commercial singing styles are those that do not use the singer's formant to be heard above the accompanying instrumentation. Gospel, rhythm and blues, country, bluegrass, pop, rock, and musical theater belting are usually considered the commercial styles of singing voice production. Often these performers have had little vocal training and may not even be aware of their absolute voice range. They sing as they talk, with the purpose of telling a story. Communication of the message through word and song is therefore critically important to their performance and to the legitimacy of their style. The shape of the pharynx is not configured to produce a "singer's formant," and they use volume with or without amplification to be heard above the instrumental accompaniment. The performer's style is dependent on the region in which he or she learned to sing and is influenced by the type of message he or she wishes to convey.

PATHOPHYSIOLOGY

Changes in vocal effort and quality are secondary to excess/inefficient use of the vocal mechanism and repeated trauma to the vocal fold mucosa. All laryngeal vibratory patterns carried to excess result in vocal fold trauma. Vibration is associated with mucosal stress and strain. The mucosa is specifically defined as the epithelium plus the superficial supporting submucosa or superficial lamina propria. Prolonged vibration leads to sloughing of the superficial layers of the epithelium plus breakdown of the anchoring filaments in the basement membrane zone, which bonds the epithelium to the underlying superficial submucosa (12).

Repeated or prolonged trauma creates injury, which the body attempts to heal. Injury induces inflammation to start the healing process. The injury and subsequent inflammation can be compounded by repeated trauma before adequate healing or by superinfection with bacteria, which may occur more readily secondary to the loss of the protective epithelial layer. It is widely believed that reflux of gastric contents also can irritate this region and impair healing. One small-animal study, however, did not show any significant alteration in the acute-phase healing after surgically injured vocal folds were coated repeatedly with gastric contents at various pH and normal saline (13).

Loss of Pliability

Inflammatory mediators induce angiogenesis (14). Therefore, these vocal fold lesions are often vascular in nature and may have associated telangiectatic vessels (Fig. 72.9). The healing process also results in excess collagen deposition and the formation of excessive cross-linkages. The regenerated submucosa is of a different nature and viscosity than the native mucosa. The vocal fold vibratory patterns are altered as the submucosa is less pliable than before injury. Early in the process, this loss of pliability is difficult to visualize. It may result in early vocal fatigue or vocal changes that are problematic only for the vocal performer. In relatively severe forms, these differences in pliability may be visualized as vibratory asymmetry on laryngeal stroboscopic examination and cause dysphonia in both the speaking and singing voice.

Benign Vocal Fold Lesions

Severe and repeated forms of vocal trauma result in a benign pathologic response (15). Because vibration is traumatic in itself, too much vibration and vibration

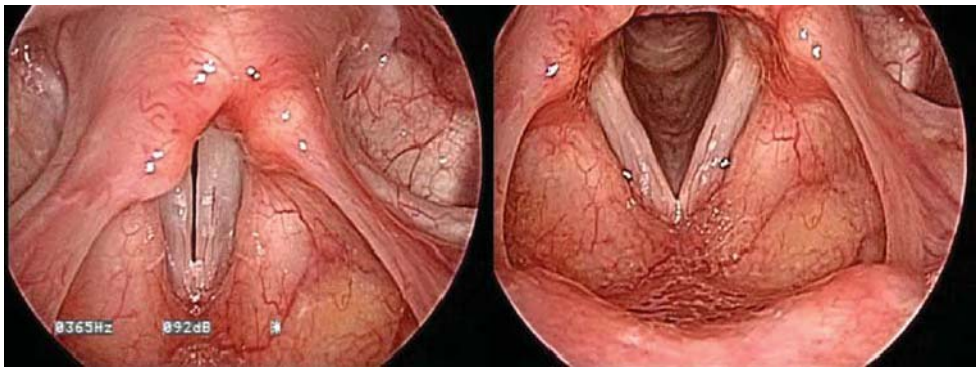

Figure 72.9 A telangiectatic vessel and vibratory asymmetry in a professional singer.

produced with inefficient application of the physiologic principle of laryngeal adduction, tension, and respiratory support are probably even more traumatic to the vocal fold epithelium. On a long-term basis, as the body responds to the trauma, the vocal folds heal in patterns that produce characteristic changes in the underlying submucosa or superficial lamina propria. These patterns are clinically referred to as benign vocal fold lesions of the lamina propria (nodules, polyps, fibrous mass). They represent a chronic response to trauma. In general, this response is acellular. It is probably regulated by vocal fold fibroblast activity that is altered by the trauma and the vibratory patterns. The epithelium, which is initially damaged in the region of each lesion, usually regenerates with minimal alteration other than slight thickening or keratosis. The basilar layers are well formed, and maturation of the epithelial layers occurs as expected. Within the superficial portion of the lamina propria, the extracellular matrix proteins are disorganized. Collagen and fibronectin concentrations are increased, and the normal laminar appearance of the lamina propria is disrupted.

Laryngeal Vibration

Laryngeal vibration is affected because of either the change in mucosal viscosity or interruption of the aerodynamic configuration of the larynx by the lesion or both. As stated, the lesion itself is made of a different arrangement and concentration of the extracellular matrix proteins than the normal lamina propria. This difference results in a change in viscosity of the lamina propria and loss of freedom for the tissue to vibrate. It also causes a change in vocal fold mass (Fig. 72.10). The lesion may be so large that the normal nearly closed laryngeal configuration cannot be achieved. In this instance, vibration is obtained only if the airflow is increased. The required increase may not be physiologically possible, and therefore laryngeal vibration will not be initiated or easily sustained. In these instances, the vibratory mechanism does not generate a harmonic sound source adequate for resonation through the vocal tract.

THE PEDIATRIC PATIENT

Special consideration must be given to the pediatric voice patient. The immature larynx differs from the adult in several different ways. Placement of the larynx is higher in the neck, the cartilages are softer and more elastic, and the ratio of membranous to cartilaginous vocal fold is lower. Most importantly the layers of the lamina propria differ significantly.

Development of the Lamina Propria

At birth, the neonate has paired vocal fold structures covered with respiratory epithelium. The trilaminar organization of the lamina propria, which is present in adults, is not yet developed (16). In the neonate, the subepithelial tissue of the vocal fold is composed of relatively densely arranged fibroblasts and extracellular matrix proteins. As the neonate produces sounds, the vocal folds vibrate. It is believed that this vibration influences the genetic expression of the fibroblasts to produce the mature components of the extracellular matrix (17). Through growth and maturation, the subepithelial tissues in the region of the vocal folds organize into various layers based on the concentrations of the major extracellular proteins. This specialized arrangement is identified by age 14 years. This theory of development is supported through histologic evaluation of the lamina propria from patients of various ages (18). Alterations in the passive movement of laryngeal fibroblasts in cell culture have been demonstrated to influence genetic expression of these cells (19). Because activity influences genetic expression, it is possible that vocal activity during the formative years will ultimately affect overall lamina propria development. Therefore, childhood voice use or vocal abuse may affect the potential development of these structures.

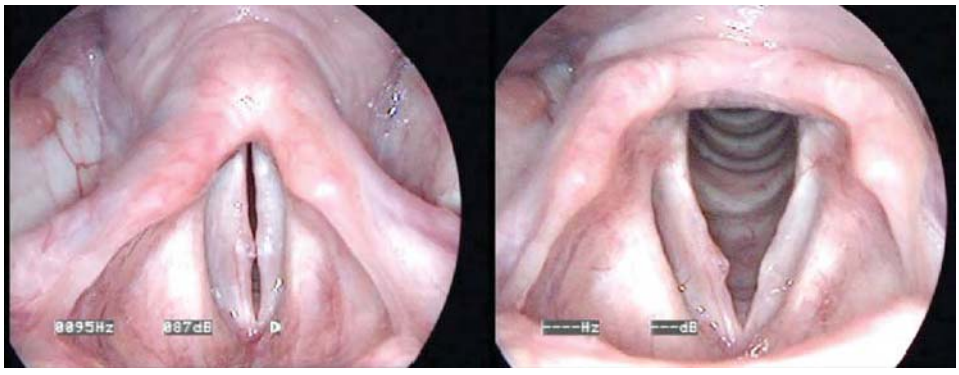

Figure 72.10 Bilateral vocal fold lesions secondary to voice overuse in a professional singer impeding vocal fold closure.

EVALUATION OF THE PATIENT WITH VOCAL DIFFICULTIES

It is nice to have the luxury of time to care for patients with vocal problems. However, patients often do not appear until their vocal difficulties have created, to them at least, a near-crisis situation. The otolaryngologist must be sensitive that what is a small vocal change could have significantly negative effects on the patient's vocal performance. The physician must counsel the patient regarding the difficulty in determining the exact cause of the voice problem. Diagnosis will require a thorough history of the vocal complaint as well as a focused physical examination of the head and neck and careful evaluation of the voice-production technique by a clinician interested in and knowledgeable about the previously discussed principles.

When speakers/performers use their voices to the maximum, abuse their voices, or use the mechanisms of voice production inefficiently, difficulties develop. Often vocal professionals will appear for evaluation when they first notice a change in their voices. If they are thoughtful about their voices, this will usually occur before others around them notice a vocal change. Therefore, their speaking and possibly their singing voice may still be normal in quality.

Complaints

The most common complaint from the singer is often a noticeable increase in effort required to produce voice or early vocal fatigue. They also may notice that this occurs more frequently in their mixed voice, in which they are attempting to adjust tension and airflow finely to regulate sound. Finally, they may also complain of a loss of the high range of their voice (especially when singing softly) when vibration is confined to the most superficial portion of the lamina propria. This may even have resulted in the loss of one or two of the top notes of their vocal range.

Singers/performers who are not so in touch with their voices may not appear until an obvious roughness or loss of occurs in their voices. However, this may have developed over years, and now the roughness is considered an integral part of their style. Often they are sought by their fans for this rough or breathy voice. The problem is frequently that they can no longer maintain stability in their voices.

History

A careful history with regard to the exact nature of the problem is critical. The physician must determine when and how the problem began. Was the onset associated with another event such as an illness, or did it occur coincident with a period of stress or a difficult performance? Once inciting events have been discussed, the physician should determine what makes the voice better and what makes it worse. Often patients will state that voice rest makes the problem better and that voice use makes the problem worse, or vice versa. The former is a fairly strong indication that the problem is secondary to abusive or inefficient vocal techniques. The latter suggests that the acute edema from voice use can help with underlying glottal insufficiency-related pathology (lesion, scar, etc.). The patient may not actually state that the voice is worse after use, but rather that voice is better on first waking and then deteriorates through the course of the day. By the end of the day or the performance, the patient may complain of neck pain or a tired sensation.

Next the physician must have the patient describe the vocal change. It is not sufficient to say that the patient is "hoarse." Rather, the physician should ask the patient about sensations of fatigue in the larynx (neck, throat), changes in quality with regard to roughness or breathiness, and last, what part of the vocal range is most affected. Often the performer is seen before obvious changes have occurred in all parts of the performing voice. The speaking voice may still be normal. Thus, some idea of vocal range and style requirements is imperative to direct the accuracy of the vocal complaint history.

Finally, with regard to history, the physician should determine what the patients have attempted to do to correct the situation. Are they taking over-the-counter, prescription, and/or a friend's medications? Have they sought counsel from friends or another physician? Have they begun treating themselves for reflux diseases? Do they have symptoms of reflux, and if they are taking medication, are they taking it properly? If so, has the medication use made a difference in the complaint? (Table 72.4).

Perceptual evaluation of the speaking voice should occur as the patient relates his or her history. The GRBAS (grade, roughness, breathiness, asthenia, strain) scale can be used to describe the voice. This is a 4-point scale wherein 0 = normal, 1 = mild, 2 = moderate, 3 = severe. In addition, the 30-question Singing Voice Handicap Index or can be used to quantify the impact of the patient's complaint on his or her quality of life (20) (Fig. 72.11). Alternatively, the

Figure 72.12 Singing Voice Handicap Index-10.

Singing Voice Handicap Index-10 has been developed as a shorter, less burdensome questionnaire with high test-retest reliability (21) (Fig. 72.12).

Physical Examination

Palpation of the external neck structures at rest and during phonation is frequently helpful in identifying unnecessary tension in these structures. At rest, the extrinsic laryngeal muscles in the neck, the tongue base above the hyoid bone, and the membranous components of the laryngeal framework should be soft and nontender. With phonation, they may tense minimally, but the patient should be able to talk with little if any difficulty while these structures are being lightly palpated. If light palpation results in significant pain, if the thyrohyoid space contracts during phonation, or if the structures are tense or become tense, then this may indicate inefficient use of the laryngeal mechanism (22). Palpation of the strap muscle attachments to the hyoid is particularly helpful to assess excessive external laryngeal muscle tension (Fig. 72.13). During palpation, the patient's neck/throat pain can often be reproduced.

The condition of the oral cavity, oropharynx, nasal cavity, and nasopharynx should be assessed for erythema, edema, inflammation, or other signs of infection. Muscular function of the pharynx should be evaluated, looking both for adequacy of palatal elevation and for lateral pharyngeal wall contraction.

Laryngoscopy

The laryngeal examination should pay close attention to vocal fold adduction and abduction. This is assessed with a constant light source and may be videotaped by attaching a camera to either a flexible or a rigid indirect laryngoscope. Mirror examination is probably no longer adequate because newer technologies such as the Hopkins rod endoscope, flexible fiberoptic scopes, or distal chip flexible endoscopes are readily available. In the majority of patients, these endoscopes allow a more prolonged visualization over the mirror examination. Depending on the clinician's techniques, patients are more comfortable with either rigid transoral telescopic examination or flexible transnasal examination. Proponents of each technique will cite advantages of their favored technique over the other. However, no adequate scientific studies have been carried out to support one technique over the other. They are probably best used as complementary techniques, and the laryngologist should become familiar with both.

Stroboscopy

After assessment of vocal fold abduction and adduction, a stroboscopic light source can be used to assess the vibratory parameters of the vocal folds. These parameters have been discussed in detail elsewhere. The otolaryngologist must understand the physiologic requirements for vocal fold vibration and what the absence of vibration may indicate. When the vocal folds are not vibrating in a relatively periodic manner, stroboscopy is of little use because the

Figure 72.13 Laryngeal palpation.

stroboscope light source flashing in a periodic manner relative to the aperiodic vibratory patterns will not produce a useful image.

Acoustic Analysis

Voice measures can be performed by a speech language pathologist to quantify the perceptual assessment of voice. There are several commercial software programs available to aid in acoustic analysis. A multitude of parameters can be evaluated including voice pitch, range, loudness, maximum phonation time, and aerodynamic measures (Fig. 72.14).

Discussion of Findings

When an obvious vocal fold lesion, impairment in glottic closure, or asymmetrical vibratory pattern is identified, the physician can point these out to the patient and begin to discuss the influence the findings may have on the function of the sound source. Caution should be used when discussing an apparent lesion(s) in the face of possible acute inflammation from recent heavy voice use or an upper respiratory infection. Before discussing the diagnosis and treatment of vocal fold lesions(s) with a professional voice performer, all attempts should be made to differentiate localized vocal fold edema versus a vocal fold lesion(s). Just because the abnormality is present, however, the physician should not always assume it is the cause of the problem unless a preexisting examination took place when the patient did not have the complaint and the lesion or change was not present. In addition, even if an obvious lesion(s) is present, the patient's behaviors most likely contributed to the formation of the lesion. If the behaviors are altered, then the lesion(s) may resolve. The patient must be asked to undergo evaluation of the vocal technique. Serial examination of the larynx during this period of altered behavior should be undertaken to assess the effect that the change in behavior will have on the lesion(s). If a significant change in the appearance occurs relatively surgical intervention is unlikely.

REFLUX

Frequently, patients have been told that reflux is the cause of their vocal difficulty and that they need antireflux medication. However, for voice problems not associated with classic reflux symptoms, this type of treatment has not been shown to be particularly successful (23). Randomized medication-versus-placebo studies for the use of proton-pump inhibitors (PPIs) for these types of patients have involved limited numbers of patients. Although these studies have not shown a particular benefit of medication over placebo for the management of nonspecific voice complaints, both studies had significant methodologic flaws that preclude definitive conclusions regarding the use of PPIs for nonspecific voice complaints (24,25). What is known about extraesophageal reflux is that it is not harmful to treat a patient for reflux disease with PPIs; that when questioned, most patients with atypical symptoms of reflux will have more typical symptoms of gastroesophageal reflux (GER);

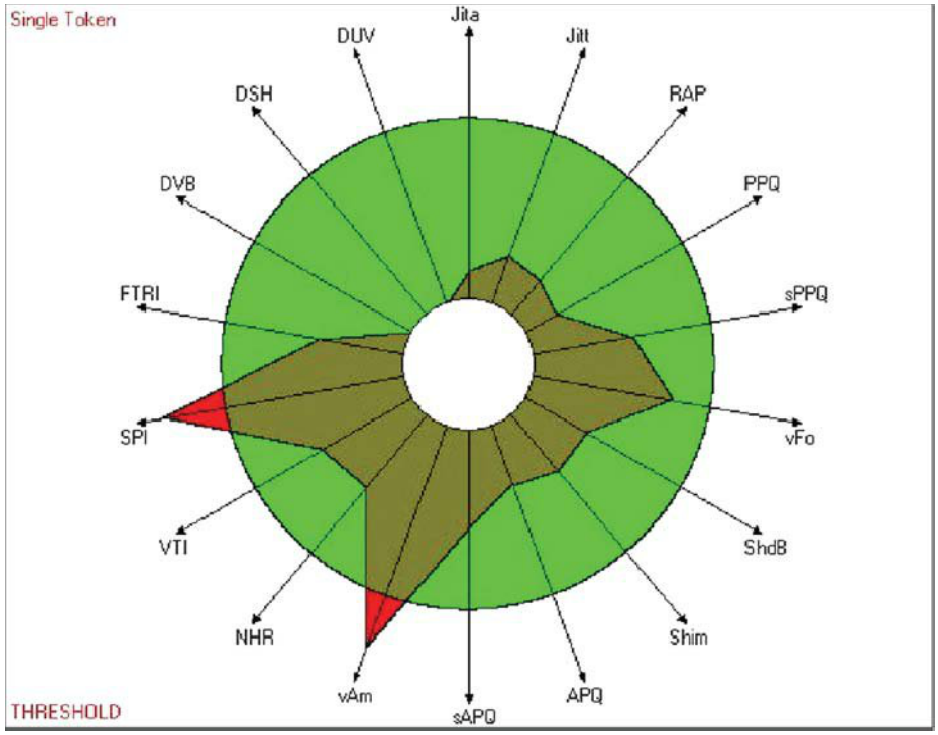

Figure 72.14 Multidimensional voice program.

and most patients with primary GER will actually have coexisting atypical symptoms. In clinical practice, therefore, if patients have typical symptoms of GER, then their voice complaints are more likely to respond, at least in part, to antireflux therapy (26,27).

MANAGEMENT

Multidisciplinary Evaluation

In most instances, vocal problems are secondary to inefficient voice-use patterns or voice abuse and overuse. Although the physician must identify and address secondary medical problems that may affect voice production, such as chronic lung disease, gastrointestinal disturbances, and systemic neurologic illnesses, treatment is primarily directed at eliminating the source of the trauma and improving the efficiency of the vocal mechanism.

The primary step in management, therefore, is patient education on the particular effects of voice production on the vocal mechanism and the potential harmful effects of irritants to the vocal fold mucosa such as smoke, nonhumidified air, and reflux (28). This education process is best undertaken by a team of clinicians. An otolaryngologist manages the medical issues and addresses the elimination of irritants. A speech–language pathologist addresses misuse and abuse of the speaking voice, and a vocal pedagogue addresses efficiency issues in the singing voice. All three clinicians must evaluate and discuss all aspects of clinical care so that a unified treatment plan can be presented to and carried out with the patient. If the evaluation by the otolaryngologist, speech pathologist, and vocal pedagogue cannot occur simultaneously, then the first clinician examining the patient, frequently the otolaryngologist, should discuss these physiologic changes and institute laryngeal hygiene interventions until the patient's vocal techniques for singing and speaking can be fully evaluated.

Laryngeal Hygiene Measures

Behavioral changes begin with lifestyle modifications such as smoking cessation, avoidance of excessively dry environments, and the elimination of extraneous and loud voice use not required for the professional career. Patients are also asked to alter their diets by changing the timing of food consumption. They are instructed to avoid foods high in fat content and foods containing natural diuretics. In addition, the patient is instructed to increase free water intake. These measures are designed to promote healing of the laryngeal mucosa by providing rest from vibration, reduction of irritation, and a healthier, thinner mucus coating to act as a lubricant for the vocal folds. These interventions are often labeled "laryngeal hygiene measures" and are a form of speech therapy (Table 72.5). Their application must be monitored, and they are most successfully used if patients are provided with a scheme for positive reinforcements. Frequently, the vocal improvements in themselves are the strongest form of positive reinforcements.

TABLE 72.5 LARYNGEAL HYGIENE MEASURES

Smoking cessation
Avoid excessively dry environments
Eliminate extraneous and loud voice use
Avoid eating prior to bed
Avoid foods high in fat content
Avoid foods containing natural diuretics
Increase free water intake

Hygiene measures in themselves usually provide some degree of relief and may eliminate the problem altogether (29). This phenomenon is particularly true in established performers as they continue to take on more obligations in both their personal and professional lives. One example is the female performer, avocational choral singer or otherwise, who finds herself experiencing vocal difficulties shortly after her children begin to speak. In addition to her previous vocal uses, she now finds herself reading or singing to her child when she would have normally rested her voice.

Performance

The performance schedule and style also should be addressed at the initial presentation. Performance schedules often require over-use/abuse of the vocal mechanism. Interestingly, most opera companies ask their singers to perform only every other day. Typically, larger companies will run two shows, with one performed on Thursday and Saturday and the other on Friday and Sunday. Opera companies must have recognized early that even classical styles of voice production are traumatic and performers benefit from rest between performances. Opera companies also expect to lose money on each performance and survive only through investment of their endowment and charitable contributions. Commercial singers on the other hand, perform four to seven nights consecutively. This habit reduces the financial costs with each performance and allows the group to survive and cover their expenses. It does not allow significant rest between performances. Patients frequently need to be counseled on the avoidance of too many consecutive shows and the need to rest their voice between performances. The reminder that they are being paid to sing and not to speak with their friends or fans is often helpful.

Voice Therapy

Laryngeal hygiene measures take away harmful behaviors. Psychological reconditioning for the elimination of behaviors is a difficult task for the patient and

clinician to accomplish. Positive reinforcement is provided through easing and improvements in vocal production; however, this may not be enough to improve the voice significantly (28). Under these circumstances, patients should undergo vocal instruction on healthier/more efficient methods of vocal production. These interventions introduce new behaviors that are more easily rewarded in a positive manner when they are completed successfully. This type of voice therapy should be directed by a clinician experienced in methods of voice production.

Speech–language pathologists completing a master's degree clinical clerkship or apprentice year are certified by the American Speech and Hearing Association. This certification does not imply that the clinician is interested or experienced in methods of voice production. Speech–language pathology is a broad field, and the clinician may have a stronger interest in language or speech rather than voice. Usually, the clinician interested in voice has had to seek out individual experiences in education in this field as only the minimum of voice instruction is required for graduation. Just as the otolaryngologist may be more interested in other areas of their specialty than laryngology, so too may be the speech–language pathologist. The otolaryngologist interested in practicing laryngology must seek out similar interested speech pathologists in their community.

Some of these techniques of vocal retraining include laryngeal manipulation techniques to allow the patient to eliminate excess cervical and laryngeal tensions through massage and repositioning. Others address reduction in cervical or laryngeal muscular hyperactivity through relaxation techniques generalized for the entire body. Still others address aspects of vocal production, such as flow phonation or resonant voice therapy, which attempt to have the patients learn new physical sensations during voice production.

With regard to retaining singing voice techniques, many performers are often fearful that someone will attempt to change their style or sound that has made them successful. The classical singers have years of study and a complicated emotional relationship with their previous teachers invested in their voices. Often they will respond only to someone who shows empathy for their experiences. The commercial performer is often a person who does not want to appear reliant on others. They may feel that their technique or lifestyle gave them what they have and could not be the cause of the vocal problem. The successful pedagogue must be aware of these feelings. Patients need to express a readiness level to change before therapy can be instituted. The otolaryngologist must identify a vocal-pedagogue colleague who has an understanding of the physiologic methods of voice production and the maturity to work with this group of patients.

ACUTE CARE FOR THE EMERGENT VOCAL PROBLEM

When patients appear for evaluation, they usually expect to have their problem fixed rapidly. They want a pill or a surgery to correct the difficulty. The physician must explain to them that most vocal problems are created through inefficient behaviors. The physician must also explain the patient's roles in creating the vocal problems and attempt to abolish the "quick fix" mentality. This can be aided by explaining the complexity of vocal production. Attempts to relate the complaints to previous voice-use pattern also can help establish the concept that the patients behaviors have contributed to the difficulty. Finally, in the resistant patient, voice rest to eliminate all inefficient behaviors can be used.

Voice Rest

For 1 week, the patient is asked to comply with absolute voice rest. He or she then returns for repeated evaluation and examination with stroboscopy. If the patient notices that the voice complaint is significantly reduced or that the stroboscopic appearance of the larynx is significantly improved, then the patient will more likely accept the fact that his or her behavior is responsible for at least a portion of the problem. Voice rest is a diagnostic tool that should not be used lightly. It is emotionally difficult to comply with voice rest, and it can have significant financial implications. Prolonged periods are not beneficial and are unnecessarily stressful. Voice rest is like a crash diet. Once the behaviors return, the lesion will enlarge. The disease-free period may allow the patient to get through a difficult or important performance, and it may improve the readiness level to accept behavioral-based intervention therapy.

Steroids

Systemic steroids also may be used to speed the temporary reversal of laryngeal inflammation induced by poor behaviors or an upper respiratory infection. Once again, these may help the patient through a difficult performance, but they are not an option for long-term management. In addition, patients need to be warned about the potential that the steroid dose, either oral, intramuscular, or intravenous, may not significantly alter the larynx and voice production and that steroids can be associated with adverse side effects. These include changes in mental status, temporary weight gain, insomnia, acne, hyperactivity, and aseptic necrosis of the hip. First-time steroid use should be avoided before a major performance. Finally, if a vascular lesion is present, steroids may be relatively contraindicated, as they can result in an increase in capillary membrane permeability and may predispose to vocal fold hemorrhage.

Topically inhaled steroids are contraindicated in the management of voice problems. These steroids are meant to reduce inflammation in the lungs. On the vocal folds, they are irritating, predispose to fungal overgrowth, and increase the likelihood of fungal laryngitis. The medications and the vehicles with which they are aerosolized dry the vocal fold mucosa; thus they alter the viscosity and create a disturbance in the vibratory abilities of the vocal folds. In addition, it has been suggested that prolonged use can lead to vocal fold atrophy. The latter, however, has not been proven scientifically.

Performance Cancellation

Occasionally, the vocal professional presents to the physician with an acute vocal problem immediately before a vocal performance. The physician will be asked to determine if the patient can perform. Accepted contraindications to performance include vocal fold hemorrhage, vocal fold ulceration, acute inflammation from presumed viral or bacterial causes, and the feeling of the patient that performance at that time will be difficult, not productive of an adequate voice quality, and damaging for the patient's image and career. The physician must document the vocal history, the laryngeal appearance, and the conversation with the patient or the patient's managerial assistant or both. This becomes a legal part of the medical record. It is shared only once the patient has signed a medical release for dissemination to the designated parties. This should not be taken lightly, as the act of canceling a performance may in itself be damaging to the performer's reputation.

The patient–doctor relationship dynamics can be strained or altered by the involvement of the institution (employer) who has employed the sick singer. The otolaryngologist must treat the issues associated with this "triangle" very carefully. Sometimes a vocal performer will seek the assistance of an otolaryngologist to obtain help in getting out of a pending singing obligation (usually in favor for a more lucrative role elsewhere). This situation must be handled with great delicacy, and documented permission must be obtained from the patient before communication with the employer is attempted. It is best to review, in detail, the medical "report" that will be given to the employer (once patient approval is obtained) before providing your opinion to the singer's employer.

SURGICAL MANAGEMENT

Indications

The mere presence of a vocal fold lesion is not an indication for surgical intervention. Because of voice overuse and abuse, performers are at increased risks of developing lesions on the vibrating portions of their vocal folds. Because these lesions develop as a histologic response to injury, the source of the injury must be eliminated. This can be done through vocal hygiene measures, which reduce the absolute activity, or the patients can be reeducated to use their vocal mechanisms more efficiently so that they can perform for longer periods with less laryngeal stress. Not every patient will want to or be able to make the required changes. For this reason, some patients never become surgical candidates. In others, the voice improves, and the lesion may or may not reduce in size. As long as the patient is able to perform to the level needed, then no reason exists to remove the lesion.

When the patient attempts to comply with behavioral recommendations, three outcomes are possible. First, the behavioral changes can result in enough resolution to allow the patient to perform to the desired level. Second, the patient may not be able to make the changes. Third, the patient may appear to make the changes, but the lesion may not become small enough to allow the patient to function properly. In the second and third conditions, surgery may be indicated. In the second situation, the hope is that by improving the laryngeal configuration, the patient will be able to function more efficiently so that the lesion does not reoccur. In the third situation, the hope is that the lesion is not persistent because of continued unrecognized harmful behaviors. In both of these instances, the surgeon must trust the opinions of his speech–language pathology and vocal pedagogy colleagues.

The patient must be counseled about the risks of surgery, including undesirable healing with stiffening of the vocal fold and further impairment of laryngeal vibratory function. The patient must be aware that a risk exists that the postoperative voice or function could be worse secondary to poor healing. The patient also must be aware that postoperative behavioral changes will be necessary to lessen the likelihood of recurrence of the lesion, and this period of healing and reeducation will take 2 to 6 months before the patient is ready to perform at the optimal level. Finally, the patient must be aware that if he or she is unable to make the required behavioral changes, then the lesion or a similar lesion may reoccur.

If a patient is noncompliant with the recommendations of the voice care team, then even if the lesion is enlarging, the patient should not undergo surgery as long as the surgeon is certain that the lesion is not of neoplastic origin. In this instance, if the vocal fold lesion(s) is removed and the abusive phonation style continued, the patient's voice will not improve or will even deteriorate. This poor outcome will be blamed on the surgeon. This patient has not expressed a readiness level for surgery. These conversations must be documented with the patient and become part of the medical record. The discussion does not excuse poor surgical techniques but documents that these potential outcomes and alternative therapies have been considered. In this manner, the patient is fully informed of all options.

Surgical Techniques

In professional voice patients, as in most patients with vocal difficulties not due to neurologic impairment, dysphonia results from traumatically induced acellular changes in the vocal fold as a response to repeated injury. These lesions disrupt the normal laryngeal vibratory patterns and lead to a disordered sound-source signal. These lesions usually develop within the superficial portion of the submucosa. Surgery is designed to restore the normal laryngeal configuration with minimal involvement of the unaffected regions. Techniques using high magnification and microinstrumentation have been developed to aid in the accomplishment of these goals. These techniques, termed microflap surgeries, have been used for more than a decade. They have been used by multiple surgeons and are associated with reliable outcomes (30–32).

CONCLUSIONS

The techniques used to care for professional voice patients are based on an understanding of laryngeal anatomy and human physiology for voice production. The laryngologist must have an understanding of the vocal demands of the voice patient. These concepts are important for both professional and nonprofessional voice patients and should be generalized from one group to the other. The difference between the groups of patients is that, because of performance requirements, professional voice patients may place their laryngeal mechanism at greater risk of damage than do nonprofessional patients. The otolaryngologist is best able to treat the patient when he or she has taken the time to learn these special demands or partners with someone who has.

HIGHLIGHTS

- The vocal fold lamina propria develops into an organized trilaminar structure by age 14 years. The genetic expression of the fibroblasts that direct this organization are likely affected by use.
- Human voice production requires that power derived from air from the lungs drives the vocal folds passively into vibration. This vibration creates a sound source that is modulated through the supraglottic vocal tract.
- During voice production, the speaker controls the sound output through fine regulation of subglottic pressure, laryngeal closure, and vocal fold tension.
- The harmonic sound source from the larynx is modulated by changes in the shape, length, and distal opening of the supraglottic vocal tract. These physical changes in the supraglottic vocal tract are created by muscular contraction and movements of the tongue, pharynx, and lips.
- The harmonic regions that are amplified by the vocal tract are termed formants. The first two formants are responsible for vowel differentiation, whereas the third, fourth, and fifth formants provide the sound timbre. The singer's formant is created by changing the shape of the supraglottic vocal tract to boost the higher formants.
- Many vocal problems are secondary to inefficient use of the mechanisms of voice production.
- Most vocal fold lesions of the lamina propria result from prolonged or repeated trauma due to inefficient laryngeal vibratory patterns. The lesions form as a response to injury.
- Evaluating patients with voice complaints requires a thorough history specific to voice, a complete head and neck examination, probably including laryngeal stroboscopy, and knowledge regarding the vocal requirements and the physiologic principles used for voice production.
- Laryngeal stroboscopy is used to evaluate vocal fold vibratory activity.
- Laryngoscopy is used to evaluate cricoarytenoid-joint motion.
- Voice rest is a diagnostic tool. Prolonged voice rest can be emotionally difficult and financially damaging and is rarely indicated.
- Systemic steroids may be beneficial in reducing vocal fold edema. Topical steroids are irritating to the vocal folds, are associated with increased incidence of fungal laryngitis, and are contraindicated in the management of voice problems of patients.

73 Office-Based Procedures in Laryngology

Manish D. Shah *Michael M. Johns III*

Laryngologic procedures were originally developed over 100 years ago to be done under local anesthetic in the office setting. Medical and surgical advances—such as general anesthesia, endotracheal intubation, and the operating microscope—led to a movement of procedures to the operating room. These advances provided surgeons with the advantages of bimanual dexterity, binocular vision, and high-power magnification and, thus, increased precision. Recently, there has been a resurgence in the popularity of awake office-based laryngeal procedures (1–3).

Several technologic advances have facilitated the revival of awake office-based laryngeal procedures. Distal-chip flexible endoscopes, ultrathin esophagoscopes, a variety of injection materials, and fiber-based lasers have all contributed to this trend (1,4).

Conducting laryngeal procedures in an awake patient has numerous advantages. First, awake procedures are substantially more convenient for patients when compared to procedures under general anesthesia or sedation. They may leave the hospital on their own and even return to work the same day. Patient safety is increased by avoiding the risks associated with general anesthesia, which is especially important for patients with significant medical comorbidities.

Second, there are significant advantages for the surgeon. The ability for the patient to phonate allows the surgeon to monitor voice quality before, during, and after the procedure. Furthermore, diseases that were once observed until severe enough to warrant exposing the patients to the inconveniences and risks of general anesthesia, such as glottal leukoplakia/dysplasia or papillomatosis, can be treated as frequently as indicated by clinician concern and patient symptoms.

Finally, there is a cost savings by avoiding expensive operating room resources (5,6), and patients and their families can minimize or avoid lost work days.

LARYNGEAL VISUALIZATION

The development of endoscopic technology and illumination has led to improved visualization of the larynx, which is essential to the diagnosis and treatment of laryngeal pathology. Laryngeal videostroboscopy, kymography, and high-speed cinematography are all techniques that allow for detailed examination of vocal fold vibration that cannot be appreciated with standard mirror or fiberoptic laryngeal examination. These topics are covered in more detail elsewhere in this book (see Chapter 65).

For awake office-based procedures, both rigid and flexible endoscopes can be used, as is described in this chapter. Rod-lens endoscopes generally provide superior image quality when compared to flexible fiberoptic endoscopes due to larger and more stable light-carrying fibers. However, the development of flexible endoscopes with a chip-based camera at the end of the scope ("distal-chip") has led to image quality that is near equivalent in quality to rigid rod-lens scopes (7).

PATIENT SELECTION AND PREPARATION

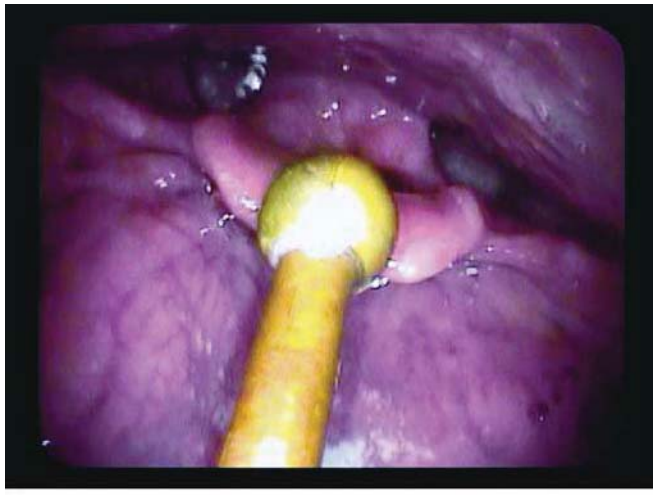
For the purposes of this chapter, "office-based" implies that the patient is awake, with no or minimal sedation, sitting upright, and able to provide phonatory feedback. Procedures may actually be done in a hospital-based procedure room such as an endoscopy suite, but the advantages of these procedures are realized as long as there is adherence to these principles.

The vast majority of patients will tolerate an awake laryngeal procedure; however, patient preparation is essential. The surgeon must clearly explain the procedure, including the application of topical anesthesia, and gauge the patient's level of comfort and anxiety. It is essential to explain the abnormal sensations produced by topical

anesthesia of the pharynx and larynx as well as the mild discomfort the patient may feel during the procedure itself. Procedures should not be attempted on patients who seem too anxious to proceed; however, even very anxious patients will tolerate an awake procedure if they are adequately informed ahead of time and coached throughout.

Patients must have a patent nasal airway for passage of a flexible laryngoscope and must be able to tolerate such an examination without an intense gag reflex. Patients who are not able to remain still for the duration of the procedure, such as patients with cervical dystonias or severe head tremor, may be difficult to treat (8). Those on anticoagulants should stop taking these medications prior to injections or biopsies. However, the experience of the authors and of others (3,8) suggests that complication rates are not higher in these patients even if they are unable to stop these medications.

ANESTHESIA



Adequate anesthesia of the laryngopharynx is of utmost importance to the success of any awake laryngeal procedure. This can be achieved by either topical application of anesthetic medication or superior laryngeal nerve (SLN) blocks (Fig. 73.1A). Almost always, the former will suffice; however, the latter can be useful in certain patients. Whichever method is used, patients must be instructed to remain NPO for 30 to 45 minutes after the procedure due to the risk of aspiration secondary to laryngopharyngeal anesthesia.

A

B

C

Figure 73.1 **A:** Equipment and medications required for laryngopharyngeal topical anesthesia. Shown in the photograph are topical 4% lidocaine solution, oxymetazoline, spray bottle to aerosolize medications for nasal anesthesia, Abraham cannula, and syringe with needle for transtracheal injection of anesthetic. **B:** Transtracheal injection of anesthetic for topical laryngotracheal anesthesia. **C:** An Abraham cannula is used to drip topical anesthetic onto the larynx.

Topical

The nasal cavity should be anesthetized and decongested if a flexible scope is to be used for the procedure. Our preference is to use oxymetazoline and 4% topical lidocaine. The laryngopharynx can then be anesthetized by one of four methods:

1. Transtracheal injection of 2 to 4 mL of 4% lidocaine into the lumen of the trachea (Fig. 73.1B). This will elicit a strong cough reflex, delivering the lidocaine to the subglottic, glottic, and supraglottic levels. The airway should be entered below the cricoid cartilage as opposed to through the cricothyroid membrane. This avoids the plexus of blood vessels found at the cricothyroid membrane and minimizes bleeding in the larynx, which can obscure structures during the procedure itself. If the patient has a tracheostomy, instillation of the anesthetic through the tracheostomy tube with subsequent occlusion of the tube during the cough will produce a similar effect.
2. With a flexible or rigid scope used to visualize the larynx, an Abraham cannula (Pilling; Teleflex Medical, Research Triangle Park, NC) can be used to deliver 2 to 4 mL of 4% lidocaine to the base of tongue, epiglottis, and larynx (Fig. 73.1C). A "laryngeal gargle" is performed by having the patient phonate during the delivery of the anesthesia in order to maximize contact time with the laryngeal mucosa (9).
3. The anesthetic can be delivered via a syringe attached to the working channel of a flexible laryngoscope. As above, a "laryngeal gargle" will maximize effectiveness of anesthesia.
4. Lidocaine can also be nebulized for anesthesia; however, further topical anesthesia is often required for patients to tolerate the procedure (1,4).

Lidocaine will result in 45 to 60 minutes of anesthesia within 90 seconds of application. However, most patients will only tolerate the procedure for approximately 20 to 30 minutes (1,8). Various topical anesthetic medications may be used as long as the maximum dose guidelines are strictly followed (1,8).

Superior Laryngeal Nerve Block

The site of injection for an SLN block is halfway between the hyoid bone superiorly and the superior border of the thyroid cartilage inferiorly, and halfway between the anterior midline and the superior cornu of the hyoid bone (10). This corresponds to the point where the internal branch of the SLN pierces the thyrohyoid membrane to enter the larynx. One to two milliliters of anesthetic is injected in this area, superficial to the thyrohyoid membrane, to provide a nerve block. The duration of anesthesia will depend upon the agent(s) used. The procedure should be done on both sides of the larynx.

Complications of Topical Anesthesia

Significant complications of topical anesthesia are very infrequent (10). Vasovagal reactions can rarely occur (10), but actual syncope can often be prevented if the prodromal symptoms are recognized. The procedure should be aborted and the patient placed in a reclined position.

Systemic toxicity may result from inappropriately high doses of topical anesthetic agents. Early symptoms can include perioral and tongue paresthesias, visual disturbance, lightheadedness, dysarthria, muscle twitching, and tinnitus. These symptoms must be recognized very early as cardiovascular collapse, convulsions, and cardiorespiratory arrest are possible. This highlights the importance of strict adherence to recommended maximum doses for each anesthetic agent. Dose adjustments may be required in patients with hepatic compromise, renal insufficiency, or heart block.

Allergic reactions are also possible but are usually mild, and anaphylaxis is rare (8). Even more rare is methemoglobinemia, which results in impaired oxygen delivery to tissues and is most commonly seen with the use of benzocaine or prilocaine. Early signs include "chocolate cyanosis"—a brown or gray discoloration of the lips and mucous membranes. It can progress to involve dysrhythmias, seizures, myocardial infarction, coma, and death.

MONITORING DURING AWAKE LARYNGEAL PROCEDURES

Patients do experience significant changes in hemodynamic parameters during awake laryngeal procedures. In a study of 31 patients who had monitoring of their vital signs during their procedure, 23% of patients developed severe hypertension and 29% significant tachycardia (11). Furthermore, none of these patients reported or showed signs of abnormal amounts of discomfort (11). Despite the fact that others have found that the vast majority of patients tolerate procedures and report minimal pain or discomfort (12,13), these findings suggest that patients are experiencing significant hemodynamic changes that do not correlate to subjective comfort levels. Given the low complication rates of awake procedures, these changes likely do not pose a significant danger to patients. Thus, in general, it is the opinion of the authors that monitoring is not indicated in patients who do not receive sedation. However, patients with significant comorbidity such a severe cardiac or pulmonary disease may benefit from pulse oximetry and/or blood pressure monitoring.

AIRWAY EVALUATION AND ASSESSMENT

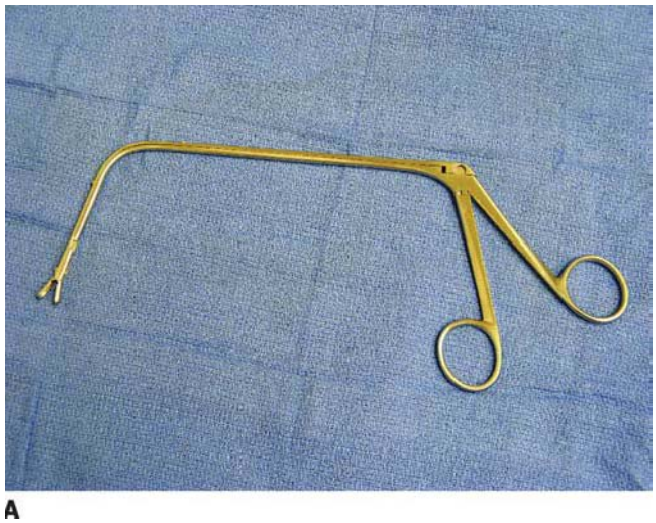
With adequate anesthesia, the airway can be examined fully in the office. It allows for evaluation of both dynamic and fixed obstruction, which cannot be done under general

anesthesia with rigid endoscopy. This can yield important information to help plan and guide any potential operative intervention, as well as to monitor operative results during follow-up. Concern of laryngospasm and lack of patient tolerance often prevent clinicians from employing these techniques. However, it is a very safe technique (9) that can provide immediate and valuable information.

Cricoarytenoid Joint Fixation and Posterior Glottic Stenosis

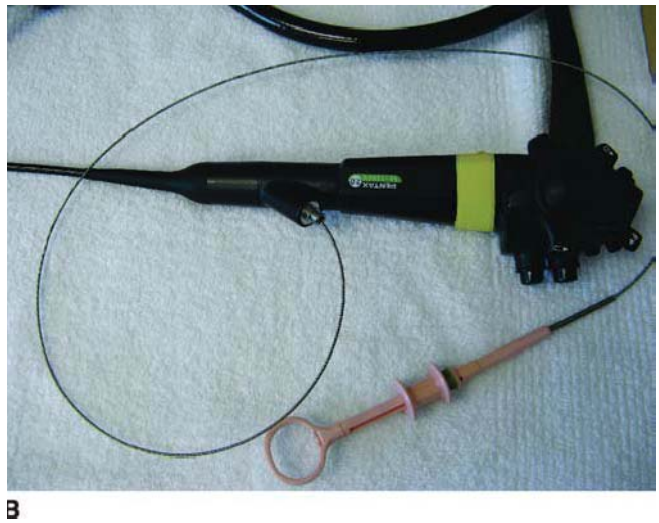
When a patient presents with an immobile vocal fold, one must distinguish between cricoarytenoid (CA) joint fixation and nerve paresis or paralysis if their history is suggestive of the former as a potential etiology. This determination is important to guide therapy and determine prognosis. CA joint mobility can be assessed by looking for the "jostle sign." An immobile arytenoid due to nerve paresis or paralysis will be "jostled" by the mobile arytenoid with phonation, whereas the arytenoid of a fixed CA will not jostle. However, this can be a very subtle sign to diagnose.

CA joint mobility can be more reliably assessed via palpation, which has classically been done via direct laryngoscopy under general anesthetic. Palpation can, however, be done awake if the larynx has been adequately anesthetized (14,15). A flexible or rigid endoscope is used to visualize the larynx while the surgeon or patient holds the tongue, and a curved forceps or Abraham cannula can be used to provide gentle pressure at the vocal process of the arytenoid cartilage in a lateral and posterior direction.



Similarly, it is often important to distinguish between bilateral vocal fold immobility due to a neurologic cause and posterior glottic stenosis. A similar maneuver to that described above can be done with two instruments simultaneously to assess for CA joint mobility as well as posterior glottic stenosis (15).

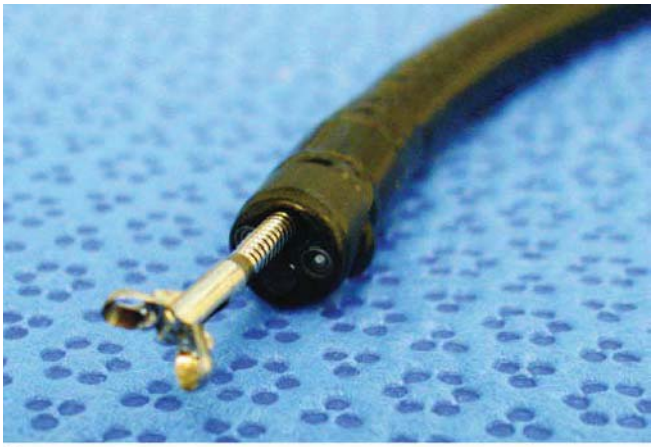
Subglottic and Tracheal Stenosis



The complete tracheobronchial tree can be evaluated with adequate topical anesthesia. With the anesthesia techniques described above, examination to the level of the carina is possible. Further examination of the bronchi usually requires application of topical anesthesia to the bronchi via the working channel of the scope. A flexible endoscope can easily be passed distal to the vocal folds with no significant risk of laryngospasm and is well tolerated by the majority of patients (9). Subglottic and tracheal stenosis, laryngeal and upper airway tumors, and tracheomalacia can be evaluated closely. The latter is easier to examine awake as opposed to under general anesthesia due to its dynamic nature. The length and degree of stenosis can be assessed, although length may be difficult or impossible to assess in severe stenoses if the scope will not pass through easily or if the patient has the sensation of airway obstruction.

LARYNGOPHARYNGEAL BIOPSY, PANENDOSCOPY, AND TUMOR STAGING

Biopsies may be done peroral with a rigid scope and a long curved biopsy forceps (Fig. 73.2A) after appropriate topical anesthesia of the larynx. The patient holds on to their tongue while the surgeon holds the scope and directs the biopsy forceps. However, this technique can be difficult to perform and is not well tolerated by all patients. The development of flexible endoscopes with working channels that pass easily through the nasal cavity has facilitated biopsies to be done in this manner. Generally, this technique is better tolerated by most patients. The scope is advanced to a position with the lesion of interest in view, and a 1.8-mm flexible cup biopsy forceps (Fig. 73.2B and C) is passed through



A

the working channel by an assistant until visible beyond the tip of the scope. The forceps are then opened and the scope is advanced until the forceps come into contact with the lesion (Fig. 73.2D). The forceps are then closed and removed from the scope. The scope can be left in place and multiple biopsies can be taken, which is advisable as the small size of the biopsy forceps can result in false-negative results.

The ability to conduct biopsies, along with transnasal esophagoscopy (TNE) and awake bronchoscopy, allows for awake panendoscopy and tumor staging to be done in the office setting. This has been demonstrated to be as effective as operative staging under general anesthesia (16).

VOCAL FOLD INJECTION

Like many procedures in laryngology, vocal fold injection began as an office-based procedure but became a well-established technique under general anesthesia. Awake injections are certainly more convenient for patients and also avoid the risks of general anesthesia. This is significant for patients with significant medical comorbidity or who are recovering from a recent operation. The latter situation can pose a dilemma in patients with operative injury causing vocal fold immobility (17), and an awake injection offers a safe alternative.

The majority of awake office-based vocal fold injections are done for injection laryngoplasty. Indications for injection augmentation include vocal fold paralysis or paresis, vocal fold atrophy, scar, sulcus vocalis, and postsurgical defects. This chapter focuses on these indications. Other indications for injection include more superficial injection of steroid, cidofovir, or bevacizumab (1,18,19).

Numerous studies have shown awake injection laryngoplasty to provide excellent results in treating glottal insufficiency (17,20), even when compared to traditional injection laryngoplasty done under general anesthetic (5,21). Furthermore, there is a substantial cost savings associated with awake injection over traditional injection under general anesthetic (5).

Injection augmentation provides almost immediate relief of symptoms. Using a temporary material in the setting of a vocal fold paralysis or paresis alleviates symptoms while waiting for potential recovery of nerve function. It also can serve as a trial to determine if a more long-lasting injection or procedure would be of clinical benefit to the patient (22). Furthermore, early injection laryngoplasty in patients with potentially recoverable vocal fold paralysis seems to reduce the need for permanent medialization in the form of laryngeal framework surgery in the future, possibly by creating a more favorable vocal fold position that can be maintained by synkinetic reinnervation (23,24).

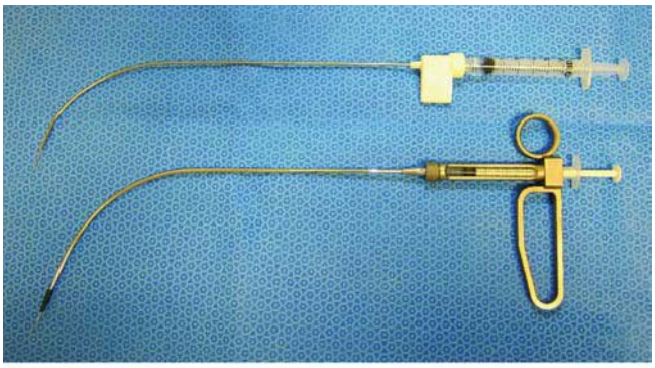
The treatment of vocal fold scar, sulcus vocalis, and vocal fold atrophy can be complicated and is covered elsewhere (see Chapter 68). Injection augmentation may be beneficial in these patients to help correct glottic insufficiency that may be contributing to their vocal handicap. Again, using a temporary injectable material provides a trial for both the clinician and patient with regard to potential benefit (22).

Techniques for Awake Vocal Fold Injection

Adequate visualization and anesthesia of the larynx are essential for a safe, precise, and effective injection. In addition to the application of topical anesthesia as described above, the skin overlying the injection site for the percutaneous approaches should be anesthetized appropriately. Apart from the peroral technique described below, all injections will require an assistant to hold the scope in position during the procedure.

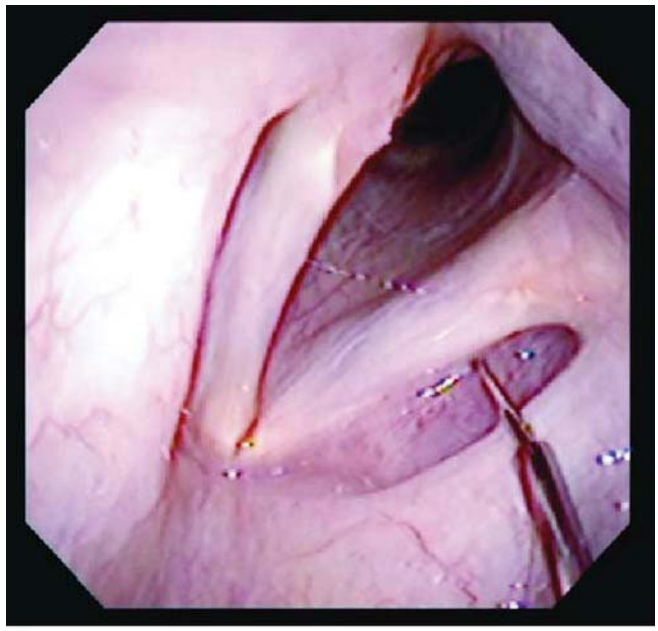
The location and amount of material to be injected is similar irrespective of the approach used for the injection (see Chapter 69). The injection should be placed within the vocal fold muscle, lateral to the superior arcuate line. Injection of material into the superficial layers of the vocal fold will disrupt normal vocal fold vibratory patterns. Placing the injection too far lateral is not harmful but will not result in significant medialization as the injectable will fill the paraglottic space. In terms of the anteroposterior dimension, the injection should be placed lateral to the vocal process of the arytenoid and at the midpoint of the membranous vocal fold. Anterior injections should be avoided as they will result in abnormal mucosal wave propagation and a "pressed" voice.

The amount to be injected to correct glottal insufficiency depends on each individual case, but most vocal folds are adequately medialized with 0.5 mL or less of material. Overcorrection is required such that there is a slight convexity to the margin of the vocal fold to account for the aqueous component of most injectable materials that will resorb. The patient's voice can be tested through the procedure to determine the most appropriate amount and location of material to be injected—a distinct advantage of awake injections.



Peroral Approach

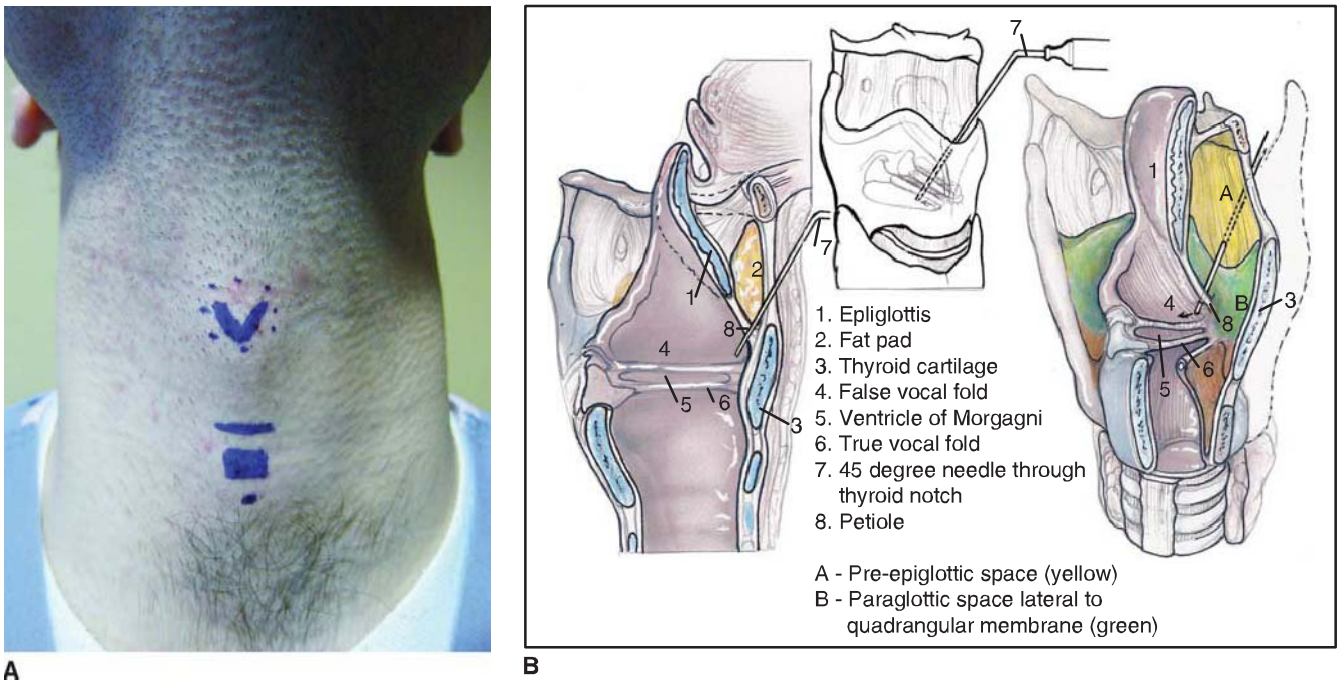
After appropriate laryngopharyngeal anesthesia, the patient's tongue is held by the patient or the surgeon, and the larynx is visualized with either a flexible or rigid scope. The latter offers the advantage of eliminating the need for an assistant as the patient holds their own tongue while the surgeon holds the scope in one hand and the needle for injection in the other. Use of the flexible scope held by an assistant, however, is generally better tolerated by the patient and allows the surgeon to have bimanual control of the needle.



A long curved needle is required. The curved orotracheal injector (Medtronic Xomed, Jacksonville, FL) is designed for peroral injections (Fig. 73.3A). This device allows for injection of materials and liquids with low viscosity such as hyaluronic acid and collagen-based materials. Other long needles designed for injection during direct laryngoscopy in the operating room can often be bent to the required shape for peroral injection, such as the needle shown in Figure 73.3A (24-gauge rigid injection needle, Merz Aesthetics, Franksville, WI). The needle is advanced to the injection site through the oral cavity and past the oropharyngeal structures. Needle placement can be easily controlled and visualized, allowing for a precise injection (Fig. 73.3B).

Thyrohyoid Approach

The thyroid notch must be readily palpable in order to employ this approach (Fig. 73.4A). In addition to topical laryngeal anesthesia, the skin overlying the thyroid

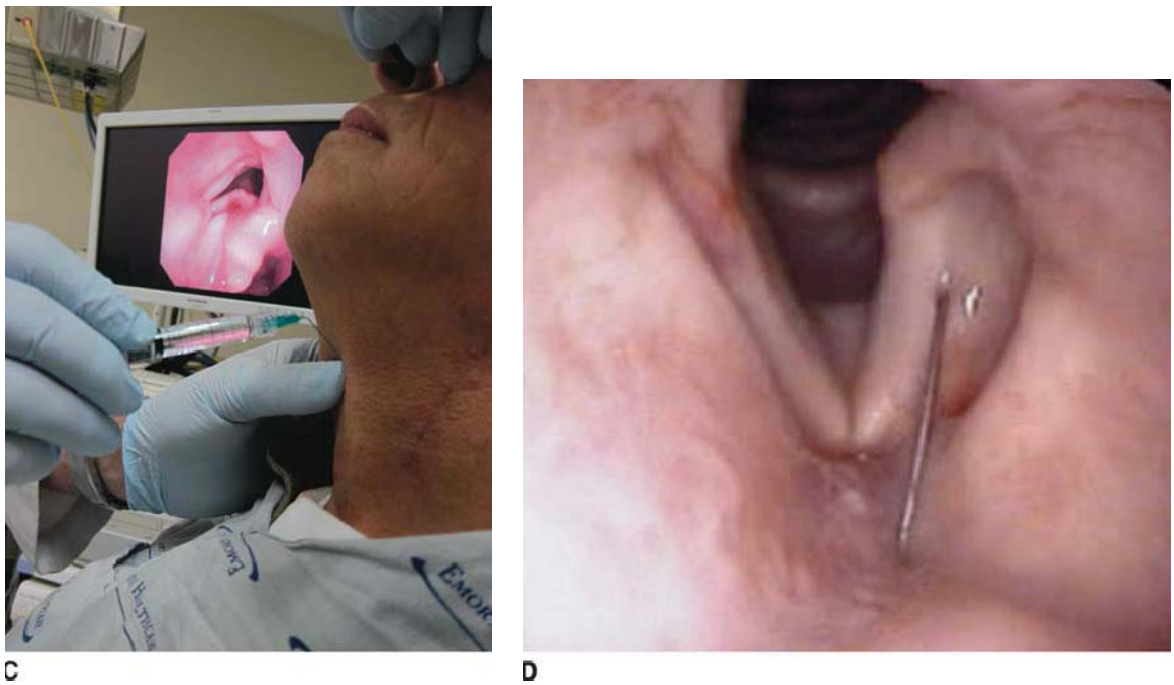


A

B

Figure 73.3 **A:** Equipment for peroral vocal fold injection. A bent needle from Merz Aesthetics (**top**: Franksville, WI) and the orotracheal injection instrument (**bottom**: Medtronic Xomed, Jacksonville, FL) are shown. **B:** Peroral vocal fold injection.

notch should be anesthetized. A flexible scope is used to visualize the larynx. A 1.5-inch 23- or 25-gauge needle is then inserted at the notch and guided acutely downward, through the pre-epiglottic space (Fig. 73.4B and C), aiming to pierce the laryngeal mucosa at the petiole of the epiglottis in the midline. The needle can then be guided to either vocal fold for injection (Fig. 73.4D). Similar to the peroral approach, there is clear visualization of needle



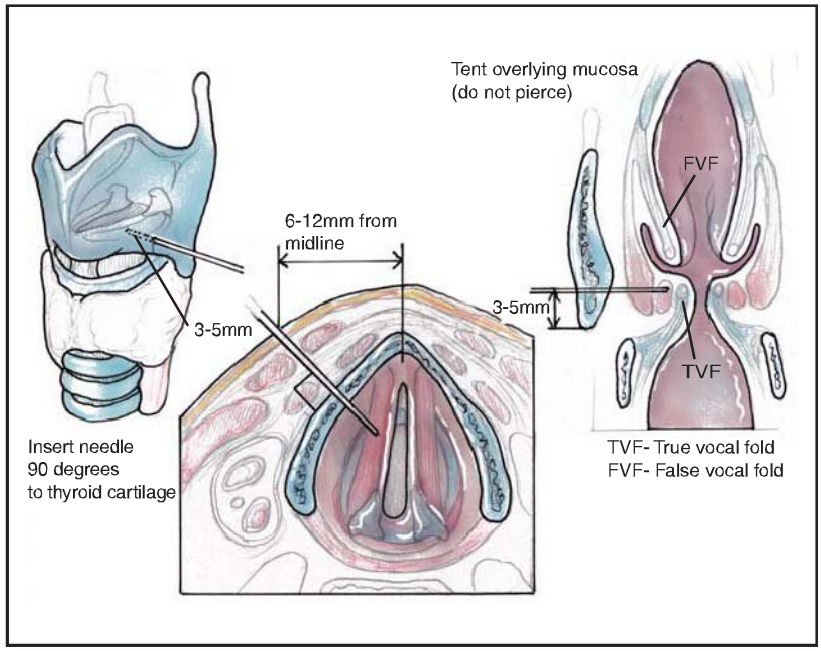


Figure 73.4 **A:** Landmarks for thyrohyoid approach to vocal fold injection. Shown are the thyroid notch ("V"), inferior border of the thyroid cartilage (*thin line*), and the cricothyroid space (*thick line*). The *dotted circle* shows the area of skin that should be anesthetized. **B:** Thyrohyoid approach for vocal fold injection. The needle enters just above the level of the thyroid notch and is directed acutely downward through the pre-epiglottic space to pierce the laryngeal mucosa approximately at the level of the petiole of the epiglottis. **C:** Thyrohyoid approach for vocal fold injection. **D:** Needle pierces laryngeal mucosa near the petiole of the epiglottis for the thyrohyoid approach for vocal fold injection.

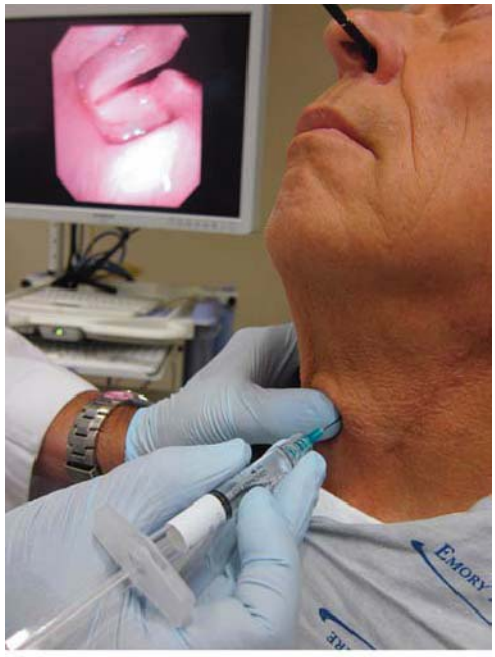
placement, allowing for a very precise injection (25). We prefer to bend the needle to approximately a 45-degree angle, which allows one to achieve the acute downward vector required for injection without the syringe hitting the patient's chin.



Transthyroid Cartilage or Transcricothyroid Membrane Approach

The skin and soft tissue overlying the thyroid cartilage, down to the level of the perichondrium, should be anesthetized (Fig. 73.5A). The goal of these two approaches

A

B

C

D

Figure 73.5 **A:** Landmarks for transthyroid cartilage and transcricothyroid approaches for vocal fold injection. Shown are the thyroid notch ("V") that marks the midline, inferior border of the thyroid cartilage (*thin line*), and the cricothyroid space (*thick line*). The *dotted circle* shows the area of skin that should be anesthetized. **B:** Transthyroid cartilage approach for vocal fold injection. The needle is inserted through the thyroid cartilage at a point approximately 6 to 12 mm lateral to the midline and 3 to 5 mm above its inferior border. The angle of the needle insertion is exactly perpendicular to the lamina of the thyroid cartilage. **C:** Transthyroid cartilage approach for vocal fold injection. **D:** The needle is seen "tenting" the mucosa from within the right vocal fold to confirm needle position during the transthyroid cartilage and transcricothyroid approaches.

is to conduct the injection without entering the lumen of the larynx; that is, the path of the needle is entirely submucosal. In theory, these procedures can be done without topical laryngeal anesthesia. However, we prefer to use topical anesthesia in case the laryngeal mucosa is breached—this prevents patient discomfort and allows for the procedure to continue uninterrupted.

For the transthyroid cartilage approach, a 23-gauge needle is inserted through the thyroid cartilage at a point approximately 6 to 12 mm lateral to the midline and 3 to 5 mm above its inferior border. The angle of the needle insertion is exactly perpendicular to the lamina of the thyroid cartilage (Fig. 73.5B and C). Once through, the tip of the needle can be used to "tent" the overlying mucosa without piercing it to confirm needle position prior to injection (Fig. 73.5D). Significant calcification of the thyroid cartilage in older patients may make this approach impossible. The Casiano transcervical laryngeal injection medialization needle (Medtronic Xomed, Jacksonville, FL) may help overcome this limitation.

The transcricothyroid membrane approach is similar to that used for botulinum toxin injection into the vocal fold. A 23-gauge needle is inserted approximately 5 mm lateral to the midline of the thyroid cartilage just below its inferior border. Once past the inferior border, the needle tip is aimed cephalad and laterally. As with the transthyroid cartilage approach, once in the vocal fold, the tip of the needle can be used to "tent" the overlying mucosa without piercing it to confirm needle position prior to injection. If the surgeon has difficulty locating the tip of the needle, the airway can be entered in the midline and the needle tip visualized prior to insertion into the vocal fold. For this reason we prefer using topical anesthesia in all patients.

The disadvantage of both of these techniques is that they are partially blind—apart from "tenting" the mucosa, the tip of the needle is not seen. Thus, it is more difficult to determine the exact depth of injection into the vocal fold.

Injection Materials

Awake office-based injections have been facilitated by the development of a variety of safe injectable materials. Any material that can be injected under general anesthetic can be injected in the office, except autologous fat. Experience with injection techniques is recommended prior to using long-lasting injectable materials. The types of materials available to be injected are covered in more detail elsewhere (see Chapter 69).

Postprocedure Care

Patients are advised to expect a poor voice immediately postprocedure due to edema and overcorrection. This will slowly improve over the subsequent 1 to 2 weeks. Postprocedure pain is usually minimal, and acetaminophen will typically suffice.

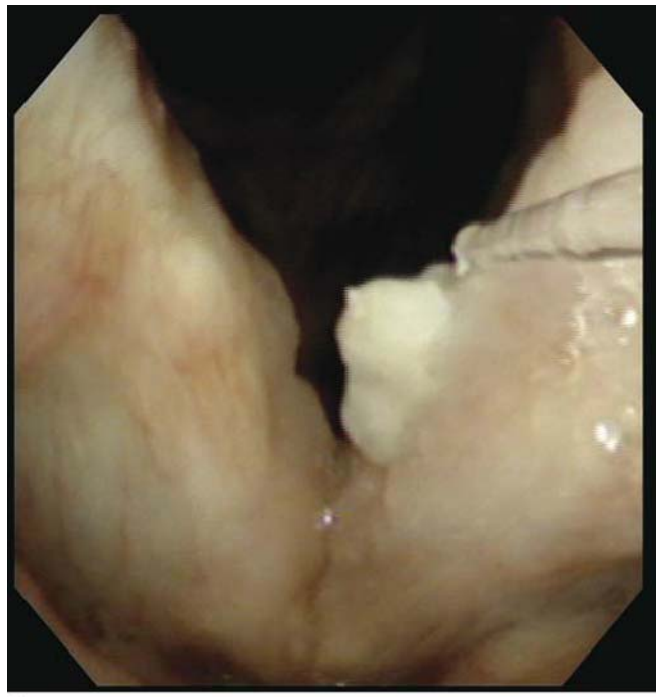
Potential Complications

Overall, it has been shown that awake vocal fold injections are safe with a very low complication rate (17,20,21,26,27). The most serious potential complication is airway obstruction, from overinjection, edema, or development of a hematoma. Patients who are unable to stop their anticoagulant medications are theoretically at a higher risk of bleeding; however, it is still a rare occurrence. Infraglottic submucosal collections of injectable are possible, most likely due to improper needle placement during injection (27). It has also been hypothesized that migration of material postinjection may lead to undesirable results.

Injection into the superficial lamina propria of the vocal fold is likely the most common significant complication. This will cause impairment of the normal vibratory function of the vocal fold, resulting in prolonged dysphonia. A superficial injection may necessitate removal under general anesthetic, especially if a long-lasting injectable such as calcium hydroxylapatite was used (28). Mathison et al. (21) did find that this complication occurred more frequently with awake injections compared to those done under general anesthetic.

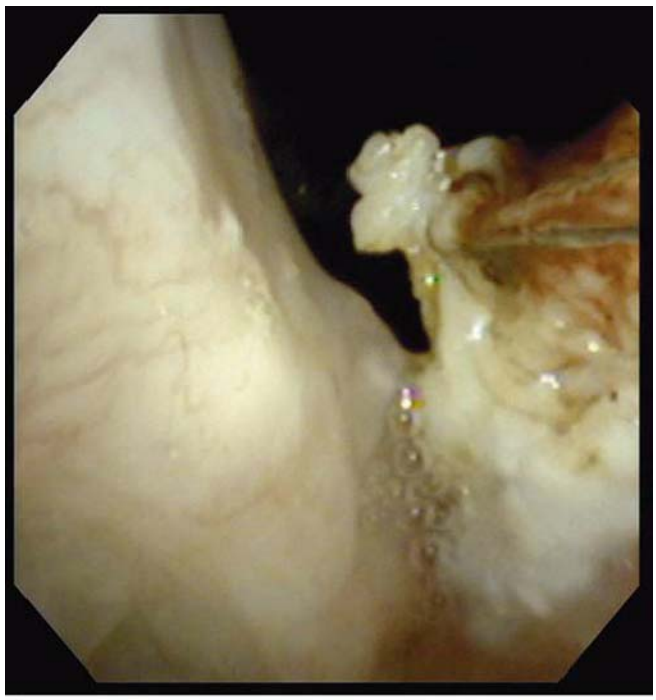
LASER PROCEDURES

Awake laser procedures have revolutionized the management of certain laryngeal pathologies. As with all awake procedures, the risks of general anesthesia can be avoided in those with significant medical comorbidity. Furthermore, they allow certain laryngeal pathologies, such as recurrent respiratory papillomas and glottal dysplasia, to be treated at the earliest sign of recurrence as opposed to the traditional approach of waiting for more significant disease in an attempt to minimize exposure to repeated general anesthesia. This allows for a lower patient and surgeon threshold for conducting a therapeutic procedure.



Awake laser procedures are well tolerated in patients who have received adequate topical anesthesia (29–31). Most patients experience minimal pain, typically do not require any postoperative analgesia, and prefer the awake procedures to procedures done under general anesthetic (12). Studies have shown that awake laser treatment of a variety of laryngeal pathologies is effective and safe. Complication rates are very low, with patient mild discomfort during the procedure being the most common complication (29–32). It should be emphasized that appropriate laser safety precautions by the surgeon, patient, and other staff involved are essential.

Laser Selection



The ideal laser for laryngeal surgery should have superficial penetration, produce minimal collateral thermal injury, and be able to cut and coagulate (1). For awake office-based laser procedures, the laser must be deliverable through a fiber that can be passed through the working channel of a flexible

A

B

C

Figure 73.6 **A:** Patient and surgeon positioning for awake office-based laser procedure. **B:** Recurrent respiratory papillomas of the true vocal folds being treated with the pulsed KTP laser. Noncontact mode is being used to ablate the superficial papilloma while avoiding any bleeding. Notice the blanched color of the treated papilloma. **C:** Treatment of papillomas on the true vocal folds with pulsed KTP laser in contact mode. This allows for removal of the treated superficial papilloma and further treatment of deeper papilloma.

endoscope (2 mm) (Fig. 73.6A). Each laser has a specific energy absorption spectrum, thus targeting a distinct chromophore. This is what determines the effect of a particular laser on each tissue type. This effect is further determined by the laser power, pulse width and interval, and spot size. The tissue characteristics further influence the interaction, such as the distribution of the chromophore and the heat dissipation ability of the tissue. The commonly described lasers for awake laryngeal surgery are discussed here.

CO_2 (Wavelength 10,600 nm; Chromophore Water)

The CO_2 laser was the first laser used for laryngeal surgery and has remained popular as it fulfilled almost all of the above properties of an ideal laser. Until recently, the CO_2 laser was not able to be delivered via flexible fiber and was limited to mirror reflected line-of-sight surgery, typically with an operating microscope.

However, with the development of the photonic bandgap fiber assembly (OmniGuide, Cambridge, MA), the

CO_2 laser can now be delivered through a fiber that can be passed through the working channel of a flexible endoscope (33–36).

Due to the fact that there is a high concentration of water in laryngeal tissue, CO_2 laser energy is dissipated quickly without deeper penetration (35). It cuts through tissue with minimal collateral thermal injury—one of the major reasons for its popularity for laryngeal surgery.

Thulium (Wavelength 2,013 nm; Chromophore Water)

The thulium laser has similar properties to the CO_2 laser due to having water as its target chromophore. It has similar cutting capabilities; however, its coagulation capabilities are superior providing excellent hemostasis (37). It can be delivered through a small flexible glass fiber, not requiring the expensive fiber required for flexible CO_2 laser delivery. It does seem to have a greater thermal effect on tissues; however, postoperative healing is clinically similar to that observed with CO_2 laser (37). The thulium laser can be used in contact and noncontact modes, a distinct advantage in awake laser surgery.

Pulse Dye Laser (Wavelength 585 nm; Chromophore Oxyhemoglobin)

The mechanism of action of the pulse dye laser (PDL) is presumed to be ablation of the blood supply of a lesion, leading to involution. Due to its selectivity for oxyhemoglobin, it is thought that tissue damage is confined to the walls of microvessels and the surrounding perivascular tissue ("photoangiolysis"). However, it has also been shown to be effective for nonvascular lesions, suggesting that another mechanism of action is also at play. This laser can also be used in contact or noncontact mode (29).

Potassium Titanyl Phosphate Laser (Wavelength 532 nm; Chromophore Oxyhemoglobin)

Similar to the PDL, it is theorized that the potassium titanyl phosphate (KTP) laser ablates the blood supply of a lesion due to its chromophore being oxyhemoglobin. However, its wavelength is more strongly absorbed by oxyhemoglobin, and it has a longer pulse width when compared to the PDL. It is thought that this results in more efficient intravascular coagulation and avoidance of vessel rupture and bleeding that can be encountered with the PDL (30,38). Furthermore, the KTP laser can be used in both contact and noncontact modes, as well as either pulsed or continuous, the latter being useful for hemostatic cutting. However, when used in this setting it has the potential to create more thermal injury when compared to the CO_2 or thulium lasers (1).

Clinical Indications

Papilloma

Microsurgical CO_2 laser excision and ablation or cold steel excision has classically been the standard surgical management for recurrent respiratory papillomatosis (RRP). However, due to the selectivity of the PDL and KTP lasers for oxyhemoglobin, and the abundant vascular supply to papillomas, these lasers have become popular in treating RRP in the office setting (Fig. 73.6B and C). Several studies have shown that these lasers provide effective and safe treatment for papillomas (29,31,32,39,40). Thulium and flexible CO_2 lasers have also been used for awake treatment of papillomas (32,37).

Patients presenting with a new diagnosis of RRP should likely be treated for the first time under general anesthetic for appropriate disease mapping and biopsies. Subsequent procedures can be done with the patient awake as long as the amount of disease is not too bulky. The amount of disease that can be treated awake will depend on each patient's tolerance of the procedure as well as surgeon experience. Bulky disease can be treated superficially (Fig. 73.6B) and then removed with a combination of contact with the fiber and suctioning with the flexible scope (Fig. 73.6C). This will expose untreated disease below, which can be treated further.

Awake procedures allow disease to be treated at the earliest sign of recurrence as opposed to the traditional approach of waiting for more significant disease in an attempt to minimize exposure to general anesthesia. Both the patient and surgeon can have a lower threshold for conducting a procedure.

Glottal Leukoplakia/Dysplasia

There are a variety of management options for patients with glottal leukoplakia or dysplasia that include biopsy and observation, laser resection or ablation, and phonomicrosurgical excision. Patients with recurrent or persistent glottal disease, however, often pose a dilemma as the surgeon will want to avoid the negative consequences of repeated general anesthesia and vocal fold surgery. Thus, patients are often observed until their symptoms become quite problematic or the surgeon becomes concerned about the clinical behavior of their glottal disease. Awake laser treatment offers the surgeon and patient a low-morbidity and low-cost option for treatment of these problems (29,30). Given the importance of the microcirculatory supply to the pathogenesis of these lesions, the PDL and KTP lasers have gained popularity for their presumed photoangiolytic properties and have been shown to be effective and safe (29–32,40).

Vascular Lesions

Vascular ectasias and varices often require surgical treatment as they can rupture, causing vocal fold hemorrhage, and they can impair the normal vibratory pattern of the vocal fold. Due to the presumed photoangiolytic properties of the PDL and KTP laser, these have been successful in treating such lesions (31,40,41).

Other Laryngeal Pathology

A variety other lesions have been treated with mixed success using awake laser procedures, including vocal fold polyps, granulomas, Reinke edema, and laryngeal amyloidosis (31,32,42–45).

TRANSNASAL ESOPHAGOSCOPY

TNE has become an essential tool in the evaluation and management of patients with dysphagia, head and neck cancer, and gastroesophageal or laryngopharyngeal reflux disease. Studies have shown that TNE is equivalent to conventional esophagoscopy in terms of diagnostic capabilities (46). Furthermore, it is safe and well tolerated with topical anesthesia and no sedation (13). TNE is covered in more detail in Chapter 57.

MISCELLANEOUS PROCEDURES

Secondary Tracheoesophageal Puncture

Traditionally, secondary tracheoesophageal puncture (TEP) is done under general anesthesia using a rigid esophagoscope. However, with the development of TNE, it is possible to safely conduct this procedure with local anesthetic in the office setting (47,48). The TNE scope is used to visualize the upper esophagus, and air insufflation is used to provide distension. As the light of the TNE scope transilluminates at the tracheostoma, an appropriate site for the puncture can be chosen. Local anesthetic should be injected into the site and a puncture made with an 18-guage needle. The TNE scope should be used to insufflate the esophagus to provide maximal anteroposterior distension to prevent injury to the posterior esophageal wall. The puncture site can then be widened with standard TEP dilators over a guide wire passed through the needle or with an 11-blade and a hemostat, all under direct vision of the TNE scope. Once adequately dilated, a 14-French red rubber or Foley catheter is passed through the puncture into the esophagus.

Airway and Esophageal Dilation

Dilation of airway and esophageal stenosis has long been performed under general anesthesia using rigid or flexible endoscopes and a variety of dilators, including hydrostatic balloon dilators.

Balloon tracheal or subglottic dilation can be performed awake with adequate topical anesthesia. It avoids the risks of general anesthesia and provides an option in patients with a difficult or impossible to expose larynx with standard rigid endoscopy. There is a risk of tracheal laceration with balloon dilation—in a large series of patients, approximately 50% experienced a laceration (49). However, none of the lacerations were transmural. The vast majority were superficial and of no clinical significance.

A guide wire is passed through the working channel of a flexible scope that has been introduced through the nasal cavity. The guide wire is then advanced through the area of stenosis. The scope is removed while leaving the guide wire in place. The scope is reintroduced beside the guide wire such that the entire procedure is visualized. An appropriate-sized balloon catheter is then passed over the guide wire, into the area of stenosis, and inflated for 30 seconds or until the patient requires a breath. This procedure has been reported to be safe and effective (50); however, formal data in the literature are lacking. The use of lasers to make radial incisions in an area of stenosis prior to balloon dilation has also been described (50,51), but further research is required to determine if these techniques are safe and effective in the awake setting.

A similar technique has been described for esophageal dilation and seems to be safe and well tolerated with only topical anesthesia (52). However, it is unknown if the awake procedure provides similar efficacy to balloon dilations performed under sedation or general anesthetic.

CONCLUSIONS

Awake office-based laryngeal procedures offer both the patient and surgeon numerous advantages and benefits. In many cases, when carefully selected, awake procedures allow the surgeon to achieve equivalent and sometimes superior results to those that can be achieved in the operating room. However, there are still certain instances where the advantages of the operating room setting and general anesthesia allow for a superior outcome. Insight, prudence, and sensible clinical judgment must be used when determining which treatment will provide the patient with the best possible outcome.

HIGHLIGHTS

- Awake office-based laryngeal procedures have experienced a resurgence in popularity secondary to numerous technologic advancements that permit precise, safe, and effective procedures.
- Use of only topical anesthesia avoids the risks associated with general anesthesia and maximizes patient convenience.
- Awake laryngeal procedures have been shown to be safe and effective for the treatment of a wide variety of laryngeal pathologies.
- Sensible clinical judgment is required when determining which patients and clinical problems can be dealt with effectively in an awake office-based setting.

Principles of Trauma

74

Peter J. Koltai *James Chan*

Trauma is the leading cause of death and disability of Americans younger than 40 years (1). In the United States, more than 150,000 violent deaths occur each year, and more than 500,000 trauma victims are left with permanent disabilities. Annually, approximately 30 to 40 million visits are made to emergency departments for injury treatment (2). The cost to our society is significant. In 2000, $117 billion was spent by Americans, which accounts for 10% of all medical expenditures (3). This is comparable to the percentages attributable to other public health issues such as obesity (9.1%) and smoking (14.4%) (4).

Deaths from trauma fall into three categories—immediate, early, and late. Immediate death occurs within minutes of injury and is caused by acute airway obstruction or major vessel disruptions of the brain, heart, or other internal organs. Early death occurs in the first few hours after injury and is associated with excessive hemorrhage, blood accumulation around the brain, or respiratory failure. Late death occurs days to weeks after trauma and is caused by sepsis and multiple organ failure.

More than half the deaths due to trauma occur within several minutes of the accident. Because immediate treatment is rarely available, accident prevention is the most logical way to decrease this number. Many public health injury prevention strategies have been successfully implemented including use of seat belts (5) and bicycle helmets (6), implementation of blood alcohol limits (7), and fire safety education including widespread smoke alarm use (8). Early deaths account for about one-third of all trauma deaths. Although not all of these patients can be saved, many can be treated effectively with rapid and definitive response. This requires a parallel system of coordinated prehospital care and hospital care at dedicated trauma centers.

Death at an accident scene is usually related to head injury with associated hypoventilation due to loss of consciousness. Intubation in the field can thus be lifesaving. Massive hemorrhage is another common cause of prehospital death. When intravenous catheters are inserted at the scene, circulatory volume can be maintained until the hemorrhage can be surgically controlled. Rapid transport to a hospital with an organized team of surgeons, anesthesiologists, and trauma professionals is vital for the effective treatment of trauma patients. In urban areas, ambulances usually provide efficient transportation to the hospital. In rural areas, distance becomes a critical factor and helicopters or airplanes can be lifesaving.

Trauma patients undergo rapid and severe changes in normal body function, including hemorrhage, tissue hypoxia, cellular damage, and disrupted function of vital organs. The physiologic response to massive injury is dramatic and occurs both systemically and locally. Systemic responses include activation of the clotting sequence, shifts of extravascular fluid into the circulatory system, redistribution of blood flow to the heart and brain, and alterations in renal and pulmonary function to maintain acid–base balance. Metabolic changes include skeletal muscle and fat breakdown to provide substrate for the body's fuel-intensive response to trauma. Local responses include immunologic activation with leukocytes mobilization, acute-phase protein synthesis, inflammatory cell migration into the injured area, and onset of fibroblast proliferation and blood vessel ingrowth to begin the wound repair process. Understanding the restorative mechanisms that occur in an acutely injured patient is necessary for the complex task of treating these patients with regard to fluid maintenance, nutritional requirements, wound healing, and susceptibility to infection (9,10).

NEUROENDOCRINE RESPONSE

Hemostatic adjustments to trauma are mediated by the neuroendocrine system. Stimuli such as hemorrhage, hypoxia, and tissue damage stimulate a graded response that increases to a peak level, after which additional response is no longer possible. Pain is the first signal from

the central nervous system (CNS) to reestablish homeostasis. The hypothalamic response to pain stimulates the pituitary gland to release corticotropin, which stimulates adrenal secretion of cortisol. Pain causes elaboration of antidiuretic hormone for fluid conservation. Pain activates the sympathetic nervous system and stimulates direct adrenal secretion of epinephrine.

Blood loss stimulates vascular pressure and volume receptors and precipitates a CNS-mediated decrease in cardiac output, an increase in peripheral vascular resistance, and redistribution of blood flow to vital organs. Hypoxia and hypercapnia cause chemoreceptor stimulation, vasomotor activation, and increased respiratory drive. At later stages, stimulation of the hypothalamus by interleukin 1 initiates the hypermetabolic response to injury manifested by the elevated temperatures experienced by injured patients (11,12).

The hormonal response to trauma is marked by a rise in the catabolic hormones, corticotropin, cortisol, growth hormone, glucagon, epinephrine, and norepinephrine. In contrast, plasma concentrations of the primary anabolic hormone, insulin, are decreased due to CNS-mediated sympathetic inhibition of the pancreas. Posttraumatic hyperglycemia provides non–insulin-mediated tissues such as the brain with a preferential supply of glucose.

Glucagon, cortisol, and catecholamines maintain blood glucose levels and prevent hypoglycemia. The primary function of glucagon, which is produced in the pancreas, is to promote gluconeogenesis in the liver. After trauma, direct sympathetic stimulation of the pancreas enhances glucagon secretion. Corticotropin release by the anterior pituitary gland causes adrenal production of cortisol, which promotes the breakdown of skeletal muscle into amino acids and facilitates gluconeogenesis in the liver. The hypoglycemic effect of cortisol counteracts insulin.

Release of catecholamines is the most fundamental hormonal reaction to trauma. Epinephrine, released by the adrenal medulla in response to direct neurostimulation, is a potent regulator of the circulatory system and systemic metabolism. Epinephrine's hemodynamic effects include vasoconstriction, increased cardiac rate, and increased myocardial contractility and conductivity. Epinephrine also promotes glucose production by enhancing hepatic gluconeogenesis and inhibiting insulin release. Norepinephrine, the primary sympathetic nervous system neurotransmitter, exerts a direct effect on the circulatory system and vital organs. With massive and prolonged sympathetic discharge, norepinephrine can enter the bloodstream and exerts a direct vasoconstrictive effect on the vascular system similar to that of epinephrine (9,10).

METABOLIC RESPONSE

The postinjury period is characterized by catabolism. Negative nitrogen balance, hyperglycemia, and heat production reflect the increased energy requirements for ongoing reparative and inflammatory processes. Increased energy expenditure is due to sustained release of circulating catecholamines and increased activity of the sympathetic nervous system. The primary energy source during this period comes from oxidation of lipids promoted by the elaboration of the catabolic hormones (9,10).

Although fat is the primary energy source after injury, protein is also broken down to produce energy. In a fasting catabolic patient, glucose can be generated only from the breakdown of protein. Lipid breakdown to triglycerides and glycerol contributes minimally to form precursors for the synthesis for new glucose. As a result, protein is rapidly broken down to form precursors for new glucose synthesis in a trauma patient in the catabolic state. The result is rapid loss of muscle mass. The depth and the length of the catabolic state are related to trauma severity. Although it represents an adaptive mechanism, a persistently prolonged and severe catabolic state leads to severe malnutrition, multiple organ failure, and death (9,10,13–15).

TREATMENT OF A PATIENT WHO HAS SUSTAINED TRAUMA

The key to improving survival and managing disability in the trauma patient are the initial evaluation and resuscitation performed at a dedicated trauma center. The American College of Surgeons has developed a protocol taught in advanced trauma life support courses to improve the care of injured patients during the early hospital phase. It is based on a primary and secondary survey approach that allows physicians to handle the complex, multisystem problems of trauma patients. This treatment algorithm can be divided into four categories—primary survey, resuscitation, secondary survey, and definitive care.

The primary survey involves hierarchical assessment of airway, breathing, and circulation. The purpose is to identify extreme, life-threatening injuries and institute immediate life-sustaining maneuvers. Resuscitation is performed simultaneously with the primary survey. The secondary survey consists of a rapid but systematic head-to-toe physical examination with the patient completely disrobed. This global assessment is done to identify all potentially life-threatening and occult injures. An important part of the primary and secondary survey are radiographic studies including the use of ultrasonography. Samples are drawn for baseline blood studies, typing, and cross-matching. Once these priorities have been addressed, vital signs are rechecked. When the patient's condition is stable, a detailed management plan is established.

Primary Survey

Airway

The foremost emergency measure is establishing the airway, which may be lost to a variety of causes. The oropharynx, larynx, and trachea can be obstructed by secretions,

blood, and foreign bodies. Oropharyngeal airway collapse can occur with loss of consciousness and from facial fractures (Chapter 78). Direct trauma to the larynx and trachea may cause airway obstruction below the oropharynx (see Chapter 77). Manuevers to secure an adequate airway range from the simple to the complex and begins with manual cleaning of the oropharynx followed by suctioning of secretions (Chapter 63).

The primary risk during early airway management is neck movement when there is an occult cervical spinal fracture. The airway must be controlled with the assumption that such a fracture exists. The neck must be completely immobilized in a neutral position. One member of the trauma team must be assigned to kneel at the head of the stretcher to maintain inline manual head stabilization and avoid hyperextension by holding the cervical spine with the hands while immobilizing the head with the forearms (Fig. 74.1). Traction on the head is avoided, because distraction with further injury to the spinal cord can occur if the patient has an unstable cervical spinal injury. Once the neck of an unconscious patient has been secured, forward traction of the mandible is performed to overcome pharyngeal collapse (Fig. 74.2). The next step is oropharyngeal airway placement in the unconscious patient. If the patient is conscious, a nasopharyngeal airway is used. Once the airway has been established and the patient is spontaneously breathing, supplemental oxygen can be provided through nasal prongs or a face mask.

When these simple measures are unsuccessful, more aggressive airway management is needed. Nasotracheal intubation is the preferred technique for establishing an airway in a conscious patient who may have a cervical spinal injury because it can be done without excessive neck mobility. Nasotracheal intubation is better tolerated by an awake patient than is orotracheal intubation and does not necessitate sedation or muscle relaxation. Nasotracheal intubation is precluded if the patient has extensive maxillofacial injuries.

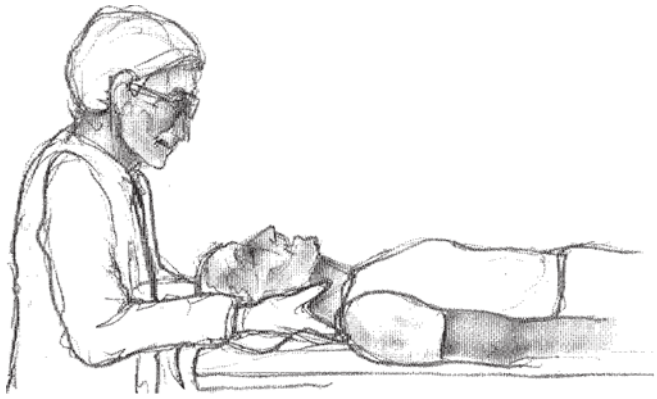

Figure 74.1 Stabilization of the cervical spine during primary survey of an injured patient.

If the nasotracheal route cannot be used, orotracheal intubation is the next step. In ideal circumstances, a cross-table lateral cervical spine radiograph is obtained before orotracheal intubation to evaluate for a possible cervical spinal fracture. It is nevertheless important to remember that even a normal cross-table lateral radiograph of the cervical spine does not definitively exclude the presence of cervical spinal fracture or instability (16). When emergency airway control with orotracheal intubation is indicated, intubation proceeds with inline stabilization whether or not radiographs have been obtained. Bag-mask intubation can be an effective method of maintaining the airway until radiographs are obtained. If the patient is unconscious and cervical spinal injury has been ruled

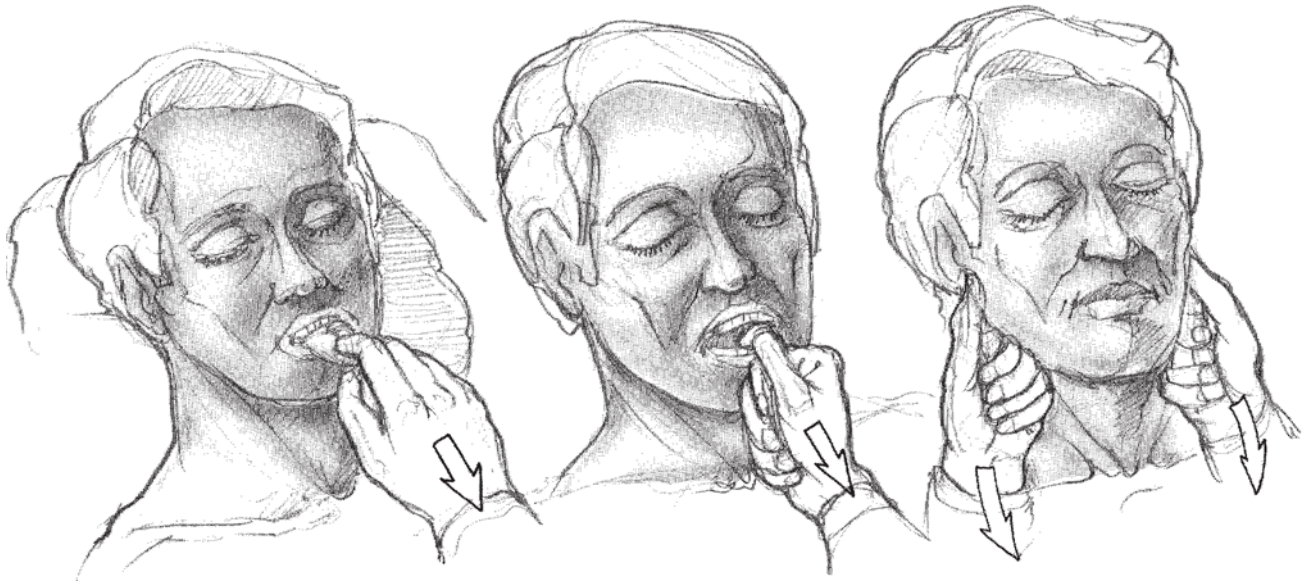

Figure 74.2 Once the neck of an unconscious patient has been secured, forward traction of the tongue and mandible is performed.

out, orotracheal intubation can be readily accomplished. A patient who is awake must be paralyzed with succinylcholine for successful orotracheal intubation.

After intubation, the chest is auscultated to ensure that the tube is in the trachea and not in the esophagus or in one of the mainstem bronchi. Correct endotracheal tube positioning can be confirmed reliably by the presence of end-tidal carbon dioxide. Carbon dioxide from the lungs can be detected rapidly by observing a color change on a disk that can be connected rapidly to the endotracheal tube. If no carbon dioxide is detected, the endotracheal tube is in the esophagus, and a new airway is attempted. If the patient is in cardiac arrest, end-tidal carbon dioxide is unreliable in confirming the positioning of an endotracheal tube. A follow-up chest radiograph to confirm the position of the tube must be obtained expeditiously.

If an endotracheal tube cannot be inserted, as when a patient has major facial fractures or has sustained laryngotracheal trauma, surgical airway intervention may be needed. There are four surgical methods of obtaining an airway—needle cricothyrotomy, conventional cricothyrotomy, tracheotomy, and percutaneous transtracheal ventilation.

For children, needle cricothyrotomy is the best procedure. The procedure is performed by placing a number 12 or number 14 intravenous cannula with a plastic sheath through the cricothyroid membrane into the tracheal lumen. Once in the airway, the needle is withdrawn and the plastic sheath is advanced. When properly positioned, the sheath is connected with intravenous tubing to wall or bottled oxygen at 50 pounds per inch of pressure (about 15 L oxygen per minute). Ventilation is accomplished by means of 1-second intermittent injections of oxygen followed by 4-second exhalations. Patients can be maintained for up to 30 minutes with this technique, after which hypercapnia becomes a problem.

Surgical cricothyrotomy is the preferred approach for adult patients who need surgical airway intervention (Fig. 74.3). It consists of a small vertical skin incision over the area of the cricothyroid membrane followed by a horizontal incision through the cricothyroid membrane itself. The blunt end of the scalpel is inserted between the cricoid and the thyroid cartilages and rotated 90 degrees to make an opening through which an endotracheal tube or tracheostomy tube can be inserted.

For patients with laryngeal trauma, tracheal trauma, or tracheal disruption, cricothyrotomy is inadvisable, and emergency tracheotomy is performed. Percutaneous transtracheal ventilation, a technique similar to needle cricothyrotomy, is an acceptable alternative in the treatment of these patients. In the trauma patient, continuous pulse oximetry monitoring is extremely helpful in determining the adequacy of oxygenation and is used in the care of all critically injured patients to allow early detection of arterial oxygen desaturation.

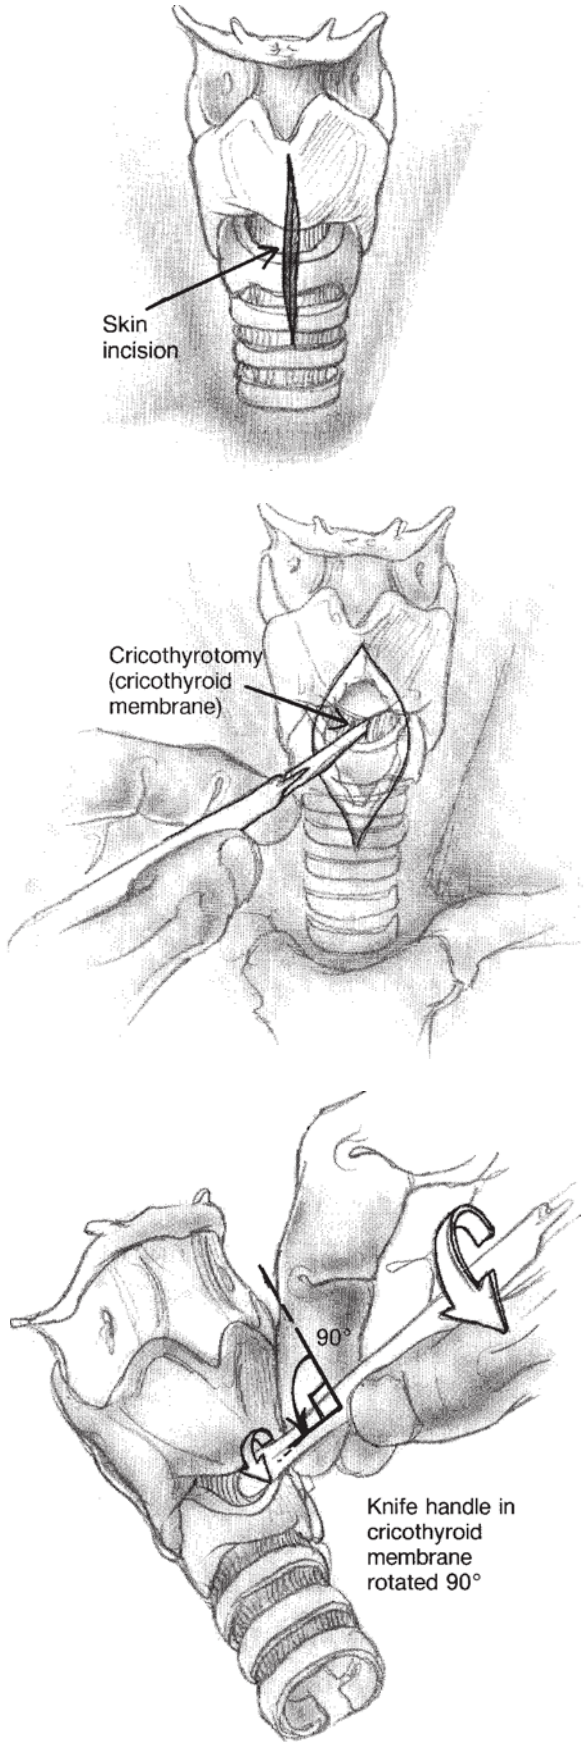

Figure 74.3 Cricothyrotomy.

Breathing

Loss of respiratory drive among trauma patients is most commonly caused by severe head trauma. Ventilation is provided with a bag-mask until cervical spinal injury is ruled out. An endotracheal tube is then inserted, and mechanical ventilation begun. As part of the primary survey, injuries to the chest wall and structures within the thoracic cavity that can cause hypoventilation must be recognized and rapidly managed. These injuries include sucking pneumothorax, massive pneumothorax, and tension pneumothorax.

Sucking pneumothorax occurs when there is a defect in the chest wall larger than the tracheal diameter. Because of reduced resistance through this opening, inspiratory and expiratory efforts result in movement of air through the opening in the chest wall into the pleural space rather than through the trachea. Occluding the chest wall defect and chest tube placement followed by intubation with positive pressure ventilation is the best management of this injury.

Massive hemothorax is vented promptly. Although blood loss of 1,000 to 1,500 mL into the thoracic cavity almost always necessitates emergency thoracotomy, initial management is aimed at decompressing the chest cavity so that adequate ventilation can proceed. Tube thoracotomy is performed by means of making an incision at the fourth or fifth intercostal space in the midaxillary line (Fig. 74.4). A short subcutaneous tunnel is developed by means of finger dissection, and the tube is passed posterosuperiorly along an intrapleural tract toward the pleural apex. Continued hemorrhage at a rate of greater than 200 mL/h is an indication for thoracotomy.

Tension pneumothorax develops when a pleural, bronchial, or tracheal tear allows air to be forced into the pleural space without a means of egress. The result is collapse of the ipsilateral lung. As pleural pressure increases, the mediastinum and trachea shift to the opposite side, compress the contralateral lung, and compromise oxygenation. The mediastinal shift kinks the inferior and the superior vena cava; the kink impairs venous return, and hypotension develops. Signs and symptoms of tension pneumothorax are acute shortness of breath, tracheal deviation away from the injury, increased resonance to percussion, distention of the neck veins, and decreased breath sounds over the injured hemithorax. Tension pneumothorax is a clinical diagnosis made on these clinical grounds. Diagnostic chest radiographs should not delay chest decompression as this may lead to the patient's death. Tension pneumothorax is managed by means of allowing air to escape through needle thoracocentesis with a large-bore, 12-gauge intravenous cannula inserted into the second intercostal space in the midclavicular line (Fig. 74.5), followed by definitive treatment with chest tube insertion. Pneumothorax also can cause hypotension owing to its effect on myocardial performance. Any patient who remains in shock after chest trauma needs empirical chest ventilation.

Circulation and Shock

Once the airway and breathing have been reestablished, the next step is to assess the adequacy of the circulatory system. Shock is the clinical manifestation of the inability of the heart to maintain adequate circulation to vital organs. This low-flow state can be caused by cardiac dysfunction,

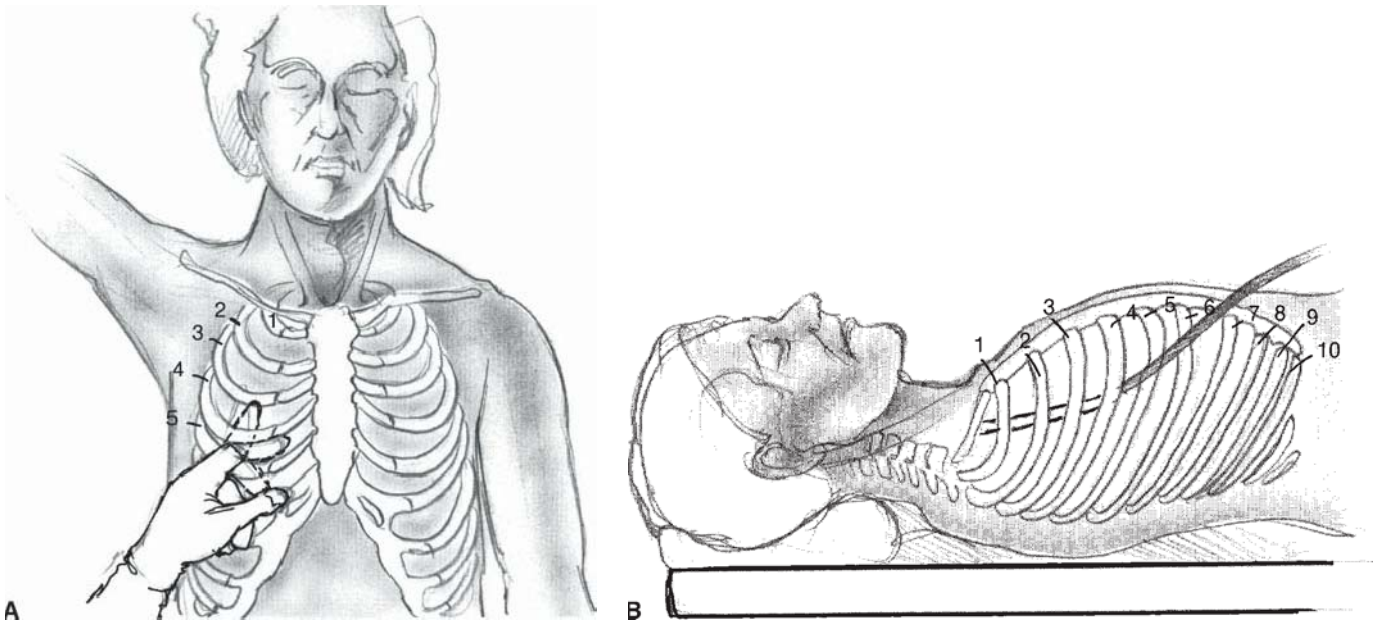

Figure 74.4 Tube thoracostomy. An incision is made in the fourth or fifth intercostal space in the midaxillary line. **A:** A short subcutaneous intrapleural track is developed by means of finger dissection. **B:** The tube is passed posteriorly and superiorly toward the pleural apex.

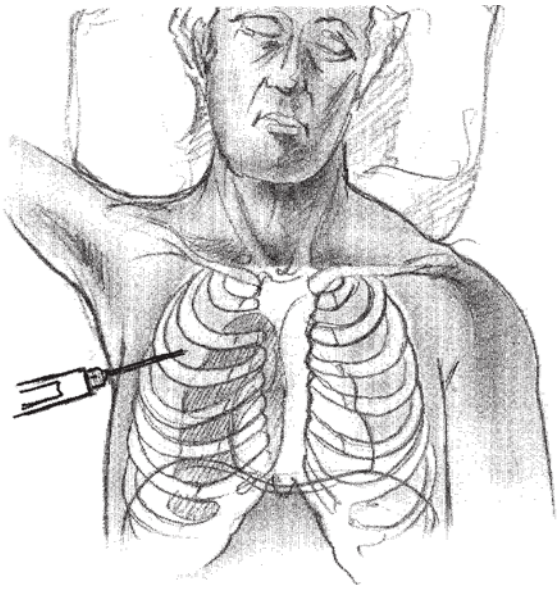

Figure 74.5 Needle thoracentesis for management of pneumothorax. The needle is inserted into the second intercostal space in the clavicular line.

loss of blood volume, loss of vascular resistance, and an increase in venous capacity (13). The cellular response to shock is a shift from aerobic to anaerobic metabolism in nonvital organ systems. The result is lactic acidosis. If hypoperfusion persists, oxygen delivery to vital organs becomes inadequate, and acidosis deepens. Unless oxygenation and perfusion are restored, organ failure progresses, and the patient dies.

The clinical presentation of shock depends on the severity. A patient with mild shock may be anxious and restless; if shock is severe, the patient appears listless or exhausted. The skin is cool and sallow with decreased capillary filling in the nail beds. Thirst, nausea, and vomiting are common. Blood pressure is low, and the pulse is fast and weak. Poor filling of peripheral veins makes it difficult to place intravenous catheters. There are four categories of shock—hypovolemic shock, neurogenic shock, cardiogenic shock, and septic shock. The first three are associated with the acute phase of trauma.

Hypovolemic Shock

Hypovolemia is the most common cause of shock after trauma. Hemorrhage is assumed to be the cause unless proved otherwise. Attempts have been made to classify the severity of hemorrhagic shock as follows to give better guidelines for resuscitation:

Class I hemorrhage is the loss of about 15% of blood volume. The primary manifestation is mild anxiety.

Class II hemorrhage is the loss of 15% to 30% of blood volume. The result is tachycardia and tachypnea, anxiety, decreased capillary refill, and decreased urine output. Supine blood pressure remains normal.

Class III hemorrhage is the loss of 30% to 40% of blood volume. Patients often are extremely anxious or combative and have marked tachycardia and tachypnea, prolonged capillary refill time, and a marked decrease in urine output. Only at this stage of severe hypovolemia does supine hypotension occur.

Class IV hemorrhage is the loss of more than 40% of blood volume. The result is marked hypotension and tachycardia. Urine output is almost completely shut off, and mental status can range from anxiety to coma. Blood loss of this magnitude is often fatal.

Hypovolemia should be managed with rapid volume replacement. Patients needing acute fluid resuscitation are usually those in whom venous access is most difficult. For most patients, 14-gauge intravenous catheters can be inserted into the antecubital veins with little difficulty. If the systolic blood pressure is so low that percutaneous access in the antecubital spaces is precluded, greater saphenous vein cutdown can be performed. Percutaneous femoral vein or subclavian catheterization is another alternative, but the surgeon must be familiar with the anatomic features of the area (1–7,10,12).

Crystalloids, such as lactated Ringer solution or normal saline solution, are the preferred fluids for resuscitation. In adults, blood volume is about 7% of total body weight (about 5 L for a normal-sized man). In children, blood volume is 8% or 9% of total body weight; in infants, 10%. The requirements for crystalloid resuscitation can be based on the results of clinical assessment of the percentage of blood loss and the knowledge of the approximate blood volume of the patient. Circulating volume can be restored by infusing 3 mL crystalloid solution for each milliliter of estimated blood loss. This ratio can be much greater in massive hemorrhage. The crystalloid solution is infused as rapidly as possible until blood pressure and heart rate return to acceptable levels. Further fluid replacement can be monitored according to the adequacy of the urine output (1–7,10,12).

When crystalloid replacement is inadequate, blood replacement becomes necessary. As a rule, trauma patients who arrive in the emergency department with supine hypotension likely need transfusion. Blood is added to resuscitation when the crystalloid infusion exceeds 50 mL/kg. Cross-matched, type-specific blood rarely is available to acutely injured patients, but un-cross-matched type-specific whole blood can be obtained rapidly in most hospitals and rarely causes serious complications. If type-specific blood is unavailable, type O-negative (universal donor) blood can be given safely to a trauma patient in need of emergency blood transfusion. The risk of transfusion reactions with O-negative blood in this situation is minimal.

Substantial clotting problems can occur with massive crystalloid and blood replacement therapy for hemorrhagic shock. Although blood components are not used

in early resuscitation, dilutional coagulopathy can develop after substantial transfusion. This dilutional coagulopathy is managed with fresh-frozen plasma and platelet transfusion, depending on the degree of ongoing bleeding. Platelets and fresh-frozen plasma are administered according to the degree of coagulopathy, not the specific number of units of blood administered. As a rule, using fresh-frozen plasma can be considered after the tenth unit of banked blood and then after every fourth unit. Use of platelets can be considered after the fifteenth unit of blood, and then after every fifth unit. Coagulation profiles can be monitored.

Adjunctive steps can be helpful in the care of patients sustaining hemorrhagic trauma. In cases of external hemorrhage, the bleeding often can be controlled with minimal pressure. Tourniquets usually are not helpful, because direct compression can control blood loss. Blind clamping must be avoided to prevent injury to adjacent nerves. The scalp may be the source of profuse bleeding, and rapid temporary suturing may be needed.

Military antishock trousers (MAST), which are inflatable pants, can be placed around the patient's legs and pelvis to decrease circulation to the extremities and thereby improve central circulation. They are not meant to replace adequate fluid therapy but can be useful in the prehospital phase of the trauma delivery system. Caution must be exercised in using MAST because abdominal compartment inflation can impair respiration, and leg compartment overinflation for long periods can cause compartment syndrome.

Neurogenic Shock

The purpose of fluid restoration is to reestablish adequate perfusion to vital organs. Measurements such as blood pressure, heart rate, urinary output, and level of consciousness help measure the success of fluid resuscitation. When these signs do not change in response to adequate resuscitation, other causes must be suspected. One such cause can be neurogenic shock, which is caused by brainstem dysfunction or spinal cord injury that denervates the sympathetic nervous system. The result is vasodilatation and decreased peripheral vascular resistance and consequent loss of blood pressure. Neurogenic shock is characterized by the absence of tachycardia, warm extremities, and lack of anxiety in the presence of hypotension. No patient should be presumed to have neurogenic shock, despite evidence of neurologic injury, until all other causes of shock have been systematically evaluated and eliminated. Once this has been done, neurogenic shock management is fluid resuscitation to replete intravascular volume, vasopressors to restore lost vascular tone, and appropriate neurosurgical intervention (13).

Cardiogenic Shock

Cardiogenic shock is loss of circulatory perfusion because the myocardium cannot produce sufficient flow to maintain tissue oxygenation. Among trauma patients, cardiogenic shock is generally associated with three injuries: tension pneumothorax, cardiac tamponade, and myocardial contusion. Cardiogenic shock is suspected when hypotension persists despite appropriate resuscitation. The most common features of cardiogenic shock are distended jugular veins and elevated central venous pressure in the presence of hypotension. These signs may not occur until the patient has undergone adequate fluid replacement. Cardiogenic shock may coexist with hypovolemic shock.

A common feature of tension pneumothorax is impaired myocardial function due to decreased venous return. Increasing intrathoracic pressure distends the jugular veins and causes hypotension. In an emergency, tension pneumothorax can be confused with cardiac tamponade because both conditions are associated with hypotension and neck vein distention. In some instances, it is impossible to differentiate these two conditions, and empiric thoracocentesis is necessary on the side most likely to be affected. If there is a rush of air with restoration of hemodynamic status, the diagnosis of tension pneumothorax is confirmed. If not, the procedure is repeated on the opposite side of the chest. If the patient's condition does not improve, cardiac tamponade is considered, and the patient is empirically treated.

Cardiac tamponade in a trauma patient is caused by blood accumulation between the myocardium and its pericardial covering. Because the pericardium is nondistensible, small volumes of blood can accumulate in the acute setting resulting in marked myocardial impairment. The pathophysiologic changes leading to cardiogenic shock are caused by a decrease in ventricular filling during diastole and myocardial contractility impairment due to ischemia from coronary circulation impairment. The classic cardiac tamponade signs are hypotension, jugular venous distention, and distant heart sounds. The jugular veins may not become distended if the patient has hypovolemia; thus diagnosis often is made as the result of suspicion based on an injury such as a penetrating chest wound.

Emergency department treatment of a patient with cardiac tamponade is pericardiocentesis (Fig. 74.6). The procedure is performed by inserting a 14- or a 16-gauge catheter in the left subxyphoid position with the needle aimed toward the posterior portion of the left shoulder. Aspirating as little as 10 to 20 mL of blood can bring about dramatic improvement in myocardial function; however, frequent false-negative and false-positive results under extreme circumstances may prompt a left anterior thoracotomy with direct pericardial decompression.

Emergency thoracotomy is an option when a trauma patient does not respond to resuscitation and is in cardiac arrest. Other considerations for emergency thoracotomy include initiating direct cardiac massage and controlling massive hemothorax due to cardiac puncture or tears in the thoracic aorta.

Myocardial contusion, another cause of cardiogenic shock after trauma, is caused by blunt injury, typically

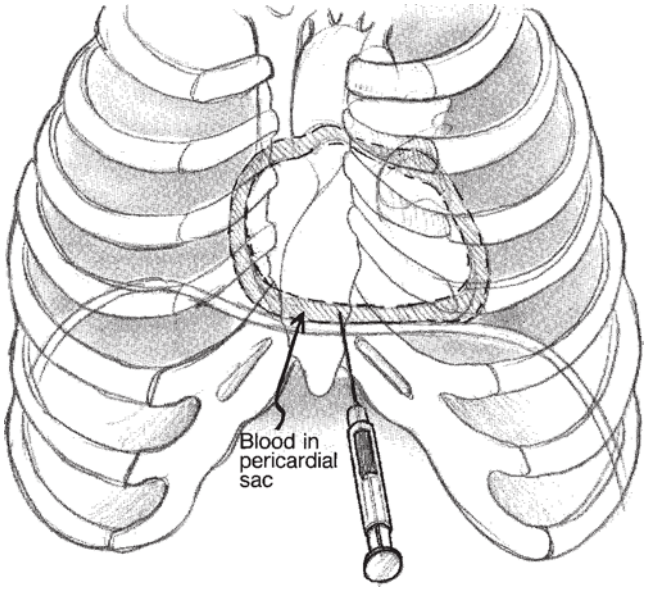

Figure 74.6 Pericardiocentesis for acute cardiac tamponade performed through the left subxyphoid approach.

when the chest hits a steering wheel. Physical signs include ecchymotic discoloration of the anterior chest wall and flail chest. Severe myocardial contusion is unusual, whereas blunt chest trauma is common. Marked myocardial contusion can be confirmed with transthoracic or transesophageal electrocardiography. Wall motion, valvular dysfunction, and the presence of pericardial fluid or tamponade can be seen with echocardiography. Management is aimed at preventing fluid overload while maintaining cardiac output and medically suppressing ventricular arrhythmia. With the increasing frequency of trauma among elderly patients, the possibility of an acute myocardial infarction, arrhythmia, or congestive heart failure precipitating an accident must be strongly considered (13).

Secondary Survey

The secondary survey consists of a detailed physical examination with the patient fully exposed. It is undertaken once the lifesaving priorities of the primary survey have been addressed. The breadth and speed of this examination depend in large measure on the patient's injuries and the need for definitive surgical intervention. Valuable information regarding the patient's history must be collected, including the mechanism of injury, preexisting medical problems, current medications, known drug allergies, and when the patient last ate. Routine objective studies also can be performed at this time, including a complete blood cell count, chest radiography, and urinalysis. If drug overdose or alcohol consumption is suspected, appropriate toxicologic studies can be performed. Hypotension warrants blood typing and cross-matching.

Head and Spine Injuries

Altered mentation is the most frequent sign of injury to the CNS and is presumed to be caused by injury until proved otherwise. Cervical spinal and spinal cord injuries are common among patients with multiple injuries, and the greatest concern is to avoid further injury to vital neurologic structures. Rigid immobilization of the cervical spine is imperative until a complete set of spinal radiographs, including cervical, thoracic, and lumbar spine radiographs, has been obtained. The entire spine is palpated for tenderness and altered contour. For patients with definitive cervical spinal injuries, use of a rigid collar reinforced with sandbags on either side and wide tape across the forehead is mandatory (Fig. 74.7).

Altered mental status can be caused by direct injury to the cortex and brainstem, by increased intracranial pressure (ICP), or by decreased cerebral perfusion. Whereas the first two conditions necessitate formal neurosurgical intervention, the changes in pressure and perfusion can be managed in the emergency department. The tool used to assess mental status is an abbreviated neurologic examination to define the Glasgow Coma Scale score (Table 74.1). This graded evaluation is performed to assess the functions of eye opening, verbal response, and motor response. A Glasgow score less than 8 indicates serious head injury, although the score can be artificially low if an endotracheal tube is in place. Further neurologic assessment includes evaluation of pupillary reflexes, deep tendon reflexes, and rectal sphincter tone. A serious head injury can have nonneurologic signs such as hypoventilation and hypertension.

Emergency department treatment of a patient with a head injury is aimed at minimizing cerebral edema and reducing ICP. These goals are met by means of controlling the airway

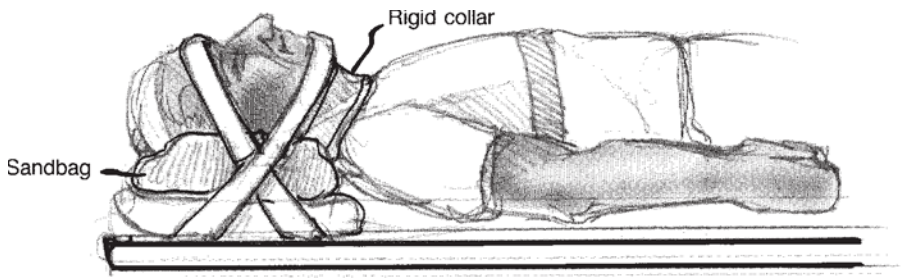

Figure 74.7 For patients with definitive cervical spinal injuries, use of a rigid collar reinforced with sandbags on either side and wide tape across the forehead is mandatory.

to maintain acceptable oxygenation. Ventilation is adjusted to maintain a carbon dioxide level of about 35 mm Hg. Patients with suspected cerebral trauma and a Glasgow Coma Scale score less than 8 need continuous monitoring of ICP. ICP is maintained at less than 20 mm Hg. Elevations in ICP are managed by means of administering mannitol, an osmotic diuretic, to reduce the amount of intracellular water in the brain. Ventriculostomy can be used to monitor ICP and can be therapeutic in that it allows cerebrospinal fluid removal to control ICP. Maintenance of cerebral blood flow, measured as a cerebral perfusion pressure (mean arterial pressure minus ICP) of 70 mm Hg with the use of fluids and vasopressors, is gaining increasing acceptance. There is no role for the administration of steroids for the control of cerebral trauma. Any patient who has changes in mental status after injury needs cranial computed tomography (CT) as part of the secondary survey (17).

The management of spinal cord injury with distal deficits has changed over the last several years. Emphasis remains on maintaining spinal immobilization to prevent additional spinal cord injury. Recent research (18) has found that administering steroids can play a role in minimizing neurologic deficits for patients with spinal cord injuries. Administering methylprednisolone as a bolus of 30 mg/kg followed by a drip at 5.4 mg/kg each hour for 23 hours led to small improvement in neurologic function among these patients when administered within 8 hours of the injury.

Once the neurologic system has been evaluated, the secondary survey continues with assessment of the rest of the head. The scalp can be a source of considerable blood loss, and immediate suturing may be needed. Basilar skull fractures can manifest as mobility of the facial bones, hemotympanum, cerebral spinal fluid otorrhea and rhinorrhea, and periorbital and mastoid ecchymosis.

Neck Injuries

All injuries to the neck are potentially life threatening because numerous vital structures traverse this area. Neck injuries are classified as blunt or penetrating. Blunt trauma to the neck can cause cervical spinal injury, pharyngeal and tracheal injuries, and carotid artery injury. Penetrating neck wounds are classified according to location (see Chapter 76). Zone I injuries are below the level of the clavicles, Zone II injuries are between the clavicles and the angle of the jaw, and Zone III injuries are above the angle of the jaw (Fig. 74.8). Posterior injuries can damage the cervical spine. Anterior and lateral wounds can injure the great vessels of the neck, the larynx, the trachea, and the esophagus as well as important nerves such as the vagus, phrenic, hypoglossal, spinal accessory, and branchial plexus. High

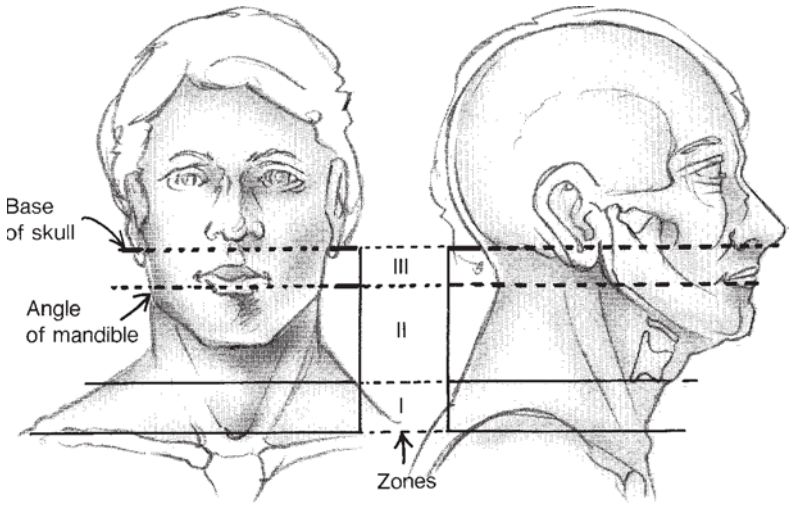

Figure 74.8 Penetrating neck wounds are classified according to location. Zone I injures are below the level of the clavicles. Zone II injures are between the clavicles and the angle of the jaw. Zone III injures are above the angle of the jaw.

penetrating injuries (Zone III) threaten the great vessels and cranial nerves at the base of the skull; penetrating injuries at the base of the neck (Zone I) threaten the great vessels exiting the thorax.

Clinical examination of an injured neck involves careful airway assessment, including evaluation for hoarseness, stridor, dyspnea, and hemoptysis. Subcutaneous emphysema, crepitus, and distorted laryngeal landmarks indicate laryngotracheal injury. Dysphagia and chest pain are characteristic of esophageal injuries. Flexible laryngoscopy is an excellent tool for examining the hypopharynx and larynx after neck injuries. It is rapid and easy to use and provides an excellent way to evaluate the patency of the airway and the function of the larynx. Flexible laryngoscopy also can aid in diagnosing laryngeal fractures and vagal injuries. CT of the neck also can help to delineate laryngeal fractures.

When laryngeal or tracheal injury is apparent and airway compromise is imminent, tracheotomy is performed. Cricothyrotomy is not used under such circumstances because of the risk of further injury to the larynx and upper trachea. Although it may be necessary to perform tracheotomy in the emergency department, this procedure is best done in the operating room, where proper instrumentation, optimal lighting, and appropriate personnel are available, especially when the patient has sustained blunt laryngotracheal disruption. This injury usually is caused by severe compression of the laryngotracheal complex between the steering wheel and the vertebral column or from "clothesline" injury, such as catching the neck on a barbed-wire fence while riding a snowmobile or a motorcycle. Under these circumstances, active airway management can be fraught with danger. Intubation may not be feasible, and tracheotomy can cause retraction of the distal trachea into the mediastinum.

Patients with penetrating neck injuries are at risk of airway obstruction, hemorrhage, and injury to the cervical spine. Important clinical signs include stridor, hoarseness, subcutaneous emphysema, expanding hematoma, external hemorrhage, hemoptysis, dysphagia, cranial nerve dysfunction, and branchial plexus injury. Active airway intervention is important when there is evidence of airway distress. It is best accomplished with nasotracheal or orotracheal intubation. Bleeding in the oropharyngeal area may preclude intubation and necessitate emergency surgical airway intervention, which can cause great difficulty if there is bleeding in the deeper layers of the neck. External hemorrhage is controlled with compression, and no effort is made to gain hemostasis by means of blind clamping.

There has been much controversy with regard to routine exploration of penetrating neck injuries, not only as definitive treatment but also as a diagnostic technique. Some authors advocate routine exploration of all injuries penetrating the platysma. Others advocate selective exploration and observation based on preoperative arteriographic findings and on the presence or absence of symptoms that suggest vascular, airway, and neurologic injury.

Most patients in stable condition with penetrating injuries to the base of the neck (Zone I) are best examined by means of arteriography, laryngoscopy, and esophagoscopy or a barium swallow radiographic study. Patients in stable condition with penetrating injuries above the angle of the mandible (Zone III) are best examined with arteriography to exclude carotid or vertebral artery injury. Patients with injuries between the angle of the mandible and the base of the neck (Zone II) can be examined by means of routine exploration or combinations of arteriography, laryngoscopy, and esophageal evaluation if the injury has penetrated the platysma. Patients in unstable condition with active hemorrhage need surgical exploration.

When a patient has marked neurologic deficits after blunt neck trauma and the findings of CT of the head are normal, the possibility of blunt carotid injury with carotid occlusion or dissection is considered and excluded with arteriography. Management of these injuries involves anticoagulation with heparin or reconstruction, depending on the nature of the injury.

Thoracic Injuries

Thoracic injuries are classified as blunt or penetrating. Most blunt injuries are caused by motor vehicle accidents. Penetrating injuries typically are from violence with knives or guns. The principal forms of life-threatening blunt chest trauma are flail chest, pulmonary contusion, tracheobronchial disruption, and torn thoracic aorta.

Flail chest occurs when part of the chest wall becomes isolated owing to multiple fractures of the ribs or sternum (Fig. 74.9). The severity is determined by the size of the flail

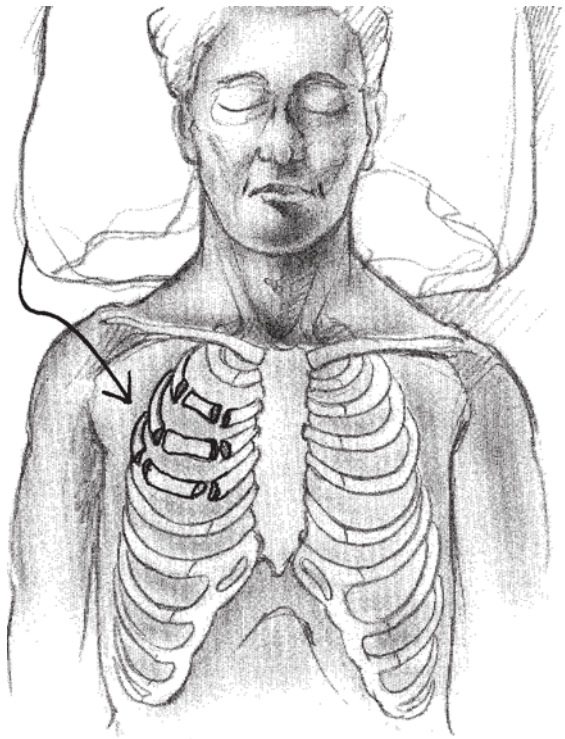

Figure 74.9 Flail chest.

segment, which moves paradoxically with inspiration and thus reduces ventilatory efficiency. Ventilation is further compromised by the size of the underlying pulmonary contusion that invariably accompanies a severe flail chest. If ventilation becomes inadequate, hypoxia and hypercapnia occur and the patient needs intubation and ventilatory assistance.

Pulmonary contusion is a common finding in blunt chest trauma. It often is associated with flail chest and hemopneumothorax and is common in multisystem trauma. Pulmonary contusion causes alveolar edema and impairs gas exchange. The primary sign of pulmonary contusion is hypoxia. Initial management is adequate oxygenation and avoidance of fluid overload, which can promote pulmonary edema. If a patient has hypovolemia and pulmonary contusion, aggressive fluid resuscitation is indicated, regardless if lung injury is present. Intubation and mechanical ventilation often are needed to support respiration.

Most intrathoracic blunt tracheobronchial injuries are caused by compression of the trachea and bronchi between the sternum and the vertebral column in motor vehicle accidents. The areas most commonly involved are the proximal mainstem bronchi and the distal trachea. Common features of this injury include pneumothorax, subcutaneous emphysema, and hemoptysis. Initial therapy often entails venting the pneumothorax. Bronchoscopy is indicated for diagnosis.

Traumatic rupture of the thoracic aorta is the most common cause of immediate death after motor vehicle accidents. In 90% of cases, the aortic injury occurs beyond the origin of the left subclavian artery at the level of the ligamentum arteriosum, where the descending aorta is relatively fixed. Motion between the more mobile aortic arch and fixed descending aorta can cause aortic injury when rapid deceleration is the mechanism. In about 10% to 20% of cases, thoracic aorta rupture does not cause immediate death because intrathoracic hemorrhage is contained by the aortic adventitia, and the patients can be saved if the injury is rapidly recognized. Although arteriography is the only definitive study for diagnosing this injury, the first indication of an aortic tear usually is evidence of superior mediastinal widening on routine chest radiographs. Clinical features, such as retrosternal or interscapular pain from mediastinal blood dissection and hypertension from sympathetic stimulation of the nerves around the aorta, can provide clues to the presence of aortic rupture. Early recognition and definitive surgical repair are crucial because the rupture becomes complete in a high percentage of patients within the first 24 to 48 hours after injury. The decision to perform thoracic arteriography to exclude aortic disruption is made early in the resuscitation and is based on findings of mediastinal widening on the initial supine chest radiograph obtained in the emergency department.

The injuries associated with penetrating thoracic trauma—hemopneumothorax, tension pneumothorax, and cardiac tamponade—are discussed earlier. After immediate management, a decision must be made regarding surgical thoracotomy when there is persistent bleeding from a chest wound. Considerations include the volume of the initial chest tube drainage, the rate of ongoing hemorrhage once the lung has been reexpanded, and the patient's hemodynamic status.

Abdominal Injuries

Abdominal injuries are life threatening because the peritoneal cavity can harbor occult blood loss and fecal contamination. Unrecognized abdominal injury is a common cause of death after trauma, and prompt recognition is of primary importance in its prevention. Diagnosis can be delayed by the silent nature of the injury, other life-threatening problems, or an altered state of consciousness.

Examination of the abdomen begins at the level of the nipples and extends to the pubic symphysis. The examination includes inspection, auscultation, percussion, and palpation. Rectal examination is mandatory for assessment of sphincter tone, pelvic crepitus, prostate position, and hemorrhage. Although the absence or presence of bowel sounds may not correlate well with the presence of injury, other signs, such as abdominal tenderness, are highly suggestive of peritoneal inflammation and can indicate the need for laparotomy.

Abdominal injuries are classified as blunt or penetrating. Blunt abdominal injuries usually are associated with injury to solid organs, such as the liver, spleen, pancreas, and kidneys. The most common finding among patients with blunt abdominal trauma and solid organ injuries is hemoperitoneum with shock. Trauma patients with persistent hypotension and possible blunt abdominal trauma require a search for occult bleeding. This can be done expeditiously with focussed assessment for the sonographic evaluation of the trauma patient (FAST) or diagnostic peritoneal lavage (DPL). These studies can be done rapidly in the trauma bay. FAST is an ultrasonographic examination performed by the trauma surgeon or emergency room physician and can detect fluid in the peritoneal cavity (19). In addition, the pericardial sac can be evaluated. In hospitals without the expertise or equipment to perform FAST, a DPL can be performed. Initial peritoneal aspiration of more than 10 mL of blood is an indication for laparotomy.

Lavage is performed by means of instilling 15 mg/kg normal saline solution into the peritoneal cavity and letting the fluid drain out by means of gravity. When the total erythrocyte count in the lavage effluent exceeds 100,000/mL, most patients have abnormal findings at laparotomy.

Abdominal CT is an excellent diagnostic study to exclude intraperitoneal or retroperitoneal injury if the patient is in hemodynamically stable condition. As experience with abdominal CT has increased, it has become clear that many patients with minor liver and spleen injuries with hemoperitoneum stop bleeding spontaneously and never need abdominal exploration.

Patients with penetrating abdominal trauma and overt signs of peritonitis or hypovolemia need surgical exploration; however, therapy is less clear-cut when the patient's

condition is hemodynamically stable or when signs of peritonitis have yet to evolve. The common mechanisms of penetrating trauma are gunshot wounds and stab wounds. With gunshot wounds, laparotomy is indicated when the missile penetrates the peritoneum. Plain abdominal radiographs are obtained to outline the missile trajectory. Broad-spectrum antibiotics are administered in anticipation of definitive surgical therapy.

Stab wounds of the abdomen can be managed selectively because the likelihood of visceral injury, even with peritoneal violation, is inconsistent. The first diagnostic steps are to ascertain the depth of the injury and to assess the integrity of the peritoneum. These steps are best done by means of exploring the wound in the emergency department with the patient under local anesthesia. Peritoneal lavage follows local exploration if there is an indication that the anterior muscular fascia has been penetrated. Criteria for a positive peritoneal lavage result differ in blunt injuries from stab wounds. Although 100,000 erythrocytes per milliliter is the accepted positive result for blunt injuries, an erythrocyte count of 5,000 to 10,000/mL is accepted as a positive result in a stab wound and indicates that laparotomy is needed. Patients with positive peritoneal lavage results need exploratory laparotomy. Those with negative peritoneal lavage results can be admitted for observation.

Extremity Injuries

During the secondary survey, the arms and legs are examined carefully to assess perfusion, neurologic function, deformity, and range of motion. Serious injuries include fractures, dislocations, amputations, and compartment syndromes. Life-threatening injuries involve massive blood loss due to pelvic fractures, traumatic amputations, and open femoral fractures. Pelvic fractures associated with hypovolemia are stabilized with application of MAST. An expanding hematoma or pulsatile, bright red bleeding indicates acute arterial injury and is controlled with manual pressure.

Before it is assumed that bleeding is coming from a pelvic fracture when the patient's condition is unstable, it is necessary to exclude ongoing intrathoracic or intra-abdominal hemorrhage. Supraumbilical DPL may be indicated to exclude an intra-abdominal source of hemorrhage in these patients. In the care of patients with persistent pelvic hemorrhage, angiography is indicated for diagnosis and definitive management by means of embolization of the bleeding vessels by interventional radiologists. A direct surgical approach to the bleeding pelvis rarely is indicated.

Rectal and vaginal examinations are an important part of the management of pelvic fractures. Patients with severe pelvic fractures may have associated injuries to the vagina, rectum, and urethra. A high-riding prostate or a positive result of a heme test of stool can alert the clinician to this possibility. Bladder rupture also is considered if a patient has a pelvic fracture and hematuria. An abnormal result of a prostate examination or blood at the urethral meatus indicates urethral injury and is a contraindication to insertion of a Foley catheter. Under this circumstance, retrograde urethrography is performed before a Foley catheter is placed.

Vascular injuries can be associated with penetrating wounds, fractures, and joint dislocation. Signs are typically those of ischemia, and the patient has pain, pallor, paralysis, paresthesia, and pulselessness. Recognition is important to preserve the extremity, and the diagnosis is confirmed with arteriography. Knee dislocation is often associated with popliteal artery injury and distal ischemia. Popliteal artery angiography is usually recommended to exclude injury if a patient has a knee dislocation.

Crush injuries to the lower leg and forearm can cause compartment syndrome due to hemorrhage and edema within recognized fascial planes. The patient typically has a painful, pale extremity with decreased sensation and pulse. The earliest sign of compartment syndrome is the patient's report of paresthesia or sensory deficit in the limb. Loss of peripheral pulses is a relatively late finding and often implies irreversible damage to the limb. Compartment syndrome occurs most often with closed fractures of the tibia and fibula. Emergency fasciotomy is the appropriate therapy.

Traumatic amputation necessitates microsurgical reimplantation when possible. Bleeding from the proximal limb is controlled with manual pressure. The amputated parts must be kept in a moistened sterile towel and placed in crushed ice until definitive therapy can be provided (11,12).

Inhalation Injuries

Thermal injuries must be managed in an orderly way, similar to that of all serious traumatic injuries. Inhalation injuries occur in 3% to 20% of all burn patients. Most inhalation injuries are caused by fires in closed spaces, but the possibility of blunt injuries to the throat or abdomen, as in blast injures or car accidents with fires, must be considered. An otolaryngologist may be asked to facilitate airway management for patients with inhalation injuries.

Although all types of trauma are suspect, specific types, such as explosive burns and burns sustained in a confined building, are associated with inhalation injury. Physical signs of inhalation include a decreased level of consciousness, singed nasal hairs, carbon deposits in the oral cavity, carbonaceous sputum, and the finding of inflammatory changes in the supraglottic larynx at flexible laryngoscopy.

The glottic and supraglottic airway can sustain marked edema from routine thermal trauma. The result is immediate or delayed airway obstruction. Patients with clear signs of supraglottic inhalation injuries need early endotracheal intubation with mechanical ventilation. The subglottic airway often is protected from burns unless the patient is exposed to superheated gas or steam. The vocal folds form

an anatomic barrier. In addition, reflex closure of the glottis also serves to protect the subglottis and trachea. Carbon monoxide levels in the blood should be measured and oxygen therapy should be given immediately. Hyperbaric oxygen therapy is considered when a patient has marked carbon monoxide poisoning (12).

Definitive Management

Once the primary and secondary surveys have been completed, the patient has been adequately resuscitated, and the patient's condition is judged to be stable, a plan for definitive care is formulated. This plan begins with a ranking of the injuries in the order in which they are to be managed. If at any point the vital signs become unstable, the primary and secondary surveys are repeated. If the instability is from an injury that warrants definitive surgical intervention, the patient is transferred to the operating room. Patients who do not need further surgical intervention are transferred to the intensive care unit or to a surgical floor for further observation. Transfer errors include inadequate management of the airway, poorly secured intravenous lines and drainage tubes, and inadequate patient monitoring. It is a tragedy to resuscitate a patient in the emergency department successfully only to lose the patient on transfer to the operating room.

ROLE OF THE OTOLARYNGOLOGIST

Since the early 1970s, the responsibility of otolaryngologists as members of the trauma team has continued to expand. In most institutions, otolaryngologists are viewed as experts in managing the airway and are expected to perform difficult intubations and provide emergency surgical airways. They are also being recognized for expertise in the management of maxillofacial trauma and penetrating injuries to the neck. Otolaryngologists often are called on to assist in the immediate care of trauma victims in the emergency department.

As valued members of the trauma team, otolaryngologists must continue to refine management skills for injuries associated with the specialty but also need to be knowledgeable about the general care of trauma patients. Otolaryngologists need to understand the concepts of the primary and secondary survey and be capable of stabilizing the neck, securing the airway, placing chest tubes, and starting intravenous lines. They also should be able to perform the complete examinations needed in the secondary survey and know how to interpret the diagnostic procedures that must be performed as part of the survey. To be fully integrated and recognized as responsible members of the trauma team, otolaryngologists involved in the care of trauma patients should be certified by the American College of Surgeons advanced trauma life support course.

HIGHLIGHTS

- The most fundamental neuroendocrine reaction to trauma is the release of catecholamines, which cause vasoconstriction, increase cardiac rate, increase myocardial contractility and conductivity, and stimulate gluconeogenesis.
- The postinjury period is characterized by catabolism with negative nitrogen balance, hyperglycemia, and heat production, all of which reflect the reparative processes.
- The most important factor in the successful care of trauma patients is the initial evaluation and resuscitation performed partly in the field and in the emergency department. Primary and secondary surveys allow physicians to manage complex multisystem problems. This treatment algorithm has four steps—primary survey, resuscitation, secondary survey, and definitive care.
- The foremost emergency measure after trauma is airway establishment. The primary risk during early airway management is movement of the neck when there is an occult cervical spinal fracture. When the airway is being controlled, it must be assumed that such a fracture exists.
- Correct positioning of the endotracheal tube can be confirmed reliably by the presence of end-tidal carbon dioxide. If no carbon dioxide is detected, the endotracheal tube is in the esophagus, and a new attempt at intubation is made immediately.
- In the trauma patient, continuous monitoring with pulse oximetry is extremely helpful in determining the adequacy of oxygenation and is used in the care of all critically injured patients.
- Techniques of surgical airway management include needle cricothyrotomy, standard cricothyrotomy, tracheotomy, and percutaneous tracheal ventilation. Needle cricothyrotomy is the best procedure for children; surgical cricothyrotomy is preferred for adults.
- Loss of respiratory drive among trauma patients most commonly is caused by severe head trauma; however, injuries to the chest wall and thoracic structures can cause hypoventilation, which must be recognized and rapidly treated.
- Shock is the clinical manifestation of the inability of the heart to maintain adequate circulation to vital organs. The patient dies unless oxygenation and perfusion are restored. The most common cause of shock after trauma and hemorrhage is hypovolemia. Treatment is rapid volume replacement with crystalloids, such as lactated Ringer solution or normal saline solution through two 14-gauge catheters in the antecubital fossa.

- Cardiogenic shock is loss of circulatory perfusion that occurs when the myocardium does not generate sufficient blood flow for tissue oxygenation. Among trauma patients, cardiogenic shock usually is precipitated by tension pneumothorax, cardiac tamponade, or myocardial contusion. The presence of myocardial contusion is best confirmed with echocardiography. Among elderly trauma patients, the possibility that acute myocardial infarction or arrhythmia has precipitated an accident must be considered.
- In the care of patients with head trauma, ventilation is adjusted to maintain a carbon dioxide level of about 35 mm Hg. Patients with cerebral edema or coma need continuous monitoring of ICP. ICP must be maintained at less than 20 mm Hg. Elevation in ICP is managed with mannitol. Maintenance of cerebral blood flow as measured by cerebral perfusion pressure is best accomplished with the use of fluids and vasopressors.
- In the care of patients with spinal cord injury, administration of methylprednisolone as a bolus of 30 mg/kg followed by a drip at 5.4 mg/kg each hour for 23 hours has been shown to lead to small but important improvements in neurologic function if administered within 8 hours of injury.
- The decision to perform thoracic arteriography to exclude aortic disruption must be made early in resuscitation. The decision is based on findings of mediastinal widening on the initial supine chest radiograph obtained in the emergency department.
- Unrecognized abdominal injury is a common cause of death after trauma. Ultrasonography, when available, is the preferred step in the initial phase of assessment and management. Peritoneal lavage is an acceptable alternative. A total erythrocyte count of 100,000/mL correlates with positive findings at laparotomy after blunt abdominal trauma. For patients with penetrating abdominal trauma, a total erythrocyte count of 5,000 to 10,000/mL correlates with positive findings at laparotomy.
- Abdominal CT is an excellent diagnostic study to exclude intraperineal and retroperineal injury if the patient is in hemodynamically stable condition.
- The extremity injury that poses the greatest risk to life is a pelvic fracture resulting in massive blood loss. The best initial management is application of MAST followed by angiography.
- The earliest sign of compartment syndrome is the patient's report of paresthesia or sensory deficit in the limb. Loss of peripheral pulse is a relatively late finding and often implies irreversible damage to the limb. Compartment syndrome occurs most often with closed fractures of the tibia and fibula. Amputated body parts must be kept in a moist and sterile towel and placed in crushed ice until definitive reimplantation can be provided.
- The physical signs of inhalation injury include a decreased level of consciousness, burned nasal hairs, carbon deposits in the oral cavity, and inflammation of the supraglottic structures. Signs of this type of injury are indications for early endotracheal intubation and mechanical ventilation.
- Definitive management follows the primary and secondary surveys and begins with ranking of the injuries in the order in which they are to be managed. If at any point the vital signs become unstable once again, the primary and secondary surveys are repeated. Transfer out of the emergency department for definitive management can be a period of risk. Transfer errors include inadequate management of the airway, poorly secured intravenous lines and drainage tubes, and inadequate patient monitoring.
- To be fully integrated and recognized as responsible members of the trauma team, otolaryngologists involved in the care of trauma patients should be certified by the American College of Surgeons advanced trauma life support course.

75 Management of Soft Tissue Injuries of the Face

Scott Shadfar *William W. Shockley*

Soft tissue injuries involving the face, head, and neck are becoming more frequent, and the experienced otolaryngologist is commonly the designated surgeon chosen to make a timely assessment and repair. The management of facial soft tissue injuries present challenges both from a functional and aesthetic perspective. Injuries to the face can affect speech, vision, alimentation, and facial expression. The resulting facial scars and deformities also can be associated with a host of psychosocial issues. This chapter is devoted to the initial evaluation, classification, and early management of facial wounds. We also provide specific anatomical considerations for different anatomic sites with respect to facial soft tissue injury management and care.

ETIOLOGY AND MECHANISM OF INJURY

The leading causes of facial soft tissue injuries are assault, motor vehicle accidents, work-related injuries, sport injuries, animal and human bites, as well as burns. In addition, there has been a surge in the literature highlighting injuries encountered from the battlefield (1). Details into whether protective measures were in place, such as helmets, seat belts, or air bags, can guide the evaluation. Injuries sustained despite these measures calls one's attention to the force behind the injury and need for further workup.

EVALUATION

Patients with serious or life-threatening injuries are first assessed in the emergency room, or trauma bay when available. Advanced Trauma Life Support guidelines are followed where airway, breathing, circulation, disability, and exposure (ABCDE) take precedence. In the critically ill patient, stabilization will proceed in a standard fashion with the insertion of two large-bore intravenous lines. Acute hemorrhage from the head and neck region is addressed at this time. An airway is established if deemed necessary. Any oral or pharyngeal hemorrhage leading to inability to protect the airway calls for airway intervention, all while maintaining cervical spine precautions. In this setting, 3% to 10% of facial injuries with fractures have concomitant c-spine injuries (2,3). Although facial injuries can bleed profusely, they can distract health care providers from other more immediately threatening injuries. Often a moist gauze and pressure dressing can be applied to facial wounds if other injuries, such as chest or abdominal trauma, necessitate urgent treatment.

A thorough history, if obtainable, is necessary when a patient presents with a traumatic injury. Knowledge of the patient's underlying comorbidities and past medical history is especially important in those patients with compromised host defenses as in patients with diabetes, immunosuppression, chronic corticosteroid use, malnutrition, and obesity.

Allergies to medications including local anesthetics, general anesthetics, and antibiotics should be documented. Social history regarding smoking, ethanol, and illicit drug use should also be obtained. In most cases of major trauma, serum alcohol levels and a drug screen should be checked as the presence of cocaine or amphetamines may delay elective operative intervention; these interactions with general anesthesia are known to increase cardiac risks. Tetanus history should also be noted at this time, with appropriate treatment based on the patient's history (see section on "Tetanus").

A complete head and neck examination should be performed with final attention focused on the injured site. A detailed description of the wound in terms of wound classification, location, depth, length, and condition of wound edges should all be assessed and documented. Cranial nerve examination is performed to identify any

deficits. Next, evaluate for deep tissue injury (clear fluids leaking indicative of cerebral spinal fluid [CSF], salivary, or lacrimal injury) (4) as well as presence of fractures or foreign bodies (gravel, wood, broken or loose teeth). When possible, photo documentation should be performed for medical and legal reasons.

Prior to extensive examination and wound preparation, appropriate anesthesia and analgesia should be provided for patient comfort. The authors seldom use sedation, outside of the pediatric population. Imaging studies pertinent to the head and neck region including plain films and computed tomographic (CT) studies should be obtained when there is concern for facial fractures, missing teeth, or foreign bodies. Noncontrast high-resolution CT imaging is the preferred imaging modality to evaluate facial fractures, while contrasted CT angiography is indicated for identification and delineation of a vascular injury as seen in penetrating neck injuries (see Penetrating Head and Neck Injury chapter). Once the patient has been stabilized, the involved physicians should prioritize further workup, management, and surgical repairs. Depending on the nature of the injuries, appropriate consultations should be obtained.

WOUND CLASSIFICATION

Abrasions

Classifying wounds on assessment aids in sorting and developing a treatment algorithm. Wounds are most commonly classified by depth, which is influenced by the mechanism. When the epidermis and partial thickness dermis has been lost, secondary to scraping the skin, this is classified as an abrasion. For these injuries, the critical steps in management include irrigation and cleansing with meticulous removal of any embedded dirt and debris. Once the wound is fully clean, topical ointment is sufficient treatment. The patient is instructed to keep the wound clean and dressed. In most circumstances, a topical antibiotic ointment is both practical and effective. Maintaining a moist environment without crusting helps promote faster reepithelialization from the remaining undisturbed skin appendages. Avoidance of direct sun exposure is recommended as this can cause skin pigmentation at the site of injury, which is most often temporary. Sun avoidance and protection should be mandatory for a minimum of 6 months.

Contusions/Hematomas

Contusions are usually from blunt force trauma without breech of the overlying skin. Disruption of the small capillaries and vessels leads to swelling and ecchymosis. These changes usually resolve over time without intervention. Expectant management is usually sufficient with head elevation and ice packs. Soft tissue hematomas result in marked swelling and can sometimes organize into a localized hematoma. In most cases, all that is needed is supportive care and observation, assuming there are no functional or airway issues. Needle aspiration can be undertaken after liquefaction of the clot, usually around 10 days post injury. If hematomas occur in the tongue, floor of mouth, or neck one must consider the potential for airway compromise. In addition, underlying vascular injuries may be suspected.

Avulsion Injuries

Avulsion injuries result from the shearing or tearing of tissues. This leads to full-thickness cutaneous injury sometimes associated with loss of the involved tissue segment. Avulsion injuries may be associated with subcutaneous, cartilaginous, or bony structures. Avulsion injuries usually arise from high-velocity activities or exposures such as motor vehicle collisions, blasts, and assaults, resulting in shearing of tissues. On occasion, microsurgical techniques will be required for reattachment of avulsed tissues. Conservative trimming of nonviable tissue margins may be necessary; however, tissue-sparing management is preferred with frequent checks to confirm tissue viability. If there are concerns over viability, steps should be taken to optimize tissue vascularity, such as suture removal or wound drainage (5). Specific considerations with respect to management are discussed under each anatomical site.

Lacerations

Lacerations typically occur from impact or sharp objects resulting in a cutting of the skin as opposed to the tearing forces that result in avulsion injuries. Lacerations can be further categorized as linear, tangential, or stellate and are many times jagged with macerated edges. The majority of facial soft tissue injuries fall under this category and the tenants of closure and management are discussed in greater detail throughout the chapter.

Puncture/Penetrating

Wounds that puncture the skin are classified as puncture wounds. Those that enter and exit the skin such as a knife or bullet are known as penetrating wounds. Many times, the underlying damage is more severe than the visible portion of the wound and caution should be exercised in assessing the patient or probing of the wound. The basic principles of acute trauma care apply. Penetrating wounds of the neck can be stratified into a level I to III classification system. Please refer to Chapter 76 for further discussion and management strategies.

Crush Injuries

Prolonged or excessive force placed on any anatomical location can lead to a crush injury. Luckily, the face is seldom the site involved with isolated crush injuries. However when segments of the face, head, and neck are

involved disastrous consequences may occur. Devitalized tissue is frequently present due to small blood vessel injury leading to necrosis and poor wound healing. Management includes conservative trimming of nonviable tissue margins. Hyperbaric oxygen treatments have been shown to be beneficial for hypoxic wounds in limb crush injuries, but no randomized controlled trials have been performed that provide useful guidelines for facial soft tissue injuries (6).

WOUND MANAGEMENT

General Considerations

Regardless of whether the injury is an abrasion, avulsion, or laceration, the initial management is the same. Keeping the wound moist with sterile saline-soaked gauze is recommended. Most wounds can be examined and repaired in the emergency department trauma bay or exam room. Exceptions include those injuries with underlying fractures, nerve, salivary, or lacrimal duct injuries, which will require more complex techniques for repair. Additionally, the pediatric population will often require conscious sedation or a general anesthetic for appropriate examination and closure, depending on the injury, patient's age, and level of cooperation.

Before repair, and many times before a thorough examination, local anesthesia is administered. Once appropriate anesthesia has been achieved, the surgeon can proceed with tissue manipulation and attention should be turned to systematic cleansing of the tissues using sterile normal saline. Various methods can be employed to accomplish removal of foreign debris and bacteria. Whether using a bulb syringe, intravenous catheter on a syringe, or pulsatile irrigator, the goal is to decrease the wound bacterial load. The presence of a wound inoculum of 10^5 bacteria per gram of tissue has been shown to increase the risk of wound infection. Three to five hours are generally needed for bacterial proliferation to reach this inoculum in a clean wound, and after 8 hours the bacterial load increases exponentially (7). Others have described using tap water (8) or forgoing any irrigation in the setting of a clean, noncontaminated, nonbite wound to the face and scalp and did not observe an increased rate of infection (9). The authors still advocate wound irrigation with sterile normal saline, as an inexpensive, effective, and noninvasive measure (4).

All dirt, debris, and foreign material must be carefully and thoroughly removed to avoid the risk of infection or traumatic tattoos. If irrigation techniques are not sufficient, then a scrub or wire brush may be used to remove all material, paying careful attention as to not further damage the delicate tissues or devitalize any partially avulsed flaps. Solvents used to dissolve materials such as tar are only used if absolutely necessary. Wound exploration and dissection may be needed to remove larger pieces of foreign material. Wound debridement of any nonviable soft tissue is performed with removal of necrotic tissue at the initial encounter and subsequent encounters. If there is a question of tissue viability, Futran advocates retaining the tissue and allowing a 24- to 72-hour window for final declaration (10).

For large open wounds, the use of negative pressure wound therapy (NPWT) can be utilized in those patients awaiting definitive therapy. This modality allows promotion of granulation tissue through increased blood flow to the wound, cellular proliferation from mechanical stress placed on the cells at the wound surface, as well as the removal of factors that inhibit wound healing, while avoiding painful dressing changes (11). Contraindications to NPWT related to soft tissue trauma are few, and include fragile skin, ischemic tissue, and the presence of infection (11). Contours of the face, nose, lips, and ears can make this technique difficult to apply in many cases.

Timing of Repair

The proper sequencing and staging of surgical care of facial trauma patients is important in decreasing postoperative complications and obtaining optimal results (5). Based on the wound classification and extent, decisions are made as to whether the injury is amenable to repair in the emergency room versus the operating room. Often patients will be prioritized based on other injuries.

Although the timing of repair has been controversial over the course of the past 20 years, the paradigm has shifted to immediate definitive repair after irrigation and initial meticulous debridement of devitalized tissue. Hochberg et al. argue that the best period for primary repair is within 8 hours of the injury. Tissues are less vulnerable to infection, and wound healing is at its optimum during that time, although this is also dependent on the etiology, the patient's health, and the type of injury (12).

In patients with life-threatening injuries such as intracranial, cervical spine, and severe abdominal or thoracic injuries, surgical closure can be delayed. In those patients with contaminated wounds, delayed repair is preferred due to increased risk of infection. Local wound care and secondary healing can be considered in grossly contaminated wounds as well as those with tissue loss. Allowing wound contracture to occur may minimize the ultimate defect. Delayed closure is reserved for grossly contaminated wounds, selected animal bites, infected wounds, and wounds greater than 24 hours old. Treating with antibiotics and local wound care for approximately 3 to 5 days has been shown to yield the lowest bacterial counts at 96 hours after the injury, optimizing healing following delayed closure (7,13).

Anesthesia

Local Anesthesia

Local anesthesia is usually sufficient to repair most facial lacerations in adults and children. The choice of local anesthetic depends on the length of procedure as well as any known allergies or side effects noted by the patient.

Lidocaine (1%) with 1:100,000 dilution of epinephrine provides a dense block with appropriate time to close most lacerations. The epinephrine acts as a vasoconstrictor, which prolongs the anesthetic effects of lidocaine and provides hemostasis. In the authors' experience, infiltration of lidocaine with epinephrine has been without consequence in end arterial areas such as the nose and ear, and feel there is no literature to substantiate its prohibition. The only exception would be its use in tissues, which appear to have a tenuous blood supply. Dosing limitations should be closely monitored in children and polytrauma patients, especially if multiple teams are using local anesthetics. The maximum recommended dose is 4.5 mg/kg for lidocaine and 7 mg/kg for lidocaine with epinephrine (13,14). The pain associated with the injection of the local anesthetic can be minimized and is influenced by temperature, pH, number of injections, rapidity of injection, and size of needle (15). Warming the anesthetic solution to body temperature, as well as achieving a more alkaline pH with the addition of 1 milliliter (mL) of sodium bicarbonate to 9 mL of lidocaine (1:10 dilution), should attenuate the pain of injection. Additionally, inserting the needle through the wound instead of penetrating the skin, as well as injecting slowly through a 27 or 30 gauge needle, will aid in lessening discomfort.

In the case of children, or those intolerant to local injections, topical anesthetics are available and can be used as an alternative or adjunctive method of local anesthetic administration. Several topical anesthetics are available and are generally a combination of tetracaine, adrenaline, and cocaine (or TAC); a combination of lidocaine, epinephrine, and tetracaine (or LET); or a combination of 2.5% lidocaine and 2.5% prilocaine (16). Application of topical anesthetics as an adjunct prior to needle infiltration may reduce the pain of infiltration and can sometimes be used solely for small superficial lacerations. Bear in mind that these must be applied and left in place with an occlusive dressing for 30 to 60 minutes or more for a pronounced effect.

Regional Anesthetics

Local infiltration of anesthetic suffices for most wounds although regional nerve blocks may also be appropriate in some settings. Nerve blocks of the ophthalmic division of the trigeminal nerve (supraorbital, supratrochlear, infratrochlear) are performed with an injection along the supraorbital rim from lateral to medial, while stretching the eyebrow laterally. This can be used for scalp, upper eyelid, nose, and with the addition of auriculotemporal and zygomatic branch blockade, the temporal region can also be anesthetized. Anesthesia of the lower eyelid, cheek, nose, and upper lip through blockade of the infraorbital nerve aids in closure of lacerations in these areas. Nasal blockade can be more easily performed with appropriate regional blocks and topical anesthetics. Lidocaine or cocaine can be applied to the nasal mucosa by means of cotton tip applicators or pledgets, while the lower lip and chin can be blocked through the use of mental nerve blocks (15).

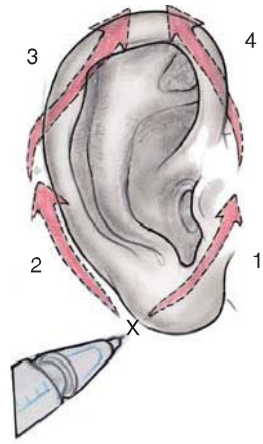

Figure 75.1 Regional block technique providing anesthesia to the entire ear, excluding the concha and EAC. "X" is the point of initial needle insertion. Numbers 1–4 denote the sequence of injections.

Complete regional blockade of the ear is possible with the exception of the concha and medial surface of the tragus which require direct injection if necessary. Prior to injection, a cotton ball should be placed in the external meatus to block any blood from entering the external auditory canal (EAC). Using a circumferential approach, a single inferior injection aimed anterior superior in the auriculotemporal distribution is performed. This is followed by a postauricular injection directed from inferior to superior through the same injection site, without removing the needle below the lobule. Once anesthesia has set in a second pain-free needle stick can be performed superiorly into the posterior auricular area following the postauricular sulcus while avoiding the postauricular artery. The final block is placed superior to the root of the helix, from a posterior to anterior approach (Fig. 75.1).

Tetanus

Tetanus vaccination history is an important feature of any trauma patient. Wounds can be divided into tetanus-prone versus those that are not. Tetanus-prone wounds include those greater than 6 hours old, stellate lacerations, avulsion injuries, wounds deeper than 1 cm, and those with a mechanism of injury from a missile, crush, burn, or frostbite. Those wounds presenting with signs of infection, containing deinnervated or devitalized tissue or contaminants such as dirt, soil, feces, or saliva are also at high risk (7). If both tetanus immune globulin and tetanus–diphtheria toxoid are given, they need to be given in different syringes and at separate sites (7,16). Dosing is beyond the scope of this chapter but recommendations from the Centers for Disease Control and Prevention (CDC) are shown in Table 75.1.

Antibiotics

According to the guidelines distributed by the American Academy of Otolaryngology—Head and Neck Surgery, the use of prophylactic antibiotics are recommended

TABLE 75.1 TETANUS PROPHYLAXIS IN WOUND MANAGEMENT

Recommendations for Tetanus Prophylaxis

	Nontetanus–Prone Wounds		Tetanus-Prone Wounds	
History of tetanus immunization	Td	TIG	Td	TIG
<3 doses or uncertain doses	Yes	No	Yes	Yes
If 3 doses or greater and:				
Last dose within 5 y	No	No	No	No
Last dose within 5–10 y	No	No	Yes	No
Last dose > 10 y	Yes	No	Yes	No

Recommendations are based upon the CDC, Department of Health and Human Services Center for Disease Control and Prevention (www. cdc.gov/vaccines/)
Td, Tetanus diphtheria toxoid; TIG, Tetanus immunoglobulin.

for traumatized or contaminated wounds, incisions or wounds crossing mucosal barriers, patients with prosthetic devices, and patients with compromised host defenses (13). Other factors that must be considered include the mechanism of injury and the time of presentation, with those patients presenting with wounds greater than 24 hours from the incident clearly having a higher bacterial inoculum and likelihood of infection. Other wounds such as compound fractures of the mandible or maxilla with mucosal breech, contaminated wounds, or injuries that occurred under water deserve prophylactic antibiotic treatment as well (17). No literature exists to support routine prophylactic antibiotic usage in soft tissue injuries to the face, so the authors follow the guidelines outlined above.

Oral penicillins are the antibiotics of choice, although in penicillin-allergic patients use of clindamycin or cephalexin should be considered. Fluoroquinolones are suitable for pseudomonal coverage in the case of underwater injury. In general 5 to 7 days is sufficient for prophylactic antibiotics. Grossly infected wounds are given therapeutic treatment with 48 hours of intravenous antibiotics, followed by a total 10 to 14 days of the oral equivalent. The pharmacology and microbiology of bite and burn wounds are discussed separately.

LACERATION REPAIR

When closing facial wounds the inherent bond between function and aesthetics cannot be overemphasized. The surgeon's closure has bearing not only on societal cues, but also in the patient's everyday functions of communication, breathing, alimentation, and display of emotions. This must also be considered when preparing and debriding the wound as distortion of contiguous structures can occur with overaggressive debridement or skin advancement. Complex or stellate wounds can sometimes be excised or converted to simple lacerations which can then be closed primarily. Delicate and atraumatic handling of the tissue edges is of utmost importance. The use of skin hooks is preferred in handling these damaged tissues as to avoid further crushing of the wound edges. Even with meticulous closure of complex lacerations, it is important to communicate to the patient and family that scar revision may be necessary.

Soft Tissue Principles of Closure

The aim of suture techniques in facial injuries is to achieve a tension-free closure with appropriate and accurate tissue approximation. When applicable, closure along the relaxed skin tension lines and abiding by the facial aesthetic units, can aid in making a scar more inconspicuous (Fig. 75.2). The amount of undermining necessary prior to closure varies with the degree of tension anticipated with the closure. A minimum number of nonreactive sutures should be used for the deep layer. Although meticulous closure may provide better tissue alignment, excess deep sutures may lead to a foreign body reaction. Too many skin sutures may compromise blood supply to the wound

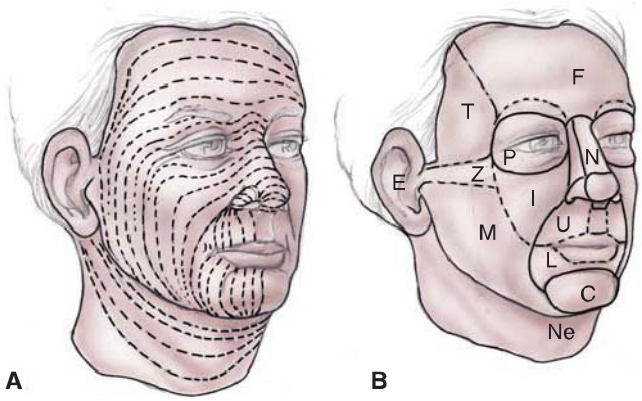

Figure 75.2 **A:** The relaxed skin tension lines (RSTL) should be used in closure design and incision planning. **B:** Depiction of the facial aesthetic units, highlighting the importance of separate reconstruction for each unit. *F*, forehead; *T*, temple; *Z*, zygomatic; *M*, mandibular; C, chin; *L*, lower lip; U, upper lip; N, nasal; I, infraorbital; *P*, periorbital; *Ne*, neck; *E*, ear.

resulting in local necrosis, most notably at the end organ sites of the nose, ear, or avulsed segments with a tenuous blood supply (5).

Suture selection is based on several factors including the depth of the injury, the extent of skin loss, the anatomic structures involved, and surgeon preference (18). Generally, a braided or monofilament deep absorbable suture is used with the knot inverted to take tension off the wound and provide appropriate reapproximation without undue strangulation or tension. Some authors, especially in the setting of contaminated or bite wounds, prefer minimally reactive monofilament sutures (e.g., polydioxanone) over more reactive, braided sutures (e.g., polyglactin) for deep closure. The theoretical increased risk of infection due to bacteria becoming embedded within the braids as well as these sutures eliciting increased tissue inflammation make monofilament absorbable preferred by some authors (19).

The subcuticular or dermal suture provides wound edge eversion and depth equality at the level of the skin for a smooth cosmetic result. The epidermal layer closure has multiple possible techniques (running, interrupted, locking) and options including sutures, staples, tapes, and liquid adhesives. Whether one uses a fine nonabsorbable (e.g., polypropylene) versus an absorbable suture (poliglecaprone 25 or fast absorbing gut) will depend on the surgeon's preference, the likelihood of the patient returning for follow-up, and whether a child will cooperate with suture removal in clinic. Parell and Becker noted no difference in long-term cosmetic results of repairs with permanent versus absorbable sutures and thus preferred absorbable sutures. The advantages were that the sutures do not necessitate removal, thereby saving the surgeon time while lessening patient anxiety and discomfort (20). Others have investigated tissue adhesives as an alternative to suture closure as means of saving time and offering greater convenience and comfort to the patient, especially in the pediatric population. Their usefulness in the management of simple lacerations is well accepted; however, they are less useful in complex lacerations, have low tensile strength, and cannot be used around moist mucous membrane due to premature adhesive dissolution and release (21). Graphic representation of various suturing techniques is depicted in Figures 75.3 and 75.4.

Postoperative Care

The importance of wound care should be stressed to patients and families. The wound should be cleansed twice daily using half strength hydrogen peroxide to prevent crusting. A topical antibiotic ointment should be applied after each cleaning. Since 7% to 13% of patients develop atopic dermatitis associated with neomycin-containing ointments, we recommend avoiding ointments containing neomycin (22). Alternative ointments include bacitracin, mupirocin, or those not containing an antibiotic such as petroleum ointment or water-based ointments such as Aquaphor (Beiersdorf AG, Hamburg, Germany). Sutures on the face are generally removed in 5 to 7 days following repair.

Once the sutures are removed meticulous care should be taken to avoid sun exposure. The use of broad spectrum UV-A and UV-B sun block with an sun protection factor (SPF) greater than 45 is recommended for a minimum of 6 months to 1 year to prevent hyperpigmentation of the scar.

Intraoral and intranasal sutures are usually absorbable and these do not require removal. Antibacterial mouthwash such as chlorhexidine gluconate 0.12% is used three times daily after meals for 1 week for intraoral lacerations. The use of saline nasal rinses can be advised with avoidance of nasal manipulation or nose blowing in the setting of nasal injuries.

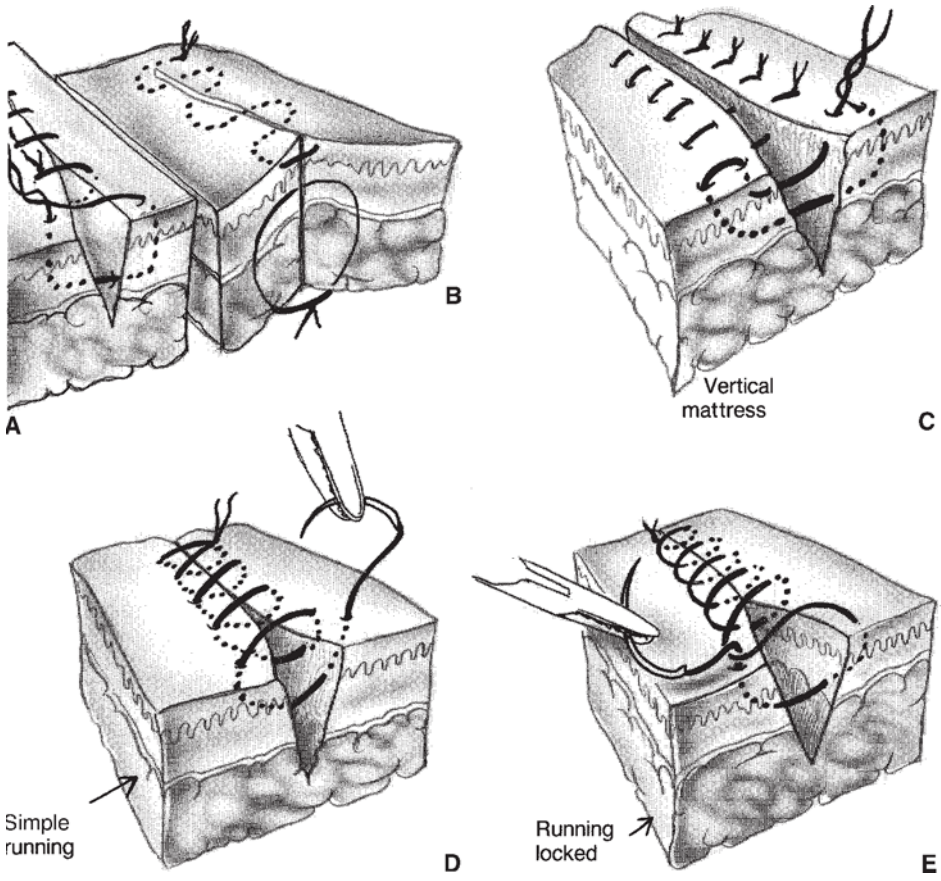

Figure 75.4 Suturing techniques. **A:** Simple interrupted. **B:** Subcuticular running. **C:** Vertical mattress. **D:** Simple running. **E:** Running locked.

Drains

The use of drains in acute facial trauma is not routine but may be advisable in wounds with extensive dead space or following closure after evacuation of a hematoma. A simple latex (e.g., Penrose) drain may be used to facilitate drainage and inhibit reaccumulation. In areas with a large dead space closed suction drains may be more appropriate.

INJURIES BY ANATOMICAL LOCATION

Scalp

Injuries to the scalp are often present as gaping lacerations or avulsions. The scalp is made up of five distinct tissue planes easily remembered by the mnemonic SCALP: S (skin), C (subcutaneous tissue), A (galea aponeurotic layer), L (loose areolar tissue), and P (pericranium) (Fig. 75.5). The layered makeup of the scalp make scalp avulsion injuries more frequent, with each layer providing a plane for dissection (23). The vessels, lymphatics, and nerves course through the subcutaneous layer just superficial to the galea, while the loose areolar tissue or subgaleal plane allows for scalp mobility. As such, scalp avulsions routinely occur through this layer, thereby leaving pericranium intact, which is an important anatomic landmark that must be distinguished at time of closure and reconstruction (23).

The scalp is a highly vascular region. The presence of a rich network of vessels contributes to the profuse bleeding seen in scalp injuries, many times out of proportion to the wound size. Direct pressure is necessary and sufficient

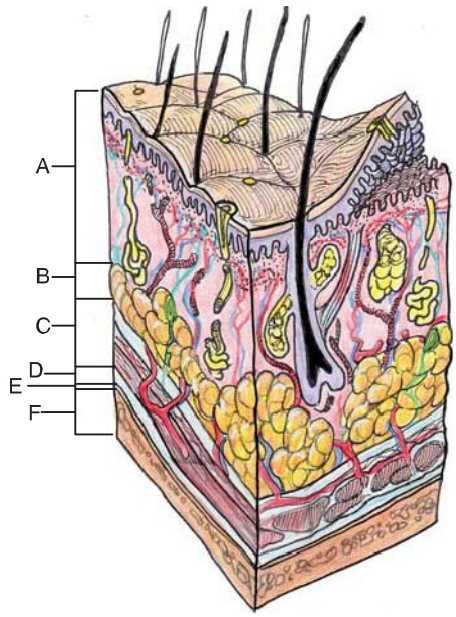

Figure 75.5 Five layers of the scalp: *A*, skin; *B*, subcutaneous tissue; *C*, galea aponeurosis; *D*, loose connective tissue; *E*, pericranium; *F*, calvarium (skull).

to temporize bleeding until further examination can be undertaken. Injection of lidocaine with epinephrine into the wound edges can help in temporizing bleeding as well. When necessary full-thickness sutures can be placed to aid in hemostasis.

Evaluation

Physical examination should proceed in a systematic fashion with specific attention turned to the neurological examination. Underlying skull fractures or associated intracranial processes must be considered. Particular attention should be paid to the present hair distribution and hairline. Wound closure should preserve these landmarks whenever possible. Small areas of alopecia may be managed by wide scar excision or hair transplantation in the future (24).

Closure

Wound preparation should be performed with copious irrigation, and undermining should proceed in the subaponeurotic plane. The scalp is known for its inelasticity, and moving adjacent tissue for wounds greater than 3 cm in size can pose great difficulty. Some authors recommend galeal incisions placed parallel to the laceration in hopes of recruiting an additional 1 to 1.5 cm of tissue and help decrease wound tension during closure. This maneuver requires clinical judgment and experience and is almost never performed by the authors. This strategy is at the expense of tensile strength and vascularity, limiting its use in larger defects (24).

For moderate defects of 2 to 2.5 cm in size, Leedy et al. (23) recommend use of V-Y flaps, V-Y-S flaps, subcutaneous pedicled flaps, or rotation advancement flaps. For large defects with intact pericranium, options include use of split-thickness skin grafts and secondary tissue expanders as well as flap reconstruction (23). If the pericranium is intact, the authors usually allow healing by second intention, thus allowing wound contraction to make the ultimate defect smaller. Reconstructive maneuvers mentioned above are seldom employed at the initial repair.

If the pericranium is not intact, but the surrounding scalp is viable, rotation or other scalp flaps can be used to fill the defect, with skin grafts or primary closure used at the donor-site defect. Large defects without pericranium can be treated with open wound care and complex reconstruction techniques such as rotation-advancement flaps or free tissue transfer can be performed in a delayed fashion.

Total avulsion or near-total avulsion injuries are best managed by microvascular reanastomosis and replantation if the scalp tissue is viable and available. If this option is not available, the authors would typically treat the open wound and then decide upon a strategy that might include a STSG versus flap reconstruction. Leedy et al. (23) feel that free tissue transfer is the best option such as a free latissimus-serratus flap.

The use of 4-0 running locking nonabsorbable suture is advocated for appropriate hemostasis and wound closure at the level of the galea and dermis. Cosmetic results following skin closure have been shown to be equivalent with the use of staples as opposed to sutures, in the pediatric population. Additionally, benefits from time savings, costs, and decreased wound closure times were noted (25). One must consider the restrictions in imaging with the use of stainless steel staples if MRI imaging is anticipated in the immediate perioperative period. If satisfactory primary closure has been obtained the authors allow gentle hair washing after 48 hours with mild baby shampoo. Whether staples or sutures are used, removal is typically at 7 to 10 days.

Complications

Specific to this area, complications include sensory deficits, hematoma formation, scar deformity, and alopecia.

Forehead, Temple, Brow

The area of the forehead, temple, and brow are anatomically linked, with features of significant esthetic importance. Damage to the neuromuscular structures that lie within these regions can leave a patient with significant functional deformities, including forehead paralysis and brow ptosis. Resulting scars may be associated with traction on the eyelid resulting in visual impairment and deformity. The unique layers of the temporal region must be examined closely and are depicted in Figure 75.6, with attention to the neurovascular structures within the various layers. The superficial temporal fascia (STF) is contiguous with the superficial muscular aponeurotic system (SMAS) inferiorly and the galea superiorly. The temporal branch of the facial nerve courses within the STF above the zygomatic arch anterior to the superficial temporal vessels. By connecting a point 0.5 cm inferior to the tragus to a point 1.5 cm lateral to the superior brow, its course can be estimated.

Evaluation

Examination should document any sensory or motor deficits. Palpation of the supraorbital ridges should be performed observing any bony step offs concerning for underlying fracture. It is important to assess for frontal sinus fractures. CSF leak may occur with posterior table involvement and may be visible in the wound. Epidural or subdural hematomas can result from injuries in the temporal region, whereas temporal bone fractures can be associated with hearing loss or facial nerve paralysis.

Closure

Often there is ample adjacent tissue to move; however, the position of important structures must be maintained. Forward or lateral movements of the hairline or eyelid, respectively, should be avoided. The contralateral brow can be used as a guide to align the involved brow. The brow should not be shaved as this is a critical landmark. The brow margins should be identified and the direction of hair growth used for proper alignment. Other considerations are the involvement of the temporal branch of the facial

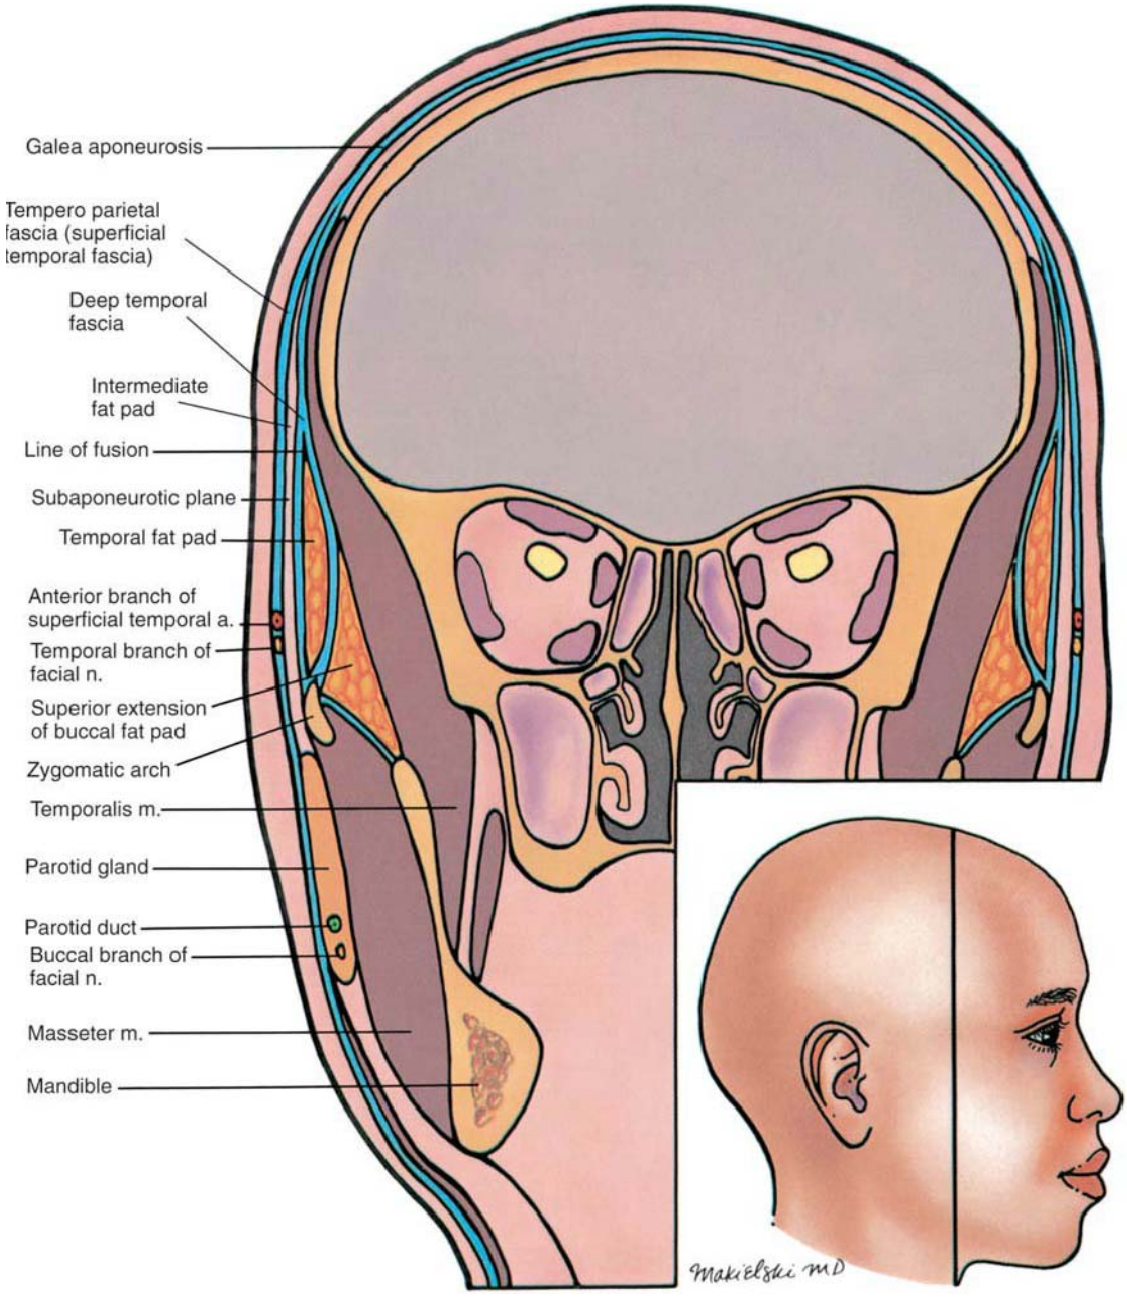

Figure 75.6 The unique anatomy of the temporal region with attention directed at the STF and the intimate relationship with the temporal branch of the facial nerve.

nerve, and caution should be exercised with deep closure in the pathway of this nerve, such as over the zygomatic arch.

The deep layers are closed in layers using a 5-0 polyglactic suture in an inverted buried manner. In the region of the eyebrow, only one or two dermal sutures should be used and superficial dermal sutures are avoided in order to avoid damage to the hair follicles. The cuticular closure consists of either a fine fast absorbing gut suture or a 6-0 polypropylene permanent suture, blue in color so that the sutures can be easily seen upon removal. This can be performed with simple interrupted or vertical mattress sutures. Sutures can be removed in 5 to 7 days. Scar revisions may be necessary, but the authors urge patients to wait 6 months after injury for appropriate healing and maturation.

Complications

Complications associated with hair follicle damage and avulsion injuries of the brow can lead to alopecia. With meticulous technique, hair loss can be minimized. Alopecia can occur despite appropriate technique, and hair transplantation can be considered.

Facial nerve injury, specifically the temporal branch, can result in frontalis muscle weakness or paralysis, causing

forehead paralysis and brow ptosis. Please see the following section on facial nerve injury.

Eyelids and Lacrimal System

The lower eyelid anatomy can be divided into anterior, middle, and posterior lamellae. The anterior lamella consists of skin and the orbicularis oculi muscle which is involved in squinting, blinking, and forced closure. The middle lamella consists of the orbital septum, whereas the posterior lamella includes the tarsus and conjunctiva. The distinct layers of the eyelid become extremely important as closure is attempted, with careful attention to reapproximation of the tarsus and muscular anatomy to restore the lid's protective functional role.

The upper eyelid lamellar anatomy is similar with the exception of the levator palpebrae superioris muscle, which forms an aponeurosis as it sweeps over the globe and fuses with the orbital septum. Dense attachments to the anterior lamella, as well as the anterior surface of the tarsus or posterior lamella are also formed (26). These attachments allow the levator muscle to elevate the upper lid. The sympathetically controlled Mueller's muscle adjoins the levator palpebrae superioris muscle and acts to provide tone and static position to the upper eyelid.

The lateral canthal tendon (LCT) connects the tarsal plates deep to Whitnall's tubercle along the lateral orbital rim. Superficial anterior and posterior fibrous attachments of the tarsal plate and fibers of the pretarsal orbicularis also attach to the lateral orbital rim (27).

The medial canthal tendon (MCT) is considered to be the tendon of the pretarsal orbicularis oculi muscle with an additional posterior limb of the MCT from the palpebral portion of the orbicularis oculi muscle. The lacrimal sac, encased in fascia, is then bounded anteriorly, laterally, and posteriorly by the constituents of the MCT and medially to the bony fossa of the lacrimal sac (28). Injuries at the level of the MCT are in close proximity to the lacrimal system making concomitant injuries common.

Evaluation

Significant morbidity can occur from injuries involving the periocular area, with a substantial percentage of eyelid injuries presenting with accompanying canalicular and/or underlying globe injury. Evaluation should include mechanism, ocular history, visual field changes, blurred vision, double vision, and visual acuity changes. Periocular swelling can be substantial, especially in delayed presentation, where a standard Snellen acuity cannot be established. In these cases near vision, finger counting, and light perception can be documented. Pupillary examination should be performed with any evidence of asymmetries, shape disturbances, or poor reactivity necessitating ophthalmology consultation. This can signify an underlying Horner's syndrome, afferent pupillary defect, third cranial nerve palsy, or damage to intraocular or intraorbital structures (26).

Extraocular muscle testing should then be performed with attention paid to limitations in movement, which can signify orbital soft tissue edema, extraocular muscle injury, or entrapment from underlying fractures. Examination of the globe and anterior segment must be performed to identify the presence of foreign body, corneal injury, hyphema, or ruptured globe (26).

Lacerations and avulsions should be examined with assessment of both surfaces of the upper and lower eyelid, along with adnexal structures. Injuries to the medial canthal region raise the possibility of canalicular injury and involvement. Facial sensation, eyelid position, and asymmetries as well as telecanthus from underlying fractures should also be noted (26).

Closure

After evaluation and removal of any debris or particulate matter with copious irrigation attention can be turned toward wound closure. Important considerations include the use of corneal protectors before any injections, or closures are attempted around the area of the globe. Debridement should be fastidious and limited only to tissue deemed necrotic. The authors recommend the surgeon to use loupes or magnification for closure of periorbital injuries, and in many cases repairs in an operating room are advocated. Appropriate and optimal use of anesthesia and operating room staff and equipment is often best for the patient even with a 24- to 48-hour delay in treatment, with the exception of ocular emergencies.

When performing closure of full-thickness eyelid margin lacerations, it is critical to address all layers using a three-suture technique to avoid and minimize long-term sequelae. Avulsed segments of up to one-fourth of the lid margin may be closed primarily. First, the cut edges of the tarsal plate should be identified with the edges freshened if needed. Murchison and Bilyk (26) recommends passing a single 6-0 prolene stitch at the meibomian gland line, found slightly posterior to the ciliary line (the lash line) and gray line, to temporally act as a traction suture and realign the eyelid margin, without tying it (Fig. 75.7).

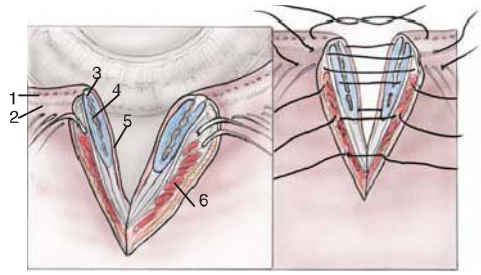

Figure 75.7 Closure of the eyelid defect highlighting the realignment of the tarsus and the three suture technique for lid margin repair. Sutures are placed at the level of the meibomian glands, gray line, and lash line. Lid margin sutures are left long to avoid contact with the cornea. *1*, meibomian orifice; *2*, gray line; *3*, mucocutaneous junction; *4*, inferior tarsus and meibomian glands; *5*, palpebral conjunctiva; *6*, orbicularis oculi m.

The tarsus is then reapproximated with partial-thickness sutures. Care must be paid to the lamellar boundaries being careful to not pass into the conjunctiva to avoid post repair corneal irritation from suture material. Begin near the eyelid margin and then proceed along the vertical length of the plate using a 5-0 or 6-0 polyglactin suture.

Once the tarsus is realigned the eyelid margin traction suture can be tied with long tails, followed by placement of an anterior single suture at the ciliary line and an additional suture at the gray line (Fig. 75.8). Care must be taken to avoid corneal irritation with the tails of the lid margin sutures left long and draped onto the skin of the eyelid

Figure 75.8 **A:** Full-thickness injury to the left eyelid with brow involvement. **B:** Exposed globe and periorbital fat concerning for levator injury. **C:** Reapproximation of the levator (grasped by forceps) with visualization of the insertion into the tarsus. **D:** Skin closure with long tails left long and incorporated into a separate skin suture in order to avoid corneal irritation. **E,F:** Postoperative outcome with appropriate brow realignment and mild lid contour deformity noted.

where they are sutured to the underlying skin. The skin and orbicularis are then closed with absorbable or nonabsorbable suture in an interrupted or running fashion. Suture material choices should be carefully considered in the trauma population. However, if the patient is unlikely to return a long-lasting absorbable suture may be used. The lid margin repair should be with a nonabsorbable suture to prevent premature dissolution or breakage.

Upper eyelid injuries with herniation of fat and ptosis are concerning for injury to the levator superioris muscle or aponeurosis. Care must be taken to thoroughly explore the wound and identify the levator muscle and/or aponeurosis with appropriate repair. The violated orbital septum should not be repaired for concerns of eyelid retraction.

Lateral canthal injuries, whether from blunt, sharp, or penetrating trauma put the globe at risk, given the poor bony protection laterally. Murchison and Bilyk advocate two tenets in repair of LCT injuries. First, repair begins by suturing and reapproximating the retinaculum of the LCT to the inner aspect of the lateral bony orbital rim at Whitnall's tubercle. This maneuver will allow for appropriate functional aesthetic curvature of the lid and avoidance of ectropion. The second principle addresses the lateral canthal angle with a separate suture from meibomian gland line on the lower lid to meibomian gland line of the upper lid. This allows for a sharp lateral canthal angle (26).

The intimate anatomic relationship of the lacrimal drainage system to the MCT make associated injuries more frequent. Injuries medial to the puncta or those associated with animal bites also confer an increased risk of canalicular injury (29). Examination should proceed with careful and methodical probing after anesthetizing the eye and lacrimal puncta with topical ocular anesthetic, as this can otherwise be quite uncomfortable for patients (Fig. 75.9). Especially in the case of canalicular injury, direct anesthetic injection can increase edema at the injury site making identification and cannulation of the canalicular orifice more difficult. Injured canaliculi are then intubated with silicone stents, either monocanalicular or bicanalicular. Once identified and intubated, further repair of the canalicular injury can be undertaken. Kersten and Kulwin (30) advocate repair of the pericanalicular orbicularis oculi muscle, with reapproximation from stenting and a single mattress suture. Repair of the MCT should be performed using a posterior medial vector with deep absorbable suture placement in the periosteum.

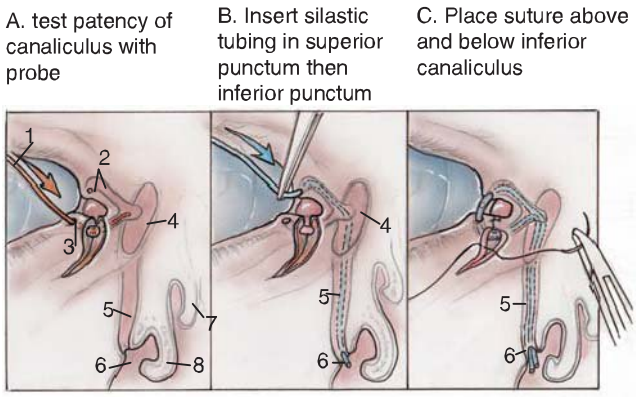

Figure 75.9 Approach to canalicular injuries. **A:** Probing the inferior canaliculus to test patency. **B:** Stent placement. *1*, probe; *2*, superior punctum and canaliculus; *3*, inferior punctum and canaliculus; *4*, lacrimal sac; *5*, nasolacrimal duct; *6*, NLD osteum; *7*, middle turbinate; *8*, inferior turbinate. **C:** Suture placement.

Avulsion injuries with subsequent tissue loss pose a complex reconstructive dilemma. In addition, adequate corneal protection is paramount. With eyelid avulsion injuries, the goals of repair are to create a functional eyelid with adequate tearing and preservation of vision. In selected cases, a lateral canthotomy with cantholysis can be performed for mobilization of additional tissue to aid in closure. In the rare cases of total avulsion, corneal lubrication and protection take precedence and delayed multistage reconstruction will be necessary. Bacitracin ophthalmic ointment should be applied twice daily in the care of wounds and lacerations of the periorbital region. Canalicular stents remain in place for 12 weeks and can be removed in the clinic setting.

Complications

Despite timely and appropriate care, these injuries can result in periorbital and eyelid complications. Many can be managed conservatively with observation, such as mild eyelid malposition treated with digital massage. However, those with moderate to severe dystopia, significant corneal exposure, lagophthalmos or ectropion, will require further intervention to avoid exposure keratopathy and improved cosmesis. Ptosis occurs with levator injuries and even with repair it may take several months for resolution. Other complications include notching of the lid margin and epiphora.

Nose

The nose is particularly susceptible to injury given its prominent position and is a commonly injured site following facial trauma. Injuries of the nose can result in disfigurement from scarring and distortion, as well as functional abnormalities such as nasal obstruction.

Nasal anatomical relationships become functionally important at the level of the nasal valves both internal and external. The external nasal valve is at the level of the nasal vestibule, alar lobule, and caudal septum. The internal valve is at the level of the caudal margin of the upper lateral cartilage, with the nasal septum medially, and the inferior turbinate at the inferolateral position.

Evaluation

Examination of nasal trauma should start with simple frontal inspection, and note any deviation or asymmetry to the nose. Associated facial, nasal, or septal fractures should be recognized. Anterior rhinoscopy should also be performed using either a nasal speculum or fiberoptic endoscope examining for acute septal deformity, dislocation, hematoma, mucosal tears, and CSF leak.

Next attention should be turned to cutaneous lacerations, noting any involvement of underlying cartilage, avulsed or

missing tissue or through and through involvement. Severe nasal injuries, such as nasoethmoid fractures warrant formal ophthalmologic examination, since up to 59% of midface fractures have associated ocular injuries (5).

Closure

Repair of soft tissue injuries to the nose follows the same guidelines as closure of all facial wounds, with excellent functional and cosmetic outcomes as the primary goal. Wounds are classified by depth and assessment of tissue loss in the case of avulsion injuries. Superficial lacerations extending into the subcutaneous tissues can be closed with the use of absorbable deep dermal sutures, and the surgeons preferred suture for skin closure.

Cartilaginous involvement is addressed with meticulous alignment and prevention of deviation or collapse. The use of nonabsorbable or long-lasting absorbable suture for reapproximation is preferred, and in the case of lower lateral cartilage involvement the use of interrupted nonabsorbable polypropylene suture is preferred for appropriate wound support and durability.

Full-thickness lacerations involving the skin and nasal mucosa are closed in layers beginning with the nasal mucosa using a 5-0 chromic suture in an interrupted fashion. Then this is followed by closure of the muscular, cartilaginous, dermal, and skin layers as outlined above. Many times the alar rim or alar lobule is involved and thus there is particular concern of post repair notching. Care must be taken to ensure appropriate alignment of these structures in particular.

Avulsive wounds of the nose are a common form of presentation, and repair may involve primary closure, skin grafts, composite grafts, or local flaps. Complex reconstruction is not appropriate in the acute setting.

An intranasal silastic stent can be placed to avoid or minimize vestibular stenosis or collapse.

Complications

Complications of nasal injury may result in vestibular stenosis and nasal obstruction. Deformities include scarring, alar sidewall collapse, and alar retraction. Hypertrophic scarring can also be seen in select individuals. Infection following an undiagnosed septal hematoma can be seen days later and must be kept in the differential if the patient reports acute onset of increased pain, nasal obstruction, and signs of fever. This would necessitate emergent incision and drainage.

Cheek and Parotid

The parotid gland is the largest of all salivary glands with its position in the retromandibular space between the ramus of the mandible and mastoid process. The gland is invested in a dense fibrous capsule derived from the investing layer of the deep cervical fascia, and over this fascia lays the SMAS. The SMAS also serves as the attachment for the muscles of facial expression. The deep aspects of the gland pass through the stylomandibular tunnel to rest within the parapharyngeal space (31).

The parotid duct (Stensen's duct) travels across the surface of the masseter in a horizontal plane. On reaching the anterior border of the muscle, the duct's course turns medially as it pierces the buccinator muscle toward the oral cavity. The mucosal papilla opening is found in the oral cavity opposite the second upper molar. Traveling along side the duct, in a predictable anatomic fashion, is the buccal branch of the facial nerve. This relationship on the superficial aspect of the masseter muscle makes the duct and nerve more vulnerable to injury, thus must be considered in soft tissue trauma of the cheek and parotid region.

Evaluation

Recognition of parotid injury is essential to avoid late complications. When examining the patient, the wound should be explored for evidence of clear drainage suspicious for saliva. This can be accomplished by massaging the gland and inspecting for presence of saliva within the wound. If an injury has been missed, the patient may report swelling in the area of the closed laceration, especially after meals over the course of the next few days.

If parotid injury is suspected, the wound should be thoroughly examined within 24 hours to avoid surrounding inflammation and edema from obscuring the ductal and nervous structures, and subsequent injury during exploration.

Facial nerve examination, with particular attention to the buccal nerve branch, should be conducted with any weakness documented. The course of the parotid duct and associated buccal nerve can be projected using a line drawn from the tragus to the midportion of the upper lip (Fig. 75.10). Injuries violating this line must then be inspected for ductal and neural injuries. Discussion of facial nerve injury is presented elsewhere in this chapter.

Patency of the ductal system can be assessed either with simple cannulation using a silicone catheter, retrograde injection with methylene blue or saline, or sialography. The author advocates simple cannulation using a lacrimal probe or silicone catheter.

Closure

In 1981, Van Sickels constructed a classification system for anatomical regions of injury in parotid trauma with a recent update of this schema (31,32).

Anatomic regions are divided into A, B, and C with divisions based on their relationship to the masseter muscle. Prognostic and treatment information can be derived from this classification system. Region A is the area posterior to the masseter with likely injury to the parenchyma of the gland. Wounds in this region can safely be closed in layers with particular attention paid at the level of the SMAS (31).

Region B is associated with the area overlying the masseter muscle, and carries the highest risk of ductal injury. Ductal injury increases healing time from continued salivary flow into the wound. If injury of the ductal system is visualized or suspected, cannulation of the duct through the papilla using a silicone catheter or stent should be passed retrograde. The lacerated end will be identified and

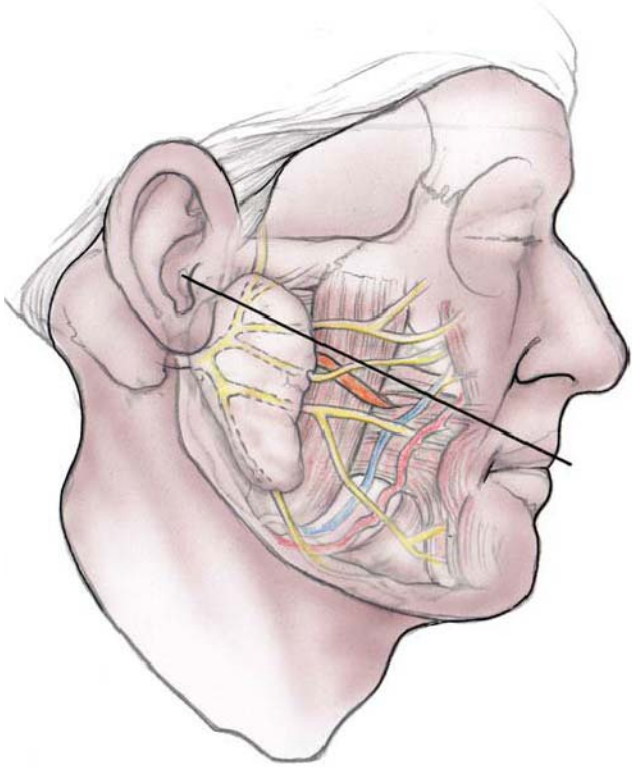

Figure 75.10 Parotid duct anatomy. Injuries violating a line drawn from the tragus to the upper lip should raise concern for injury to the parotid duct.

the opposing proximal transected duct identified. The ends are then dissected free to allow for tension-free closure of the severed ends over the silicone catheter. Microsurgical techniques, using a 7-0 to 9-0 monofilament suture, are employed for closure (Fig. 75.11). The catheter is then sutured to the buccal mucosa for 10 to 14 days to hold the duct and orifice open during healing. If the injury precludes this, the end of the proximal duct can be brought out to the buccal mucosa and sialodochoplasty is performed.

Region C is the area anterior to the masseter muscle. In this region, the distal duct or papilla is injured and reanastomosis may not be feasible. It may be necessary to divert the duct into the buccal mucosa, thereby creating a new duct orifice as noted above. A stent is left in place at the newly constructed papilla (31). Some authors mention parotid duct ligation of the proximal section resulting in acute parotid swelling, pain, and salivary back-flow with eventual glandular atrophy. We do not advocate this.

If appropriate, techniques to reduce salivary flow or reduce accumulation include placement of compressive dressings, and anticholinergic medications. In recent years, botulinum toxin A (Botox, Allergen Inc, Irvine, CA) has been successfully used in these circumstances as well. Some patients may require needle aspiration of accumulated saliva post closure.

Antibiotic coverage in the setting of injury or post injury sialocele should include coverage for *Staphylococcus aureus, Haemophilus influenzae,* and anaerobic Gram-negative bacteria (33). A second- or third-generation cephalosporin, clindamycin, or amoxicillin with clavulanic acid is usually sufficient, with considerations for methicillin-resistant *S. aureus* in persistent infections.

Complications

Injuries to the parotid and cheek region can result in prominent facial scarring and disfigurement. Specific to the this region one can also see gustatory sweating (Frey syndrome), sialocele formation, and salivary-cutaneous fistula.

Late complications are increased if the techniques noted are not employed or the injury goes unrecognized. Nonsurgical management is described above. Formerly, tympanic neurectomy was a consideration for those cases where a decrease in salivary flow was therapeutic. Now this has been largely abandoned due to the effectiveness of botulinum toxin injection. If all options have been exhausted in the setting of persistent fistula, parotidectomy may be entertained. This poses a challenge for safe facial nerve dissection in the setting of extensive scarring and fibrosis from the injury and fistula.

Facial Nerve Injury

The anatomical considerations of the facial nerve are summarized here as they relate to acute soft tissue injury of the face. Discussion is limited to the extratemporal course of the facial nerve as it exits the stylomastoid foramen and innervates the muscles of facial expression, posterior digastric belly, and posterior auricular and stylohyoid muscles. Innervation to the muscles of facial expression is all along the deep surface of the muscle with the exception of the levator anguli oris, buccinator, and mentalis muscles. This anatomical relationship is important in cases of penetrating injuries and exploration to avoid iatrogenic injury. Transection of the main trunk results in complete facial paralysis, while injuries distal to the pes anserinus or muscles themselves, will result in inability to move the involved area of the face (34).

Injury to the facial nerve can have devastating consequences resulting in diminished emotional expression for patients attempting to smile, frown, or grimace. The functional aspects affecting oral competence can be disabling and may limit social activities, eating habits, and speech. The protective mechanism of the facial nerve should also be considered, with innervation to the stapedius muscle as well as the orbicularis oculi muscle, providing eye closure and the blink reflex. Severe keratopathy from unrecognized chronic corneal exposure may lead to blindness.

Evaluation

Once the patient is stabilized and able to cooperate, facial nerve function should be tested. Other cues such as grimacing in the presence of a noxious stimulus can also aid in assessment for patients who are unable to perform

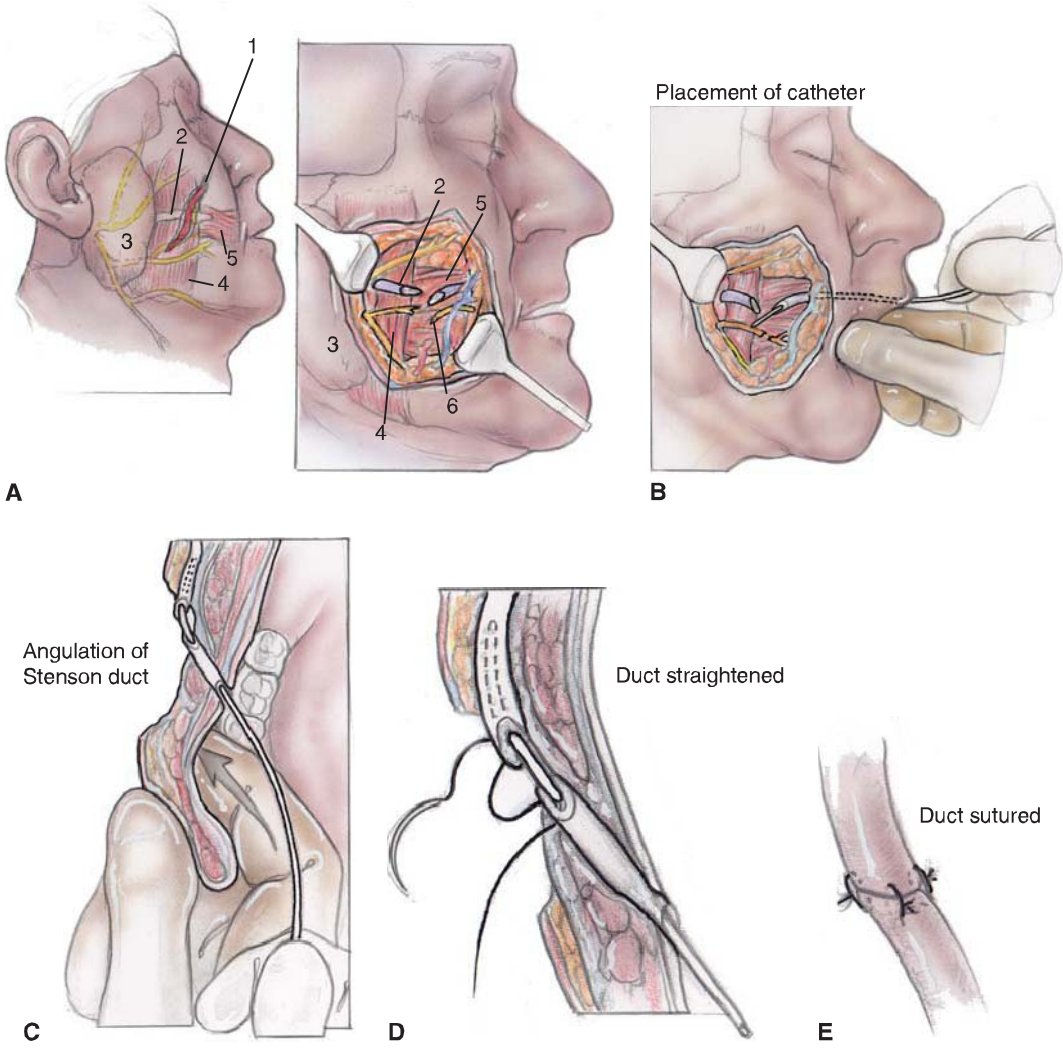

Figure 75.11 Cannulation and repair of parotid duct. *1*, laceration; *2*, Stenson's (parotid duct); *3*, parotid gland; *4*, masseter m.; *5*, buccinator m.; *6*, transected buccal branch. **A:** Right cheek laceration with severed duct and nerve branch. **B–E:** Duct cannulation and repair.

volitional movements. The examiner should ask the patient to raise their eyebrows, close their eyes, smile, purse and pucker the lips, and puff out their cheeks (34). Complete transection results in complete paralysis with no volitional movement. Crush injuries often present with normal function followed by partial or delayed paralysis, often with resolution with expectant management.

Several grading systems have been proposed with the most widely accepted and used being the House-Brackmann scale (see Chapter 155). Although other rating systems have been introduced, the authors prefer conscientious documentation using terminology that identifies the branches involved and the degree of paresis (34).

When evaluating the patient, an imaginary vertical tangent can be drawn from the lateral canthus inferiorly and injuries anterior to this line are not explored for facial nerve injury. The highly redundant collateral innervation from other branches makes recovery likely, as well as the fact that the small diameter of the nerves anterior to this line makes identification and reanastomosis difficult.

Exploration of the wound may reveal transected ends of the nerve. The use of a nerve stimulator for the distal branches can aid in identification for up to 72 hours, after which Wallerian degeneration occurs and compromises excitability of the nerve.

Closure

Facial nerve injuries should be explored and repaired as soon as possible. When nerve identification and repair is anticipated, the procedure should be done in the operating room under general anesthesia, as lidocaine would create inability to use a nerve stimulator. In the critically ill patient, the injured branches should be tagged with permanent suture or clips on adjacent tissue can be placed. Then reanastomosis can be performed once the patient is stable.

Primary neural repair provides the best chance for return of facial nerve function. This can performed with the operating microscope using 8-0 to 10-0 monofilament nylon suture. Tension-free closure of the epineural layer should be performed, although some authors recommend perineural repair as having the potential advantage of reducing synkinesis and mass facial movement (34–36).

When a tension-free direct repair is not possible, cable (interposition) grafting is advisable. The use of great auricular, sural, and medial antebrachial cutaneous nerves offers the best option for achieving volitional facial movement (37).

When facial nerve repair is not possible, facial reanimation procedures can be performed at a later date.

Complications

Complications in the setting of facial nerve injury include inability to repair the nerve injury, facial nerve paralysis, synkinesis, and mass facial movement. Often unpreventable, the risk of complications can be reduced with early recognition and management. Late complications include corneal injury from inability to attain complete eye closure with associated dry eye and keratopathy. In addition oral incompetence, brow ptosis, and dysarthria may result.

Auricle

The ear typically protrudes from the head at an angle of 25 to 30 degrees with 15 degrees of incline. This prominent position opens the ear to frequent lacerations and shearing forces leading to avulsions. The external ear consists of the auricle and EAC. The skin is tightly adherent over the compliant cartilaginous framework of the ear covered by perichondrium. The surface anatomy of the ear offers a complex topography making replication and reconstruction difficult (Fig. 75.12). Even if early repair is instituted, severe traumatic auricular injuries may require multiple procedures for reconstruction (38).

Evaluation

Examination should start with inspection of the EAC as lacerations at this site can potentially lead to EAC scarring and stenosis. The EAC should be cleaned of any debris or blood. Integrity of the tympanic membrane should be confirmed and hearing loss identified. Tuning fork examination is an appropriate initial measure and an audiometric testing can be performed if hearing loss is a concern.

Examination of the postauricular region for evidence of mastoid tenderness or ecchymosis (Battle's sign) concerning for basilar skull or temporal bone fractures should be performed. Radiographic imaging to evaluate for fractures or dislocations should be performed if concern exists. Cranial nerve examination should be performed with special attention paid to the ipsilateral facial nerve.

Inspection of the wound should be performed, noting the extent of cartilaginous involvement or loss. Height and width discrepancies can be compared with the contralateral ear. Debridement should be minimized given the relative lack of available skin for closure and cartilage coverage.

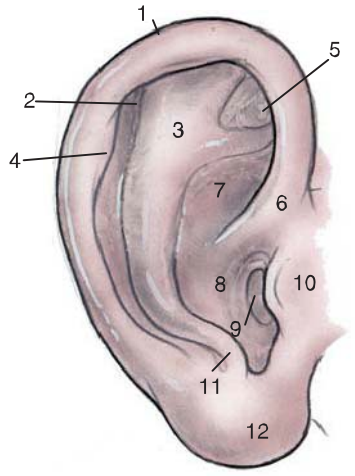

Figure 75.12 Anatomy of the external ear. *1*, helix; *2*, scaphoid fossa; *3*, antihelix; *4*, auricular tubercle; *5*, triangular fossa; *6*, crus helicis; *7*, cymba concha; *8*, cavum concha; *9*, external auditory meatus; *10*, tragus; *11*, antitragus; *12*, lobule.

Closure

Lacerations of the EAC rarely necessitate suture repair. Stenting with nonabsorbable sponges should be instituted if stenosis is a consideration, but only after tympanic membrane evaluation.

Isolated lobule injuries can be repaired with primary layered closure or z-plasty techniques to prevent any notching at the inferior margin of the lobule. Cutaneous injuries of the ear with cartilage exposure are managed by primary closure. Full-thickness skin grafts can also be used for cartilaginous coverage in cases of isolated skin loss or to avoid trimming cartilage in avulsion injuries as to not decrease the size of the ear (Fig. 75.13).

Figure 75.13 Auricular injury with exposed cartilage. Repaired with FTSG without further loss of auricle size (3 month result).

Patients with full-thickness loss of skin and cartilage present a challenge. For helical defects a wedge excision technique may be used. This can be safely performed up to 5 mm without threat of auricular deformity. Reconstructive options should aim at complete cartilaginous coverage with care to achieve a tension-free closure. If the full-thickness defect is small (less than 1.5 cm), the cartilaginous remnants can be trimmed and closed using a polydioxanone monofilament suture in an interrupted fashion using a taper needle to avoid cartilaginous tears. This allows for maintenance of auricular proportions, but may reduce the overall size of the ear dependent on the amount of missing tissue (39). Skin closure is accomplished using interrupted 5-0 polypropylene or absorbable monofilament suture (Fig. 75.14).

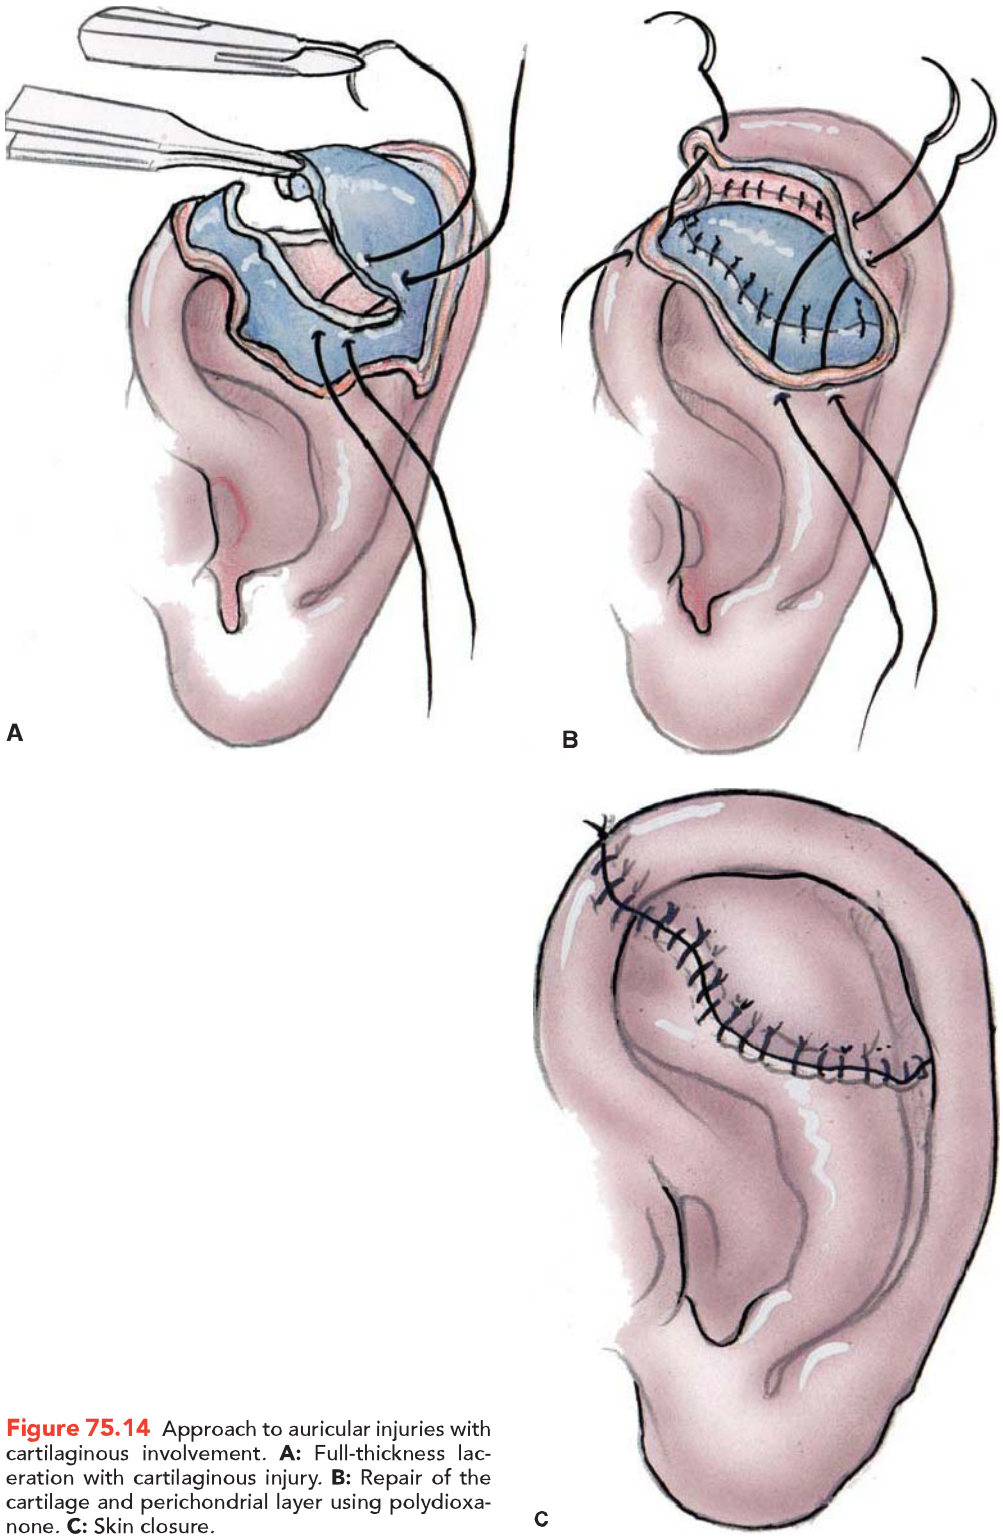

Figure 75.14 Approach to auricular injuries with cartilaginous involvement. **A:** Full-thickness laceration with cartilaginous injury. **B:** Repair of the cartilage and perichondrial layer using polydioxanone. **C:** Skin closure.

Avulsion injuries should be scrutinized for disruption of blood supply and degree of tissue loss. Injuries with a narrow vascular pedicle may be closed but the patient should be counseled about possible impending tissue loss. The authors feel that primary closure should be attempted, allowing further demarcation and necessary debridement. In the setting of complete auricular avulsion, reconstruction algorithms are dictated by whether the ear is found at the scene. In the case of a missing auricle, the wound should be closed over primarily and delayed reconstructive options discussed with the patient, including future auricular reconstruction using costal cartilage grafts versus prosthesis placement.

If the avulsed segment is found, care must be taken in the storage and transport of the ear. The tissue should be wrapped in gauze and placed in a plastic bag, which is placed in an ice bath at 4°C, avoiding direct contact with water. If microvascular expertise is available, the amputated segment should be evaluated using an operating microscope for identification of suitable vessels for microvascular reimplantation. This offers the highest survival rate for the reimplanted ear (38,39). Pocket techniques are described in which the segment is dermabraded, attached, and buried in the postauricular skin with later exposure of the attached segment (38). The authors generally advise against manipulating the postauricular skin in any way as this is the most useful skin in definitive reconstruction. The pocket principle has fallen out of favor and banking cartilage in remote soft tissue sites seems to add no advantage to reconstructive options.

Exposure or involvement of the cartilaginous framework increases the risk of perichondritis substantially. Cartilage-penetrating antibiotics effective against pseudomonas should be used with fluoroquinolones serving as a first-line therapy. In the event of EAC involvement, antibiotic otic drops are prescribed for 5 to 7 days.

Some ear injuries require a bolster to avoid auricular hematoma due to disruption of the cartilage with accumulation of blood within the cartilage fragments or the subperichondrial space. Bolsters can be fashioned using dental rolls or ointment-impregnated gauze with mattress sutures to eliminate dead space (Fig. 75.15). Undue pressure should be avoided as necrosis may result. Others have described use of thermoplastic splints as a shape-forming bolster (40,41). The bolster and EAC wick should be left in place until follow-up at the time of suture removal at 5 to 7 days.

Complications

Injuries involving the external ear can lead to a multitude of complications and concomitant injuries. Close follow-up should be maintained to evaluate for chondritis, temporal bone fracture, and associated hearing loss from ossicular disruption, tympanic membrane perforation, or EAC stenosis. Facial nerve integrity should be monitored as well.

Accumulation of intracartilaginous blood or blood in the subperichondrial plane can lead to auricular hematoma, which can be managed with simple needle aspiration (for small isolated hematomas) or incision and drainage with use of a bolster (for more extensive hematomas) (42). Unrecognized hematoma can result in cartilage loss, necrosis and formation of neocartilage and fibrosis giving the ear a cauliflower ear deformity. This deformity can be disfiguring and difficult to manage, with repair requiring surgical excision of the neocartilage and fibrosis

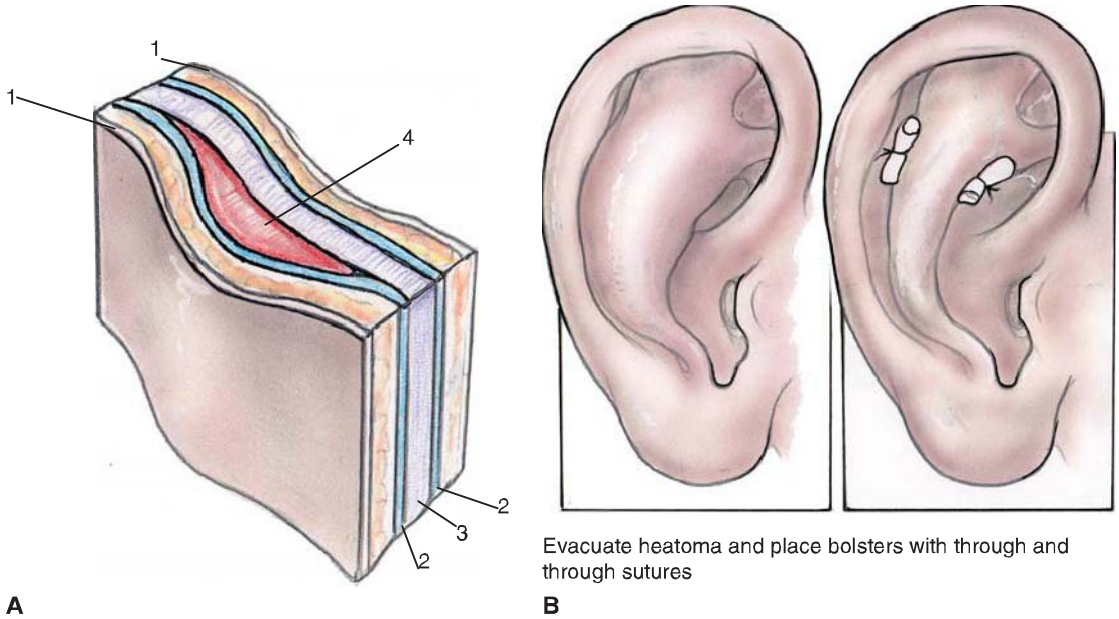

Figure 75.15 Auricular hematoma. **A:** Blood may accumulate within the cartilage fragments or in the perichondrial space. 1, skin; 2, perichondrium; 3, cartilage; 4, hematoma. **B:** Evacuation of the hematoma is followed by placement of a bolster dressing with through-and-through sutures.

using camouflaging incisions. Best practice is avoidance and the judicious use of bolsters.

Lips and Chin

The lip and perioral region embodies both aesthetic and functional components that must be considered in the setting of soft tissue repair. The anatomy of the lip demonstrates surface contours that the human eye is drawn to, such as cupid's bow, philtrum, and the vermilion border. The red lip is comprised of three layers, the outer vermilion layer, the middle muscular layer (of the orbicularis oris), and the inner mucosal layer. At the junction of the facial skin (white lip) and the vermilion (red lip) is the vermilion border with corresponding red and white rolls. The reflecting of light at these rolls makes any injury with even a one-mm misalignment at the vermilion eye-catching and aesthetically unpleasing (4). The mental crease is a horizontal groove between the area of the chin and lips influenced by the mentalis muscle. Realignment of lacerations in this area contributes to a natural division between the lip and chin regions.

The primary blood supply to the perioral region is the facial artery giving rise to the inferior and superior labial arteries which encircle the mouth. Injury here can lead to brisk bleeding making initial evaluation difficult.

Evaluation

As the lip and perioral region are examined, sensory and motor function should be documented, as well as depth and location of the injury. Any extension into the floor of mouth and buccal mucosa should alert the clinician to potential involvement of the salivary ducts. The lips and mucosal surfaces should be examined for associated injuries including changes in dental occlusion and broken or missing teeth. If injuries are present, consultation with the dental team may be necessary prior to repair in order to avoid undue tension and retraction on the suture line during dental repair (4,7).

Closure

The first step of repair is marking of the vermilion border before its boundaries are lost from edema or injections around the site of injury. When appropriate, the use of regional blocks allows the surgeon to evaluate and repair the vermilion border without distortion.

The main tenant of primary closure of lip lacerations is the layered closure, with reapproximation of the orbicularis oris muscle and alignment of the vermilion border. Whether first or last, the mucosa should be closed, usually performed with interrupted absorbable 4-0 polyglactin sutures, using large bites to avoid sutures tearing or eroding mucosa. Critically important is reapproximation of the orbicularis oris muscle to restore sphincter function, and to avoid muscular dehiscence of contraction with healing. A soft tissue deficiency, usually seen months later, is apparent in those cases where the muscle layer is not well approximated.

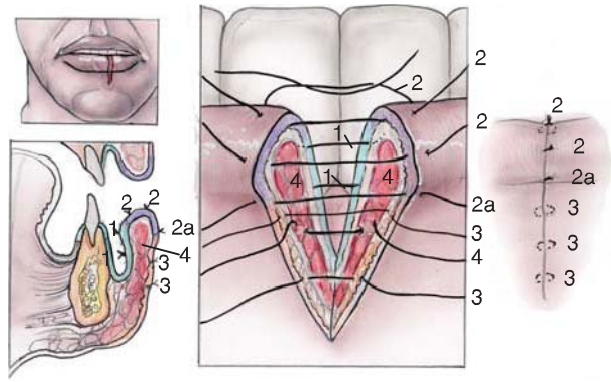

Figure 75.16 Layered lip closure. Layered closure of the lower lip highlighting the realignment of the vermilion and orbicularis oris muscle. Mucosal and skin closure also depicted. *1*, mucosal sutures; *2*, vermilion sutures; *2a*, suture at the vermilion cutaneous border; *3*, skin (dermal) sutures; *4*, orbicularis oris muscle sutures.

The most important stitch in lip reconstruction is next. Marking its importance, placing this suture first could also be considered. Using a permanent monofilament suture, such as a 6-0 polypropylene (Prolene), a single stitch is placed to align the vermilion border. This will allow accurate reapproximation, while the remainder of the vermilion (red lip) is then closed using simple interrupted 6-0 prolene sutures (Fig. 75.16). Facial skin closure is performed in standard layer fashion.

Chin lacerations should focus on recreation of the natural borders and surface landmarks without creating any traction on the lower lip, which is subject to inferior displacement.

If there is more than 30% loss of the lip, primary closure may lead to relative microstomia and undue wound tension. If the defect is too large for primary closure the edges of the defect can be closed and the full-thickness defect can be reconstructed at a later date. Closures outside of primary repair should be deferred for secondary reconstruction using various lip flaps such as Abbe, Estlander, and Karapandzic flaps and are beyond the scope of this chapter.

Complications

Post-traumatic lip deformity is the most common complication following injury. This is not unexpected given the delicate and intricate anatomical features of the lip. The degree of the deformity is directly related to the severity of the injury and the complexity of the repair. Resulting deformities include misalignment of the vermilion, cutaneous scars, and contour deformities of the red or cutaneous lip. Skill, experience, and expertise help minimize this risk and meticulous closure must be performed with special attention paid to alignment of surface landmarks and layered closure. Muscular contracture and notching of the lip are common sequelae following inaccurate closure. Functional complications, such as microstomia or oral incompetence, may occur and appropriate delayed reconstruction must be considered.

SPECIAL CONSIDERATIONS

Bites

Injuries from bites are becoming more common with 15% of all bite wounds occurring in the head and neck. According to Gilchrist et al. (43) 4.37 million people were bitten annually in 2001 to 2003, and, of these, 836 000 (19%) required medical attention, with more than 31,000 patients undergoing acute repair procedures in 2007 as the result of dog bites. Dog bites makeup the majority of animal bites (80% to 90%), with cats as the second most common (5% to 15%). Human bites account for 3% to 23% (19). Most injuries are from the patients' own pet, or pets that are known to them, as opposed to stray or mongrel animals. The size and age of the child is inversely proportional to the level of risk for bite injuries to the head and neck (44). Other bites from more exotic and less common pets are beyond the scope of this chapter. Yet, it should be mentioned that the type of animal bite becomes important in antibacterial management, and a thorough history should be elicited.

Microbiology

Infection after bites can originate from the bacterial flora of the animal or human's oral cavity, as well as the skin of the victim. The overwhelming majority of bite infections are polymicrobial, with 2.8 to 3.6 bacterial species isolated in wound cultures of both aerobic and anaerobic bacteria (44). Life-threatening viruses may also be transmitted from animal bites and must be considered during the evaluation.

Dog bites offer the lowest infection rate of common animal bites, with risk factors of significant crush injury, devitalized tissue, deep puncture wounds, exposure of cartilage, or delay in seeking care beyond 6 to 12 hours all resulting in increased infection rates (19,45,46). *Pasteurella* species are often discussed as the most common pathogen involved in dog bite infections, but the overwhelming majority are polymicrobial with numerous studies isolating various species including *Staphylococcus sp., Streptococcus sp., Corynebacterium sp., Moraxella sp., and Neisseria sp., Bacteroides fragilis, Fusobacterium, and Peptostreptococcus* (19,44,45). Additionally, the possibility of transmission of the rabies virus exists with dogs accounting for the majority of human rabies cases worldwide. In the United States, however, human transmissions are more commonly from wild animals such as skunks, raccoons, bats, and foxes (19,44).

Cat bites have higher rates of infection with more rapid progression when compared to dogs. Cats' teeth often produce deeper puncture wounds, given their shape, inoculating bacteria deeper into the wound. *Pasteurella multocida* is the pathogen most commonly involved, resulting in 50% to 75% of cases of infections from cat bites, although infections are frequently polymicrobial (19,45).

Human bites are less common than dog and cat bites, but carry the highest infection rate at 25% in the head and neck region, likely secondary to the composition of the bacterial oral flora in humans (19,47). Although polymicrobial, the most common pathogens isolated in human bite wounds include *S. aureus, Staphylococcus epidermis*, viridans streptococci, *Eikenella corrodens*, and anaerobic bacteria such as *B. fragilis* (19,44,45). Additionally, viral transmission of hepatitis B and C, herpes simplex virus, and human immunodeficiency virus (HIV) through human bites have been reported (48). Although not common, in cases of known or suspected infection by the assailant, appropriate screening and prophylaxis should be implemented. Hepatitis B immunoglobulin should be administered to victims if they are not already vaccinated, in cases of known Hepatitis B-infected attackers. If the biter is HIV positive, the victim's baseline serologic testing should be obtained, with retesting at 3 and 6 month intervals. If possible, titers for HIV viral load should be obtained from the attacker, and if elevated, prophylaxis should be offered to the victim (19).

Evaluation

Animals are often drawn to the nose and cheeks of children when attacking, making ocular examination an integral part of the examination. The patient's immunization status should be elicited and appropriate tetanus treatment given.

Classification systems have been proposed, with the majority of superficial wounds repaired in the emergency department, while those with extensive or deep injuries managed in the operating room (19). The wounds should be copiously irrigated with normal saline to reduce the inoculum. The wound should be debrided of devitalized or necrotic tissue to promote healing and reduce the risk of infection.

Closure

Most head and neck bite wounds managed acutely can be closed primarily. This decision has been controversial, with the risk factors of delayed presentation, type of wound, and species inflicting the bite all modifying the debate. Current recommendations are to repair all bite wounds of the head and neck on presentation within 24 hours of the injury, assuming there are no signs of infection (19,45,47). For those wounds presenting outside of the 24-hour period, many authors feel that wound care and treatment with antibiotics before definitive closure will decrease infection rates. Wounds not amenable to primary repair may require more complex repairs using skin grafts and local flaps (19). For massive midface tissue loss, facial composite tissue allotransplantation has been reported. In these cases, frequently, dog bite injury is cited as the inciting event.

Antibiotics

Prophylactic treatment of bite injuries is controversial as little data exists to support their benefit in cat and dog bite wounds presenting within 6 hours (49). The authors support recommendations for antibiotic treatment in all deep injuries with muscle and cartilage involvement, children,

wounds older than 6 hours, cat bites, human bites, and individuals with immunosuppressive comorbidities (19,50). Stierman et al. (47) recommends 48 hours of intravenous prophylactic antibiotic therapy prior to closure for human bites to the ear, given the significantly increased risk of infection noted at this particular site.

Empiric oral prophylaxis for cat, dog, and human bites can be covered with amoxicillin and clavulanate 875 mg/125 mg twice daily or the combination of doxycycline with metronidazole in penicillin-allergic patients. Alternative regimens include clindamycin plus ciprofloxacin, whereas trimethoprim-sulfamethoxazole is appropriate for children. Azithromycin is also acceptable for use in penicillin-allergic children and pregnant women (19).

Bite wounds found to be infected at delayed presentation merit intravenous antibiotic treatment. Recommended first-line agents are ampicillin and sulbactam, piperacillin with tazobactam, or clindamycin in penicillin-allergic patients. The parenteral course is given for a minimum of 48 hours followed by oral equivalents totaling 10 to 14 days of treatment (19).

Burns

The head and neck region accounts for only 9% of the total body surface area when calculating involvement in burns. However, significant facial burns require specialized trauma protocols for airway establishment and fluid resuscitation, preferably in the setting of a certified burn center. Considerations for tracheotomy are delayed due to increased risk of infection.

The depth of burns is a critical factor in making treatment decisions. Superficial burns are isolated to the epidermal layer and may be managed with saline irrigation and strict wound care using topical antibiotic ointments and specialized dressings, while avoiding systemic antibiotics because of the tendency to develop bacterial resistance. Superficial partial thickness burns may be treated similarly with resulting scars and contractures addressed secondarily. Deep partial-thickness and full-thickness burns vary in their treatment regimens amongst burn specialists. Many advocate for early excision and grafting using split-thickness skin grafts to the face, while conservative wound management is practiced by others (51). When planning skin grafts, the concepts of facial aesthetic units are used as a guide to optimize future contracture by grafting thick grafts over entire aesthetic units. Physical and occupational therapists play an essential role, helping avoid contracture through the use of range-of-motion exercises, pressure dressings, and splints.

Certain areas of the head and neck have unique considerations in treatment. The ear is quite often involved in head and neck burns given its prominence. The resulting burn is susceptible to suppurative chondritis, which should be managed with incision, drainage, and debridement along with local wound care. If there is evidence of cartilaginous exposure or damage then considerations for graft or flap coverage should be instituted. The authors favor local wound care with wet to dry dressing changes, allowing granulation formation, followed by STSG or FTSG.

Eyelids are involved in up to 27% of burn patients, and initial management should be directed at examination and protection of the globe (52). The globe is often spared due to protective mechanisms such as the blink reflex and instinctive protective movements of the arm to cover the face (53). Management begins with lubrication of the globe and protective dressings. In the setting of lagophthalmos placement of a temporary tarsorrhaphy suture is recommended (26,54). If both eyes are involved requiring suturing the lids closed, the patient should be sedated for comfort. Definitive treatment for major full-thickness burns will require early intervention with the use of split-thickness and full-thickness skin grafting (26).

Lip and perioral injuries from burns sometimes are secondary to electrical injuries from children biting electrical cords. Early eschar removal is not advocated, with many delaying surgical treatment to allow demarcation of the involved area. Nonsurgical conservative management after epithelialization has gained favor, using oral appliances and splints to reduce microstomia even in the setting of circumferential burns (4). Scar revision or contracture release can be performed secondarily with a variety of reconstructive techniques available.

Frostbite

Cold injury to the head and neck region most often involves the ears, nose, and cheek due to reflexive vasoconstriction in the setting of cold exposure. This directs blood away from these tissues allowing local temperature drops in the skin and eventual tissue freezing. Ice crystals may form on the skin surface drawing intracellular fluid from out of the cells and leading to irreversible injury. Hypoxia ensues followed by ischemia with thrombosis, dermal necrosis, and acidosis with cell death (5,55). Initial treatment is conservative and is directed to rapid rewarming through use of heated compresses or immersing the body part in a warm bath maintained at 100°F to 108°F. Although once considered optimal treatment, slow rewarming has been shown to lead to further tissue damage (55). It is critical to provide appropriate analgesia as the rewarming process is extremely painful. Antibiotics may be indicated as well as tetanus prophylaxis. Sufficient time should be allowed for demarcation before surgical intervention is recommended.

PEDIATRIC SOFT TISSUE INJURY

The same tenants of soft tissue injury evaluation and management should be followed in the pediatric age group as is recommended in the adult population. With anxious and uncooperative children, judicious use of sedation or general anesthesia may be needed for wound evaluation and repair. In hopes of avoiding postoperative struggle and fear during suture removal, the preferred choice of sutures used in most

repairs is absorbable skin sutures or closure with subcuticular sutures. In the appropriate setting, wound closure may be performed with cyanoacrylate glue (Dermabond, Ethicon Inc., Somerville, NJ). If the mechanism of injury does not fit the wound pattern or if suspicious behavior is recognized, the surgeon should consider abuse as a potential cause.

HIGHLIGHTS

- The evaluation begins with stabilization following the ABCDE's of trauma management.
- Liberal use of irrigation and gentle tissue handling optimize tissue healing minimizing the risk of tissue loss and infection.
- Local wound care and secondary healing should be considered in patients with grossly contaminated wounds, those with delayed presentation, and patients with extensive skin and soft tissue loss.
- Delayed closure is appropriate for grossly contaminated wounds, selected animal bites, infected wounds, and when presentation is greater than 24 hours from injury.
- Tetanus vaccination history is of critical importance in any trauma patient.
- Once the sutures are removed extreme care must be taken to avoid sun exposure, and the use of broad spectrum UV-A and UV-B sun block with a SPF greater than 45 should be recommended for a minimum of 6 months to 1 year to prevent scar hyperpigmentation.
- When performing repair of full-thickness lacerations of the eyelid margin, it is critical to address all layers and the use of the three suture technique for the lid margin alignment.
- Upper eyelid injuries with herniation of fat and ptosis are concerning for injury to the levator muscle or aponeurosis.
- Any eyelid injury, which involves the punctum or the tissue medial to the punctum likely involves the canalicular system. Repair involves cannulation and stenting of the lacrimal drainage system.
- The parotid duct and buccal branch of the facial nerve lie in a vulnerable location as they cross the masseter muscle, and both must be considered in soft tissue trauma of the cheek and parotid.
- Accumulation of blood in the subperichondrial space or within the cartilaginous fragments can lead to auricular hematoma, which can be managed with simple needle aspiration for focal collections versus incision, drainage, and a bolster for larger ones.
- The main tenant of lip laceration repair is layered closure of the vermilion, skin, muscle, and mucosa.
- Dog bites makeup the majority of animal bites (80% to 90%), with cats as the second most common (5% to 15%). Human bites account for 3% to 23% of cases.
- Human bite injuries can be associated with viral transmission of hepatitis B and C, herpes simplex virus, and HIV.
- For severe facial burns, many advocate early excision and grafting using split-thickness skin grafts.
- With frostbite injuries, the initial treatment is conservative and revolves around rapid rewarming through use of heated compresses or immersing the body part in a warm bath maintained at 100°F to 108°F.

Penetrating Face and Neck Trauma

76

Michael G. Stewart

Head and neck surgeons are often called upon to manage penetrating trauma to the face and neck. Knowledge of ballistics, injury patterns, and pertinent anatomy are all essential to the assessment and management of these potentially serious injuries.

The energy imparted into tissue by a penetrating projectile is determined by its kinetic energy (KE): KE = ½ MV^2, where M = mass and V = velocity. Since the velocity term is squared in the equation, high-velocity projectiles can potentially impart significantly larger amounts of energy into the tissue impacted. In other words, a projectile with twice the velocity will have four times the KE of a lower-velocity projectile. However, the actual degree of wounding will also depend on the energy transfer from the projectile into the tissue (1). Typically, firearms are divided into two groups by their muzzle velocity: low velocity (less than 1,000 ft/s) and high velocity (more than 1,000 ft/s) (2). Most handguns are low-velocity weapons, with muzzle velocities between 300 and 800 ft/s. A typical shotgun has a muzzle velocity of 1,200 ft/s, and a 30-30 rifle has a muzzle velocity of 2,200 ft/s.

Gunshot wounds cause tissue injury by two main mechanisms: direct tissue injury and temporary cavitation. In the past, there was some consideration about distant injury from the transmission of shock waves; however, this theory is controversial and has been discounted by many (3). Cavitation refers to the creation of a pulsating temporary cavity surrounding the actual bullet path, as illustrated in Figure 76.1. This temporary cavity results in tissue damage and tissue loss adjacent to the missile path. This is an important concept for the treating physician to understand: anatomic structures may be significantly damaged by a gunshot wound without being actually penetrated by the projectile. Because of their high KE, high-velocity weapon injuries tend to have greater cavitation and transmission effects than low-velocity injuries. Clinically, low-velocity injuries are usually characterized by tissue *damage*, whereas high-velocity injuries are typically characterized by tissue *loss*. This can be an oversimplification; for example, a high-velocity, high-energy projectile may pass through tissue and exit with a significant amount of energy remaining. So, high velocity does not always equal high-energy transfer and tissue damage.

In addition, bullets or pellets in flight have several components to their rotation, as illustrated in Figure 76.2. These rotational characteristics increase the potential that a bullet may take an erratic course after impact, and also may increase the amount of direct tissue injury (1,3). Further, projectiles may shatter on tissue impact, resulting in secondary projectiles with the potential for additional injury. Similarly, impacted bone may also shatter, and secondary bone fragments may cause further tissue damage.

GENERAL TRAUMA PRINCIPLES

The basic principles of trauma management apply to all patients with penetrating face and neck trauma. These trauma principles may be remembered using the mnemonic "ABCDE." "A" denotes assessment of *airway* and *cervical spine*, "B" stands for assessment of *breathing*, "C" refers to assessment of *circulation*, "D" denotes assessment of *disability and neurologic status*, and "E" stands for *exposure* and overall *evaluation* of the patient for other injuries. The overall prevalence of cervical spine fracture in patients with isolated facial trauma is 5% to 8% (increasing to as much as 11% when two or more fractures were present) (4), but all patients should be considered to have a cervical spine injury until proven otherwise.

In the emergency center, in addition to cervical spine x-rays, all patients with penetrating face trauma should have an AP and lateral skull and face x-ray. These films can identify remaining bullets, pellets, bullet fragments, and bony fragments, and may help define the path of the projectile. In stab wounds where the weapon is still present,

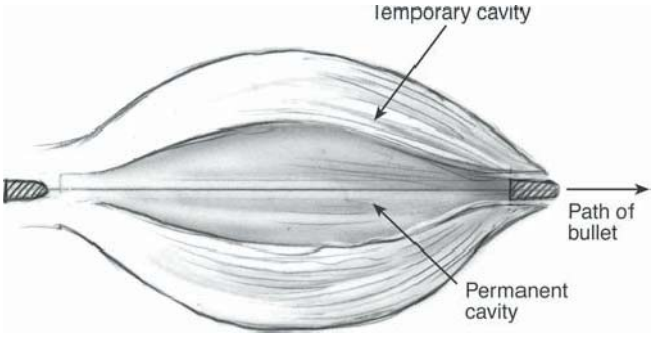

Figure 76.1 Cavitation effects of a bullet wound to soft tissue.

the depth of penetration may be identified. Further, these roentgenograms may reveal the presence of subcutaneous air or tracheal deviation.

Evaluation of the airway should be the first priority in the emergency center for all patients with penetrating face or neck trauma. The techniques of airway establishment are discussed in detail Chapters 63 and 64 of this textbook, but most patients can be carefully intubated transorally; if a cervical spine injury is suspected, the patient may be intubated while continuous in-line neck stabilization is applied. If the airway is unstable, and there is significant bleeding or edema in the oral cavity or pharynx, the patient should undergo cricothyroidotomy or urgent tracheotomy in the emergency center. Blind nasotracheal intubation should be avoided, although in the stable patient a fiberoptic-guided transnasal approach may be appropriate. In penetrating injuries to the neck with obvious tracheal injury (e.g., sucking wound, significant subcutaneous emphysema), the trachea may be carefully intubated through the entry wound itself using an armored/reinforced endotracheal tube.

Once the airway has been stabilized, the remainder of the examination may be completed, including a careful assessment of entry and exit wounds. When possible, information on the number of stab or gunshot wounds, the type of weapon, distance from assailant, etc., may be helpful in wound assessment. In patients with a stable airway, flexible fiberoptic laryngoscopy is a very helpful part of the evaluation, and helps assess the presence and extent of laryngopharyngeal injury. The physician should be aware that projectiles and bones may fragment or shatter, and projectiles may ricochet and change directions through the tissue—both of which may lead to secondary injuries. Probing entry and exit wounds or removing blood clots in the emergency center should be avoided, because this may precipitate significant bleeding. In addition, all patients with penetrating face or neck trauma should be considered for tetanus prophylaxis.

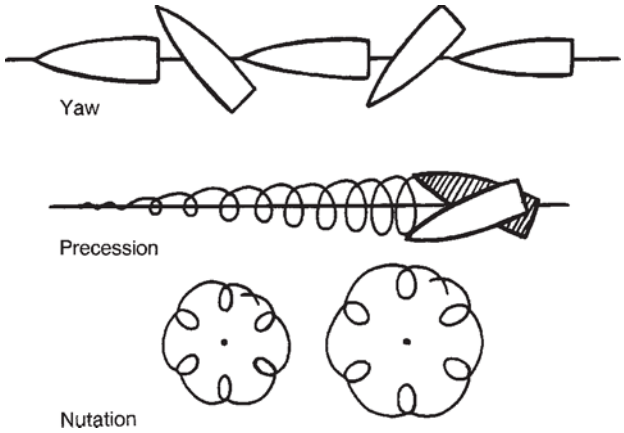

Figure 76.2 The rotational ballistics of a missile, demonstrating yaw, precession, and nutation.

PENETRATING FACIAL INJURIES

Although much attention has been focused on treatment algorithms for patients with penetrating trauma to the neck, chest, and abdomen, there is less written about penetrating injuries to the face. The first attempt to create a staging system for penetrating facial trauma was made by Gant and Epstein in 1979 (5) and later demonstrated pictorially by Gussack and Jurkovich (6). The Gant and Epstein system divided the face into entry zones I, II, and III, which was potentially confusing since neck entry zones used the same nomenclature. Further, zone I was superior to the supraorbital rims—which actually could be considered a penetrating intracranial (rather than facial) injury. The Gant and Epstein system was modified by Dolin et al. (7) into entry zones A, B, and C, but the demarcation points between zones were unclear, and two zones (A and B) actually had similar patterns of injury. Subsequently, Chen et al. (8) attempted to simplify facial zoning by designating two entry zones, "midface" and "mandible" (Fig. 76.3).

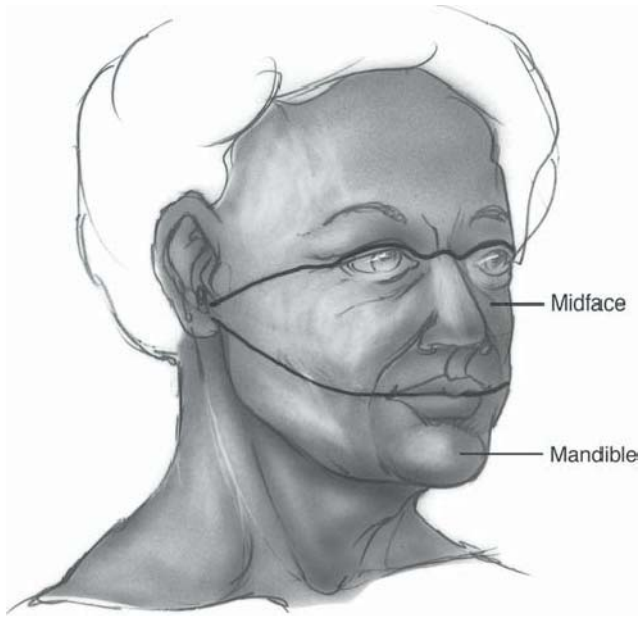

Figure 76.3 Midface and mandible zones for penetrating injuries to the face. Reprinted from Chen AY, et al. Penetrating injuries of the face. *Otolaryngol Head Neck Surg* 1996;115:464–470, with permission. Copyright 1996 by C.V. Mosby Year Book, Inc.

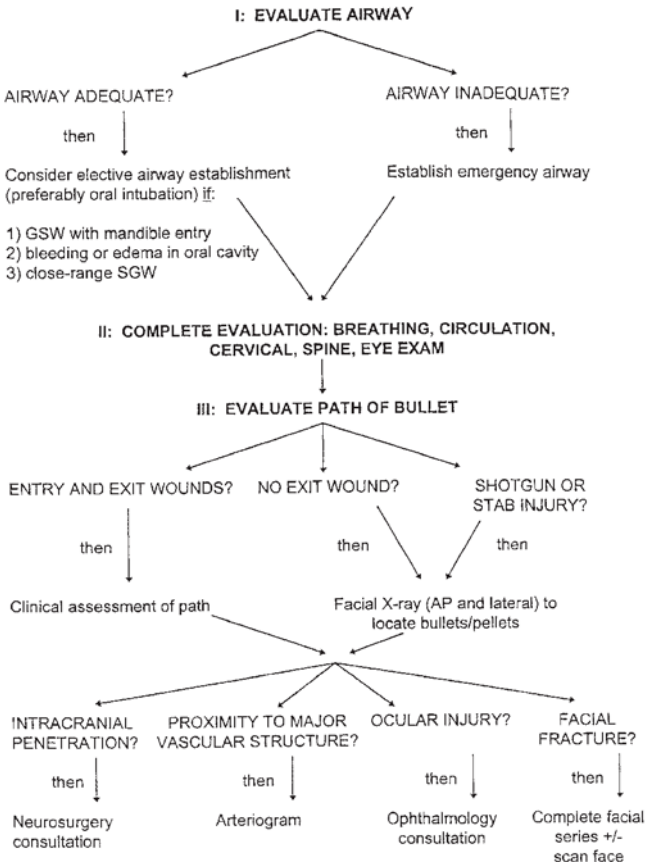

Figure 76.4 Algorithm for the initial management of patients with penetrating injuries to the face. Reprinted from Chen AY, et al. Penetrating injuries of the face. *Otolaryngol Head Neck Surg* 1996;115:464–470, with permission. Copyright 1996 by C.V. Mosby Year Book, Inc.

Injury patterns to these zones are distinct, and the system is easy to remember. An algorithm for the care of patients with penetrating facial trauma is depicted in Figure 76.4.

Shotgun Injuries

It is important to remember that shotguns have fairly high muzzle velocity, and close-range shotgun injuries may impart significant KE to facial tissue. Recognizing that the distance from weapon to victim was a key point in shotgun injuries, an early classification system classified shotgun injuries into three groups: long-range injuries (type I—more than 7 yards distance between weapon and victim) were characterized by subcutaneous or deep fascia injuries only, medium-range injuries (type II—3 to 7 yards distance) were characterized by injuries to structures deep to the deep fascia, and close-range injuries (type III—under 3 yards distance) typically created massive tissue destruction. Currently, trauma surgeons usually divide shotgun wounds into only two groups: close range and long range (9). The concept is the same: close-range injuries have very high kinetic injury and behave similarly to high-velocity rifle injuries. In addition, in close-range shotgun injuries, the "wadding" material from the shotgun shell may become imbedded into the soft tissue, and must be thoroughly removed to avoid subsequent problems with infection.

In one series (8), all patients with shotgun wounds to the face invariably had pellet penetration of both midface and mandible entry zones, so the zoning system was not helpful in predicting injury pattern. Therefore, shotgun wounds should probably be considered as a separate group. This high prevalence of ocular injury has been noted in other series as well (9,10). Shotgun wounds to the face also have a relatively high prevalence of globe injury, so careful ophthalmologic assessment is important. Shotgun wounds to the face may also cause facial fracture or vascular injury, or rarely may achieve intracranial penetration.

Stab Wounds

Stab wounds to the face may result in globe injury, vascular injury, and even intracranial penetration. If the weapon is still in place, AP and lateral skull x-rays can help predict the depth of penetration and direct further evaluation. Many authors have noted that in cases where the knife or weapon is still in place, it is important to *not* remove or dislodge it, since it may be providing tamponade of injured vascular structures. Rather, the patient should be taken for angiography with the protruding weapon in place. If major vascular injury is identified, intravascular balloons may be placed by the interventional radiologist (or proximal vessels may be isolated by the surgeon), and the weapon may then be removed under controlled circumstances in the operating room (11).

Gunshot Wounds

The midface/mandible zoning system is particularly applicable for gunshot injuries to the face, since the two entry zones have distinct patterns of injury. Gunshot wounds to the midface have a high prevalence of vascular injury, globe injury, intracranial penetration, and facial fracture requiring open reduction and internal fixation (8,10,12).

The indications for vascular evaluation in penetrating wounds to the face can be remembered as the two "P"s:

1. *Proximity* to a major vascular structure
2. *Penetration* posterior to the mandibular angle plane (MAP).

If the path of a penetrating projectile traverses near a major vascular structure, vascular evaluation is indicated. This may be difficult to assess because the path of a projectile after tissue penetration is not always predictable, and due to cavitation, the bullet may be somewhat distant from the vessel and still cause a significant injury. A useful anatomic landmark is the MAP as described by Gussack and Jurkovich (6). The MAP is an imaginary

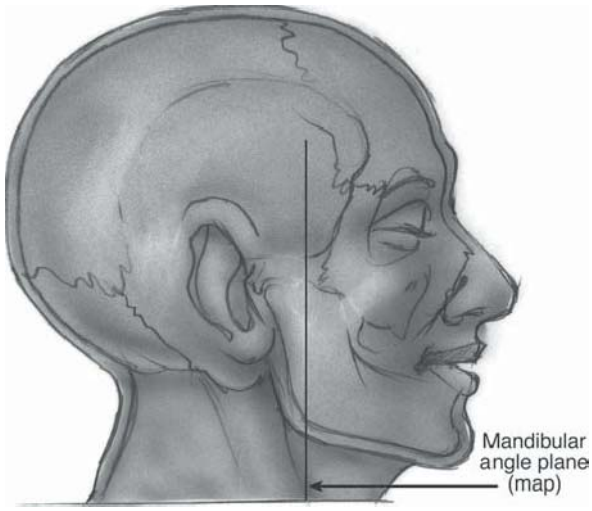

Figure 76.5 Lateral view of the face demonstrating the Mandibular Angle Plane (MAP).

vertical coronal plane at the level of the angle of the mandible (Fig. 76.5) and penetration of a projectile or weapon posterior to this plane is an indication for vascular evaluation. The appropriate radiologic test depends on the situation, and this point is discussed later in the chapter.

Gunshot injuries to the mandible entry zone often require emergency establishment of an airway because of bleeding, edema, or hematoma formation in the oral cavity or pharynx (8,12). Although these patients may appear initially to have a stable airway, they can quickly decompensate and require an emergency airway. Although more common with mandible entry, patients with midface gunshot wounds may also require an emergency airway (8,10,12). Therefore, a high index of suspicion and early elective airway establishment are important in patients with gunshot wounds to the face.

The computed tomography (CT) scan has significantly changed the management of penetrating facial injuries. Although airway establishment, hemodynamic stabilization, treatment of other serious injuries, and vascular evaluation should take precedence, axial and coronal CT scans of the face often significantly aid the head and neck surgeon in the assessment of damage, and improve treatment planning. In addition, CT scans clearly demonstrate the extent and severity of bony fractures.

Management of Specific Injuries

Facial Nerve Injury

Patients with penetrating facial trauma and immediate paralysis of one or more branches of the facial nerve are likely to have transection of the nerve. If their medical condition permits, these patients should undergo local exploration with primary nerve repair or nerve grafting, if the wound is lateral to the lateral canthus. Nerve injuries medial to the lateral canthus are typically not explored because nerve regeneration is usually adequate. Branches to the forehead and ramus mandibularis should be repaired because cross-innervation to these areas is poor; branches to the midface *may* recover function through cross-innervation even if completely transected (12,13). Severed distal branches retain electrical excitability for about 48 hours, and a nerve stimulator may be used intraoperatively. However, it is common that patients have other medical issues which delay facial nerve exploration and repair, and that is acceptable since the results after cable graft are not dependent on time of repair (12). The preferred neurorrhaphy technique is to trim back the perineurium away from the anastomosis and perform epineurial repair with 9-0 or 10-0 monofilament suture (13). Facial nerve injuries which progress from partial to total paralysis following injury, or paralysis which develops several hours after injury, are usually secondary to edema and may be treated expectantly.

Parotid Duct Injury

Wounds to the cheek below the zygomatic arch, which injure the buccal branch of the facial nerve are also likely to injure the parotid duct. If parotid duct injury is suspected (e.g., clear saliva draining from a penetrating cheek wound, or sialocele formation), the wound should be explored and the duct primarily repaired over a stent.

Facial Bone Fracture

These injuries are discussed in more detail in other chapters. Not all facial fractures will require open reduction internal fixation, but many will (10). Some fractures will require debridement only, or can be managed with closed reduction.

Complications

Even without intracranial penetration or major vascular injury, penetrating wounds to the face have the potential for early and late complications in 15% to 35% of patients. Potential complications are listed in Table 76.1. While some are directly attributable to the injury—such as blindness or facial nerve injury—some complications are potentially preventable with early recognition and aggressive management. In particular, nasal obstruction and synechia, sinusitis, and choanal stenosis may be prevented with intranasal debridement, placement of nasal stents, and the techniques of functional endoscopic sinonasal surgery to restore adequate sinus drainage. In addition, diplopia and orbital or periorbital infections may be prevented with careful reconstruction of the orbital floor to restore orbital anatomy and isolate the maxillary sinus from the orbital contents. Further, trismus and malocclusion may be prevented with adequate maxillomandibular fixation, and early mobilization and stretching of the temporomandibular joint.

TABLE 76.1 COMPLICATIONS PENETRATING FACE AND NECK INJURIES

Facial injuries
- Blindness
- Visual loss
- Diplopia
- Facial nerve paralysis
- Cerebrospinal fluid leak
- Soft tissue loss
- Bony malunion
- Malocclusion
- Trismus
- Orbital/periorbital cellulitis
- Sinusitis
- Oral–antral fistula
- Nasal obstruction/stenosis
- Choanal stenosis

Neck injuries
- Airway obstruction
- Pharyngocutaneous fistula
- Neck abscess
- Mediastinitis
- Vocal cord paresis
- Cervical spine osteomyelitis

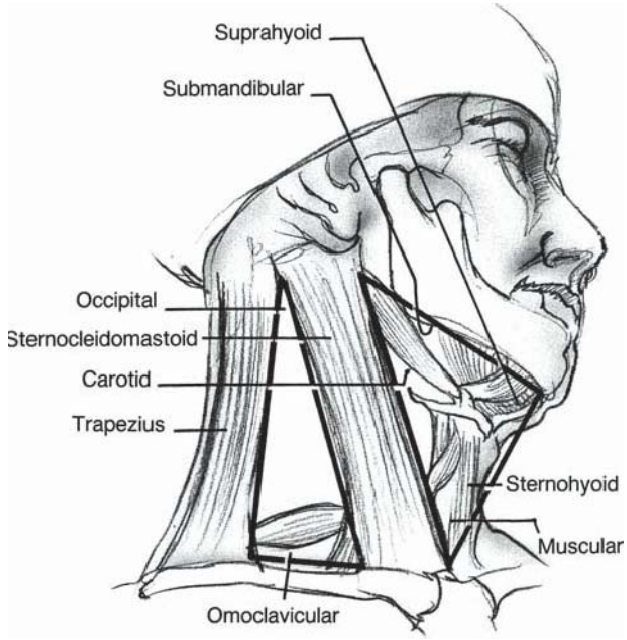

Figure 76.6 Anatomic triangles of the neck: the neck is divided into anterior and posterior triangles by the sternocleidomastoid muscle.

PENETRATING NECK INJURIES

The complex anatomy of the neck requires careful assessment of missile trajectory and site of entry. The neck can be divided into two triangles using the sternocleidomastoid muscle (Fig. 76.6). The anterior triangle contains most of the major anatomic structures of the neck: the larynx, trachea, pharynx, esophagus, and major vascular structures. The major structures of the posterior triangle are muscles, the spinal accessory nerve, and the spinal column. The platysma muscle lies just deep to the skin of the neck only in the anterior triangle. Wounds which penetrate the platysma have the potential for serious injury; wounds, which do not penetrate the platysma are superficial by definition, and do not require further evaluation.

The neck has been divided into three entry zones (Fig. 76.7). Zone I comprises the lower neck below the inferior border of the cricoid cartilage. Zone II consists of the neck between the angle of the mandible and the inferior border of the cricoid cartilage, and zone III comprises the neck superior to the angle of the mandible up to the skull base. Zone II is the largest zone and the most common site of entry in penetrating neck trauma (14,15). McConnell and Trunkey combined the results of 16 large series and found that the most commonly injured structures in the neck were the larynx and trachea (considered as

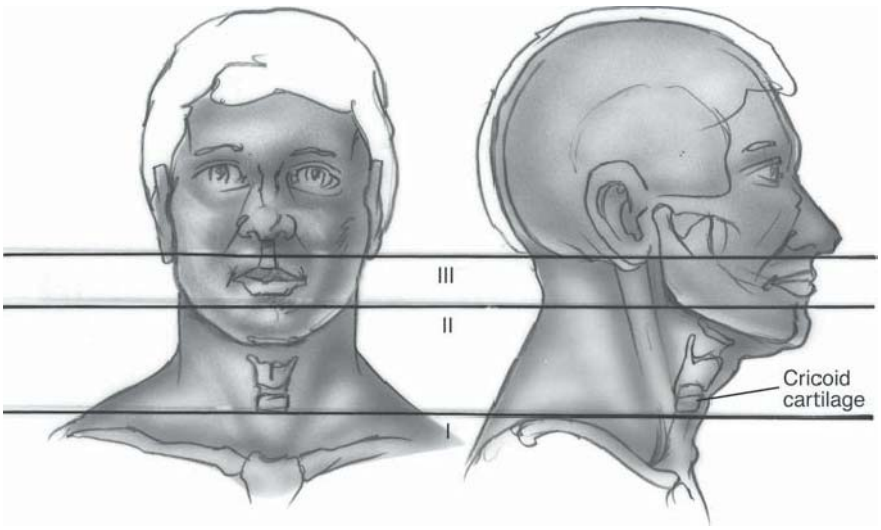

Figure 76.7 Horizontal entry zones of the neck for penetrating injuries to the neck. Modified from Jurkovich GJ. In: Moore EE, ed. *The neck.* Toronto: Becker, 1990:126.

TABLE 76.2 DIAGNOSIS PENETRATING NECK TRAUMA

Diagnosis	Signs and Symptoms	Tests
Vascular injury	Shock Hematoma Hemorrhage Pulse deficit Neurologic deficit Bruit or thrill in neck	Angiogram CT angiogram Doppler ultrasound Neck exploration
Laryngotracheal injury	Subcutaneous emphysema Airway obstruction Sucking wound Hemoptysis Dyspnea Stridor Hoarseness or dysphonia	Laryngotracheoscopy Neck exploration CT scan
Pharynx/esophagus injury	Subcutaneous emphysema Hematemesis Dysphagia or odynophagia	Contrast esophagogram Esophagoscopy Neck exploration

a group: 10% of patients), and the pharynx and esophagus (considered as a group: 10% of patients). The most common vascular structures injured were the internal jugular vein (9%), the internal and common carotid arteries (7%), the subclavian artery (2%) and the external carotid artery (2%). The vertebral artery was injured in only 1% of patients in the combined review.

The overall mortality rate for penetrating neck trauma at most major centers is 3% to 6% (14,16). The major cause of death in patients with penetrating neck trauma is exsanguinating hemorrhage from a vascular injury. Other causes include spinal cord injury, cerebral ischemia, airway obstruction, air embolism, and pulmonary embolism. Most series report at least some mortality from missed esophageal injuries, which usually manifest as sepsis.

A careful clinical exam is often an accurate predictor of the extent of injury. The clinical signs and symptoms of significant neck injury are listed in Table 76.2. Of course, patients with refractory shock, uncontrollable hemorrhage, or evolving neurologic deficit should undergo immediate neck exploration (Table 76.3). The surgeon should be prepared to control and repair major injuries to the carotid artery or jugular vein. Patients who are clinically stable but have signs or symptoms of injury to a major neck structure should undergo directed evaluation with subsequent repair of injured structures. The management of the *asymptomatic* patient with penetrating neck trauma is controversial, however.

Traditionally, all patients with penetrating neck wounds, which penetrated the platysma—whether symptomatic or not—underwent neck exploration. The rationale was that the sensitivity of neck exploration was high, and the morbidity of the surgery itself was low, whereas the morbidity of a missed injury was potentially fairly high. When mandatory neck exploration was performed, negative exploration rates of 30% to 50% could be expected. In the 1980s and 1990s as imaging and flexible endoscopic technology advanced, trauma surgeons began using serial examinations and evaluations in selected neck injuries—based on zone and clinical presentation (16). In addition, many vascular injuries are now amenable to definitive endovascular treatment by the interventional radiologist. There is good evidence that directed examination with observation and serial examinations may be as effective as mandatory exploration in selected patients (16,17); these issues will be discussed further below. An example of a simplified protocol for penetrating neck trauma is depicted in Figure 76.8.

As in penetrating injuries to the face, the mechanism of injury is important for the treating physician to consider. Although the depth of penetration of stab wounds may be difficult to assess, stab wounds tend to injure only the tissue directly penetrated. Gunshot wounds, however, may cause significant tissue loss as well as damage to adjacent structures because of cavitation and the high energy of the projectile.

TABLE 76.3 EMERGENCIES PENETRATING FACE AND NECK INJURIES

Diagnosis	Emergency
Vascular injury	Hemorrhage Neurologic deterioration Airway compression
Larynx or tracheal injury	Airway obstruction Pneumomediastinum Pneumothorax

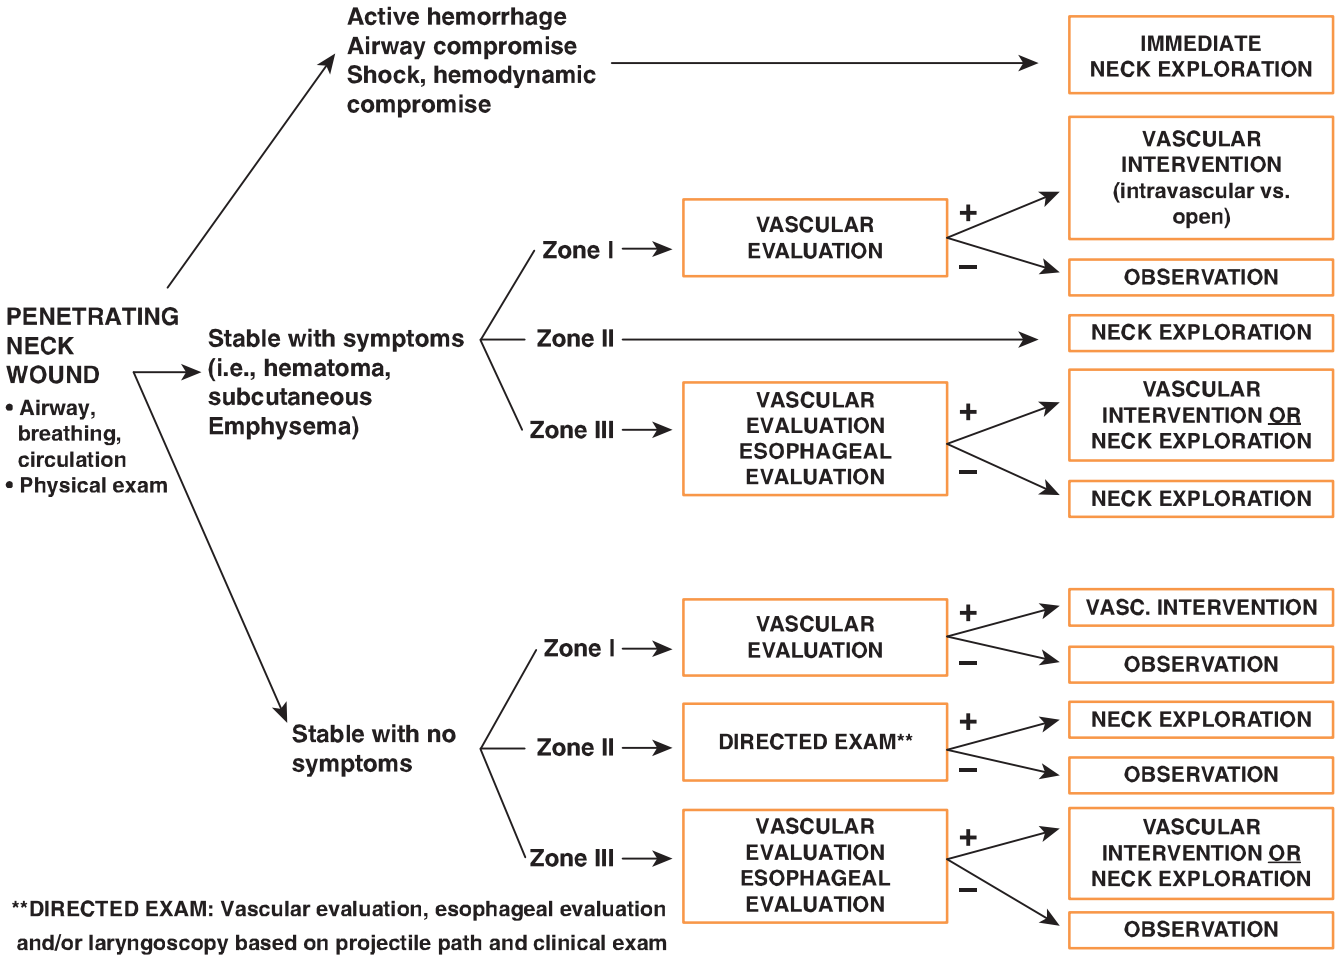

Figure 76.8 An example algorithm for the initial management of patients with penetrating injuries to the neck. Modified from Mansour MA, et al. Validating the selective management of penetrating neck wounds. *Am J Surg* 1991;162:517–521, Copyright 1991 by Excerpta Medica, Inc.

Zone I Injuries

Penetrating injuries which enter zone I of the neck are potentially lethal because of the potential for injury to the great vessels of the neck and mediastinum, as well as the cervical and thoracic esophagus. Most trauma centers advocate routine vascular evaluation of the aortic arch and great vessels, along with an esophageal evaluation—whether or not the patient is symptomatic, since up to one-third of patients with a clinically significant zone I injury may have no symptoms at presentation. Mandatory esophageal evaluation is also recommended because a missed zone I esophageal injury is potentially different from a missed zone II injury. An esophageal or pharyngeal injury in zone II will usually develop clinical signs or symptoms (such as subcutaneous emphysema) within a few hours, and overall morbidity and mortality may not be affected. A missed esophageal injury in zone I, however, may be clinically silent until mediastinitis and sepsis develop.

Opinions on the ideal diagnostic test for the esophagus and pharynx differ, and the options include endoscopy, contrast esophagram using barium or gastrografin, or CT scan. If a contrast esophagram is used, there is also a question about which contrast medium to use. Barium-based contrast is thicker, and if a penetrating injury is present, the barium is more likely to demonstrate it. However if barium leaks into the tissues of the neck, there is significant risk of infection. Gastrografin (meglumine detrizoate) is a thinner contrast material, and is less likely to promote infection if leaked into the neck, but many feel it is a poorer agent because smaller injuries can be missed. One potential solution is to first study with gastrografin. If there is a large leak, then the diagnosis is made. If there is no leak, then do a second study with barium—to ensure there is not even a small leak. A different option is to use "thin barium," or dilute barium as the initial evaluation.

Studies on the sensitivity and specificity of radiologic tests to detect pharyngeal or esophageal injury have reported as high as 90% to 100% (18,19). Similarly, flexible or rigid esophagoscopy both have high specificity and sensitivity (19), so the method can be chosen based on operator preference. Some have noted that in all cases of penetrating injury, at least *one* of the diagnostic tests—rigid or flexible

esophagoscopy, or barium swallow—demonstrated the injury (18). Therefore a combination of those tests should not miss an injury.

Another option for assessment is the CT scan (20,21). CT scans have been found to be very helpful in determining the path of the projectile (using the tract of air bubbles, damaged tissue, or projectile particles), which then helped guide decision making for further evaluation and treatment. In fact, in one study additional radiologic imaging and surgery were avoided in some patients (21).

Zone II Injuries

As previously discussed, patients with penetrating zone II injuries who are symptomatic should undergo neck exploration. Asymptomatic patients with penetrating zone II injuries may be treated with either mandatory exploration or directed evaluation and serial examinations (16,17,19). In earlier decades, mandatory neck exploration was the standard of care, and many negative explorations were acceptable. However, several prospective studies have shown that careful observation (with radiologic and endoscopic evaluation) of the asymptomatic zone II injury is an effective protocol. Patients usually underwent some additional evaluation, such as CT scan, vascular evaluation, or flexible endoscopy, and also serial examinations. If patients developed findings of injury, such as subcutaneous emphysema, they were then taken for surgical exploration and repair. Studies have shown that the observed patients did very well as a group, with virtually no missed injuries, morbidity, or mortality, and perhaps a shorter average length of stay than patients who underwent exploration. In another study, physical examination alone—using defined criteria for a positive examination—was shown to have high sensitivity (93%) and negative predictive value (97%) when used for the assessment of potential vascular injury (22).

However, these protocols require frequent availability of additional testing, and serial examinations. So in some centers, surgical exploration might be a more appropriate plan for asymptomatic penetrating zone II injuries. In addition, some surgeons still prefer mandatory exploration over observation and selective exploration, citing the prevalence of previously undetected injuries when mandatory exploration is performed. Others note, however, that many of those injuries (e.g., small vascular injuries) might never have caused a problem if simply observed.

In summary, asymptomatic patients with penetrating zone II injuries may be treated with either mandatory neck exploration, or directed evaluation and serial examinations. However, a treatment protocol utilizing observation with serial examinations requires adequate physician manpower as well as a 24-hour facility prepared for emergency testing and surgery at any time. Early neck exploration with prompt discharge home for negative explorations is an efficient and time-tested method of managing penetrating zone II injuries, and in some settings, may be preferred over multiple tests and observation.

Zone III Injuries

Penetrating injuries to zone III have the potential for injury to major blood vessels and the cranial nerves near the skull base. Some patients with arterial injuries may be asymptomatic at presentation, and surgical exposure and control of bleeding in this location may be quite difficult. In addition, many vascular injuries are amenable to definitive treatment by an interventional radiologist. Therefore, the injury can be potentially treated in the same setting as the diagnostic angiogram. Although vertebral artery injury appears to be relatively rare, this may be the result of infrequent use of four-vessel angiography in many series. Therefore, the benefit of routine four-vessel angiography is not clear. Certainly, however, if the bullet path is near the vertebral column, the vertebral arteries should be imaged.

Vascular Evaluation in the Head and Neck

As the speed of scanners and resolution of images have improved, the recommended protocols for vascular evaluation have also evolved. The American College of Radiology recommendations note that formal catheter angiography, CT angiography, MR angiography, and color Doppler ultrasound could all have a role in vascular evaluation of the head and neck (23). However, CT angiography and catheter angiography are the most practical, with the highest level of recommendation (23). The resolution of multidetector CT angiography is excellent, and the evaluation is quite sensitive, even to small intimal injuries—sensitivity is 90% to 100%, specificity is 94% to 100%, and positive and negative predictive values are 93% to 100% and 98% to 100%, respectively (24). Furthermore, the speed of modern scanners means that the scan can be quickly completed and processed. In addition, the soft tissue CT data is also very useful in evaluation of the penetrating neck injury. So CT angiography can yield very valuable information. However, obviously, CT angiography does not allow intervention if an injury is discovered. Catheter angiography does allow for both diagnostic assessment and endovascular intervention if needed. However, catheter angiography is more invasive, has the potential for increased complications at the catheterization site and intracranially, and it requires the presence of an interventional radiologist. And, in many cases of penetrating trauma, no intervention will be required. So, the selection between high-resolution CT angiography and catheter angiography could be based on clinical suspicion of vascular injury, with high-probability injuries going directly to catheter angiography—as one potential strategy. However, as discussed earlier, many patients with vascular injury are asymptomatic, so making this clinical distinction could be difficult. Finally, color Doppler ultrasound has excellent

resolution and sensitivity, but it is highly operator dependent, cannot be automated, and cannot be reliably used in certain situations when there is bone or air in the intervening space. And of course, no intervention can be performed. So, under certain situations it can be quite useful, but it is not a widely used modality.

Management of Specific Injuries

Vascular Injuries

As noted earlier, blood vessels are commonly injured in penetrating neck trauma. Whenever possible, primary repair of the injured vessel is ideal. The value of arterial repair in the face of focal neurologic deficit or coma is controversial, but most vascular surgeons tend to favor revascularization in cases of *traumatic* vascular injury (15). In any event, the assistance of an experienced vascular surgeon is strongly recommended in these cases.

Laryngotracheal Injuries

The management of penetrating injuries to the larynx has been well described by Schaefer (25) and is covered in this textbook, in Chapter 77. If the thyroid or cricoid cartilage has been damaged and is unstable, open repair with internal fixation is recommended. If the cartilage is calcified, 1.0 or 1.3 mm bone plates and screws may be used; if the cartilage is not fully calcified, wires and bolsters can be used as described by Austin (26). If the endolaryngeal mucosa has been significantly disrupted, tracheotomy with midline thyrotomy and direct repair of mucosal injuries with small absorbable sutures is used. Endolaryngeal stents are seldom used in penetrating trauma because the structural framework of the larynx is usually intact (unlike in blunt trauma), although stents may be used if the anterior commissure has been injured.

Tracheal injuries are managed with either tracheotomy through the injury or direct closure. Stab wounds can typically be closed primarily in two layers: an inner layer of absorbable suture incorporating the mucosa (with the knots on the outside of the lumen) and an outer layer of permanent suture securing cartilage ring to cartilage ring in a submucosal plane. Patients are usually kept intubated for 2 to 3 days, then extubated under controlled circumstances. Gunshot wounds to the trachea may result in tissue loss, which may compromise the safety of primary closure since minimal tension at the suture line is a key component of successful tracheal repair. Once the wound edges have been debrided, superior or inferior tracheal release techniques may be necessary to achieve a tension-free closure.

Pharynx and Esophageal Injuries

Missed injuries to the pharynx and esophagus are a significant source of morbidity and mortality in penetrating neck trauma. All patients with clinical signs or symptoms of pharynx or esophagus injury (e.g., subcutaneous emphysema, hematemesis, hypopharyngeal blood, etc.) should undergo neck exploration. Intraoperative esophagoscopy may be helpful in identifying the location of pharyngeal or esophageal penetration, especially in stab injuries. In addition, instillation of saline, methylene blue, or air into the pharynx and esophagus can assist in injury location.

However, up to 50% of patients with pharyngeal and esophageal injury may be asymptomatic at presentation. In an asymptomatic patient, if injury is suspected based on missile trajectory, the combination of esophagoscopy and contrast esophagography is probably most sensitive at detecting injury.

Esophageal injuries should be closed directly; if not, the saliva leak is a significant cause of morbidity and mortality. In fact, delay in exploration and repair beyond 24 hours after injury has been associated with poorer outcome in many studies. In earlier literature, the cervical esophagus and hypopharynx have been grouped together and considered as a unit. However, there is evidence that hypopharyngeal injuries may not always require direct closure (27,28); this is similar to oropharynx injuries.

Penetrating injuries to the hypopharynx, which are superior to the level of the arytenoid cartilage may be treated somewhat differently than hypopharyngeal injuries inferior to the level of the arytenoids (27). Primary closure is not always necessary in penetrating injuries to the upper hypopharynx; patients may be treated with parenteral antibiotics, and kept without oral intake for 5 to 7 days. Injuries to the hypopharynx *inferior* to the level of the arytenoid cartilage (e.g., in the dependent portion of the hypopharynx, where saliva and secretions tend to pool) should be treated with exploration and primary watertight closure using absorbable suture with drainage of the adjacent neck space. The patient should be kept NPO while the repair heals—typically 5 to 7 days. Injuries to the cervical esophagus should be treated similar to those of the inferior hypopharynx, with watertight closure and drainage. External drainage and bypass procedures (e.g., cervical pharyngostomy) should generally be avoided, although with severe injuries and tissue loss, diversion procedures may play a role.

Complications

The complications of penetrating neck injuries are listed in Table 76.1. Most complications are directly attributable to the injury itself, but some are potentially preventable. The potentially preventable injuries (such as neck abscess, pharyngocutaneous fistula, etc.) are usually due to missed or delayed diagnoses, so the best way to avoid these complications is to be thorough and vigilant in the initial evaluation for injuries and the immediate follow-up period after treatment. Although less common than 50 years ago, the mortality of penetrating neck trauma remains 3% to 6%.

HIGHLIGHTS

- Patients with penetrating trauma to the face and neck should undergo systematic evaluation using the ATLS protocol ("ABCDE"). Airway establishment is the first priority, particularly in gunshot wounds to the mandible and midface zones.
- High-velocity gunshot wounds have high KE, and tend to cause tissue loss and secondary injuries.
- Close-range shotgun wounds have high KE, and may cause massive tissue destruction. Always remove the "wadding" material from soft tissues in close-range shotgun wounds.
- Shotgun wounds to the face have a high prevalence of globe injury. Gunshot wounds to the midface may cause injury to the globe, may injure major vascular structures, or may achieve intracranial penetration.
- The indications for arteriogram in penetrating facial wounds are (a) proximity to a major vascular structure or (b) penetration posterior to the MAP.
- Classification of penetrating neck wounds into entry zones I, II, and III helps to direct management. Injuries that penetrate the platysma have the potential to damage important neck structures. Most of the vital structures of the neck are in the anterior neck.
- Bleeding, expanding hematoma, shock, and evolving neurologic deficit suggest vascular injury.
- Subcutaneous emphysema, dyspnea, airway obstruction, hoarseness, or stridor suggest laryngotracheal injury.
- Subcutaneous emphysema and dysphagia suggest pharyngoesophageal injury, but up to 50% of patients will have no clinical signs of injury.
- Patients with symptoms of injury to important neck structures should undergo neck exploration, except stable patients with zone I or zone III injuries; preoperative vascular evaluation and esophageal evaluation may help direct the surgical approach, or may identify vascular lesions amenable to treatment by the interventional radiologist.

Laryngeal Trauma

77

J. Randall Jordan *Byron K. Norris* *Scott P. Stringer*

Laryngeal trauma is a relatively uncommon event requiring timely, proper management of injury to preserve the patient's life, airway, and voice (1). Each case of external laryngeal trauma presents a unique set of problems, but despite the diversity of injuries, specific management guidelines can be applied. Adhering to such an approach assists in attaining the best possible outcome after blunt or penetrating external laryngeal trauma. Severity of injury and delay in treatment correlate with poor outcome.

PATHOPHYSIOLOGY OF LARYNGEAL INJURIES

Blunt Trauma

Blunt trauma to the larynx is caused mainly by motor vehicle accidents including all-terrain vehicles, personal assaults, or sports injuries. Although the mandible and sternum normally protect the larynx, the neck can be hyperextended during the trauma, which allows the laryngeal skeleton to be crushed between the impinging object and the cervical vertebral column. With a moderate blow to the larynx, the momentum of the vocal folds causes a shearing effect between the vocalis muscle and the internal perichondrium. This results in injuries such as endolaryngeal mucosal tears, edema, or hematoma. More severe trauma produces fractures of the laryngeal cartilages and disruption of the laryngeal ligaments.

Subluxation or dislocation of the arytenoid cartilage can produce an immobile vocal fold. Unilateral injury to the recurrent laryngeal nerve often is associated with cricoarytenoid joint injuries owing to the proximity of the recurrent laryngeal nerve to the cricoid cartilage. Fractures of the cricoid cartilage can occur alone or with other injuries, especially after lower cervical trauma. As the only complete ring of the airway, structural integrity of the cricoid cartilage is essential in airway maintenance.

The so-called clothesline injury that occurs in association with blunt laryngeal trauma deserves special attention because of its severity. This injury typically occurs when the neck of an individual (typically an adolescent or young adult) riding a motorcycle, all-terrain vehicle, or snowmobile strikes a stationary object such as a wire fence or tree limb. The transfer of such a large amount of force confined to a relatively small area of the neck crushes the laryngeal cartilages and commonly causes cricotracheal separation. The airway is held together precariously by the intervening mucous membrane and pretracheal fascial sleeves. Bilateral injury to the recurrent laryngeal nerve often is associated with cricotracheal separation.

Associated structures also can be injured during blunt cervical trauma. Fractures of the hyoid bone and associated epiglottic injuries can cause airway obstruction. The greater or lesser cornu of the thyroid cartilage can lacerate the pharyngeal mucosa as it is pressed against the cervical vertebrae. Sex and age differences among adults have been hypothesized as leading to different types of injuries after blunt trauma. Women are considered more likely to incur supraglottic injuries than are men because they have long, thin necks. Elderly persons have been described as being at higher risk of sustaining comminuted laryngeal fractures than are younger adults because older persons have increased ossification of the laryngeal cartilage. Neither of these hypotheses has been verified with clinical observation (2).

Blunt trauma tends to affect the larynx of a child differently from that of an adult. The larynx in children is situated higher in the neck and is better protected by the mandible than it is in adults (3). While laryngeal fractures are less common in children, the incidence is increasing paralleling the incidence of motor vehicle collisions (4). Pediatric injuries tend to be less severe than adults due to the elasticity of the pediatric cartilaginous skeleton; however, the lack of extensive fibrous tissue support and the

relatively loose attachments of the mucous membranes increase the likelihood of soft tissue damage in children, and may account for the poorer prognosis of those with more severe injuries (5,6). Additionally, relatively innocuous trauma may precipitate airway distress secondary to the small laryngotracheal diameter in children (6). Several cases of membranous rupture of the pediatric trachea due to seemingly minor blunt cervical injury have also been reported (7).

Manual strangulation or hanging-type injuries produce different patterns of laryngeal injury because the applied force is fairly static and of low velocity. This can cause multiple cartilaginous fractures without immediate mucosal laceration, submucosal hematoma, or marked displacement of the fractures (8).

Penetrating Trauma

Knife and gunshot wounds are primarily responsible for penetrating trauma. Injuries vary from minor lacerations to severe disruption of the cartilage, mucosa, soft tissue, nerves, and adjacent structures. Gunshot wounds are more likely than knife wounds to be associated with severe tissue damage, and high-velocity projectiles cause greater tissue destruction and wound contamination than low-velocity projectiles (9). Knife wounds cause less peripheral soft tissue damage than gunshot wounds and are cleaner, but it is difficult to determine depth of penetration. Injuries to deep structures, such as the thoracic duct, cervical nerves, great vessels, and viscera, can occur well away from the entrance wound. Death from penetrating trauma may be caused by complete disruption of the larynx, massive soft tissue edema, or associated neurovascular injuries. Most injuries to civilians from penetrating trauma tend to be limited to the path of the missile because they are caused by lower-velocity bullets or stabbing (9).

DIAGNOSIS AND EVALUATION

History

Any patient with anterior neck trauma is considered to have an upper airway injury. The classic symptoms of laryngeal trauma include hoarseness, laryngeal pain, dyspnea, and dysphagia (Table 77.1). It is surprising that no single symptom seems to correlate well with the severity of injury (2). When the laryngeal lumen is severely compromised, aphonia and apnea occur, signifying the need for immediate establishment of an alternative airway.

Physical Examination

After trauma, a thorough physical examination of the neck is needed to identify associated neurovascular injuries. Cervical spinal injuries must be ruled out for all patients with neck trauma. Active bleeding, expanding hematoma, bruits, and the loss of pulses are signs of vascular injury. The usual signs of laryngeal trauma include stridor, hemoptysis, subcutaneous emphysema, and tenderness or deformity of the laryngeal skeleton. The presence of tenderness to palpation helps to differentiate an acute laryngeal fracture from an old deformity. The type of stridor can suggest the location of the lesion. Inspiratory stridor typically indicates partial supraglottic airway obstruction, as might occur from edema, hematoma, foreign body, soft tissue injury, or cartilaginous fractures. Expiratory stridor may portend a lower airway abnormality caused by a tracheal injury. Combined inspiratory and expiratory stridor suggests partial obstruction at the level of the glottis.

Contrast esophagography

Cervical subcutaneous emphysema is associated with loss of the integrity of the upper aerodigestive tract and is thought to occur through shear forces of the laryngeal cartilage against the vertebral bodies (10). The amount of air can range from slight soft tissue emphysema to massive pneumomediastinum. Associated soft tissue derangements of the larynx can produce a ball-valve effect that forces massive amounts of air into the neck and chest as well. Further compromise of the airway can be caused by tracheal displacement or tension pneumothorax. Care should be taken to avoid excessive mask ventilation in patients with laryngeal trauma as this can worsen subcutaneous emphysema and potentially cause a pneumothorax (11).

Direct fiberoptic laryngoscopy is an integral component for evaluation of the patient with blunt laryngeal trauma. The larynx is examined for mobility of the vocal folds, position of the arytenoid cartilages, hematoma, lacerations, and airway patency. Rigid esophagoscopy is the best way to examine the hypopharynx and esophagus

when indicated, but should only be carried out after cervical spine injury has been excluded (12). In patients with minor laryngeal injuries, strobovideolaryngoscopy should be performed to better assess subtle intricacies of vocal fold function (13).

Radiologic Evaluation

Computed tomography (CT) (Fig. 77.1A and B) has clearly become the most useful radiologic examination for evaluating laryngeal trauma (12,14–16). CT is most useful when the results influence treatment, as opposed to documentation of an obvious injury when management will not be changed. Two groups of patients may not benefit from CT examination: (a) Patients with minimal anterior neck trauma and normal physical findings and (b) Patients with obvious fractures, large endolaryngeal lacerations, or severe penetrating injuries. While the latter patients will most often need tracheotomy, direct laryngoscopy, and open exploration, many authors now agree that CT can be of benefit even in this group in planning structural repair (15). The practical side of this is that most patients in this category will have been intubated and had a CT of the neck already performed by the time one is consulted. All patients in the intermediate group should undergo CT to assess the extent of laryngeal injury. When used, CT helps to confirm indirect or flexible laryngoscopic findings, to detect cartilage fractures that are not clinically apparent, to

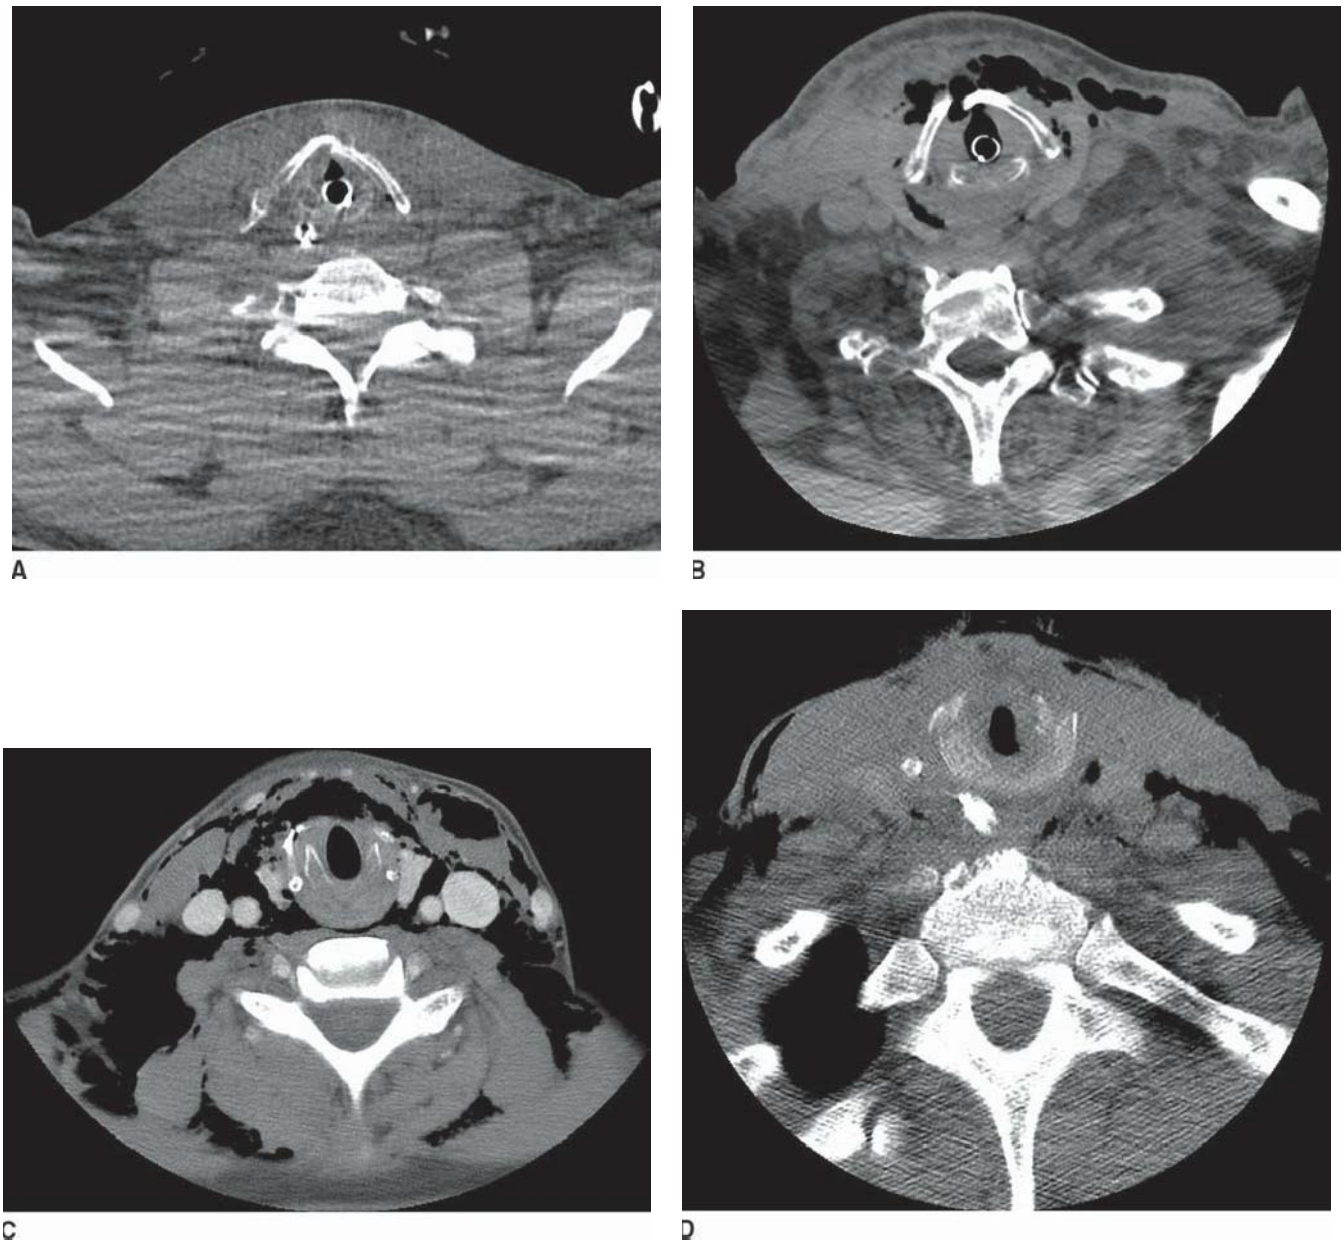

Figure 77.1 **A:** Minimally displaced laryngeal fracture. **B:** Moderately displaced laryngeal fracture. **C:** Severely displaced laryngeal fracture. **D:** Displaced cricoid fracture.

assess poorly visualized areas, such as the subglottic and anterior commissure regions, and to identify associated cervical injuries (14).

Special radiographic studies can be useful in identifying injuries associated with laryngeal trauma, especially with penetrating trauma. Cervical or "arch" arteriography continues to be most commonly used to identify vascular injury, although helical CT, MR angiography, and color duplex ultrasonography are replacing this in some institutions (12,17). Pharyngeal and esophageal mucosal penetration can be identified with the use of a Gastrografin followed by barium swallow examination, although this should be pursued with caution due to the risk of aspiration associated with laryngeal injury. Radiographs of the cervical spine are needed to rule out vertebral injury. Particular care is taken to visualize the entire cervical spine to avoid missing injuries of the lower cervical vertebrae. Ultrasonography has been considered as an adjunctive diagnostic aid in acute laryngeal trauma due to its mobility and easy handling; however, it is not widely utilized (18).

MANAGEMENT

Figure 77.2 shows a management protocol for acute injuries to the larynx. There are two primary goals in the management of acute laryngeal trauma—preserving life by maintaining the airway and restoring function as judged by lack of dependence on a tracheostomy and by voice quality. These goals are universally accepted, but the most appropriate methods to achieve them are controversial (19).

Emergency Care

The initial evaluation and treatment of a trauma patient consists of airway preservation, cardiac resuscitation, control of hemorrhage, stabilization of neural and spinal injuries, and a systematic investigation for injuries to other organ systems (Table 77.2). Controversy exists regarding the best way to establish an alternative airway in the presence of laryngeal trauma (19). If orotracheal intubation is performed in the setting of laryngeal trauma, it is best done under direct visualization by experienced personnel using a small endotracheal tube with a high-volume, low-pressure cuff with an otolaryngologist present (12). These requirements cannot always be met when laryngeal trauma is present. However, the attempted endotracheal intubation of a traumatized larynx can cause iatrogenic injury or the loss of an already precarious airway. For these reasons, some authors strongly recommend tracheotomy with local anesthesia rather than endotracheal intubation for persons who have sustained laryngeal trauma and need an alternative airway (2,15,20). Patients with minimal laryngeal

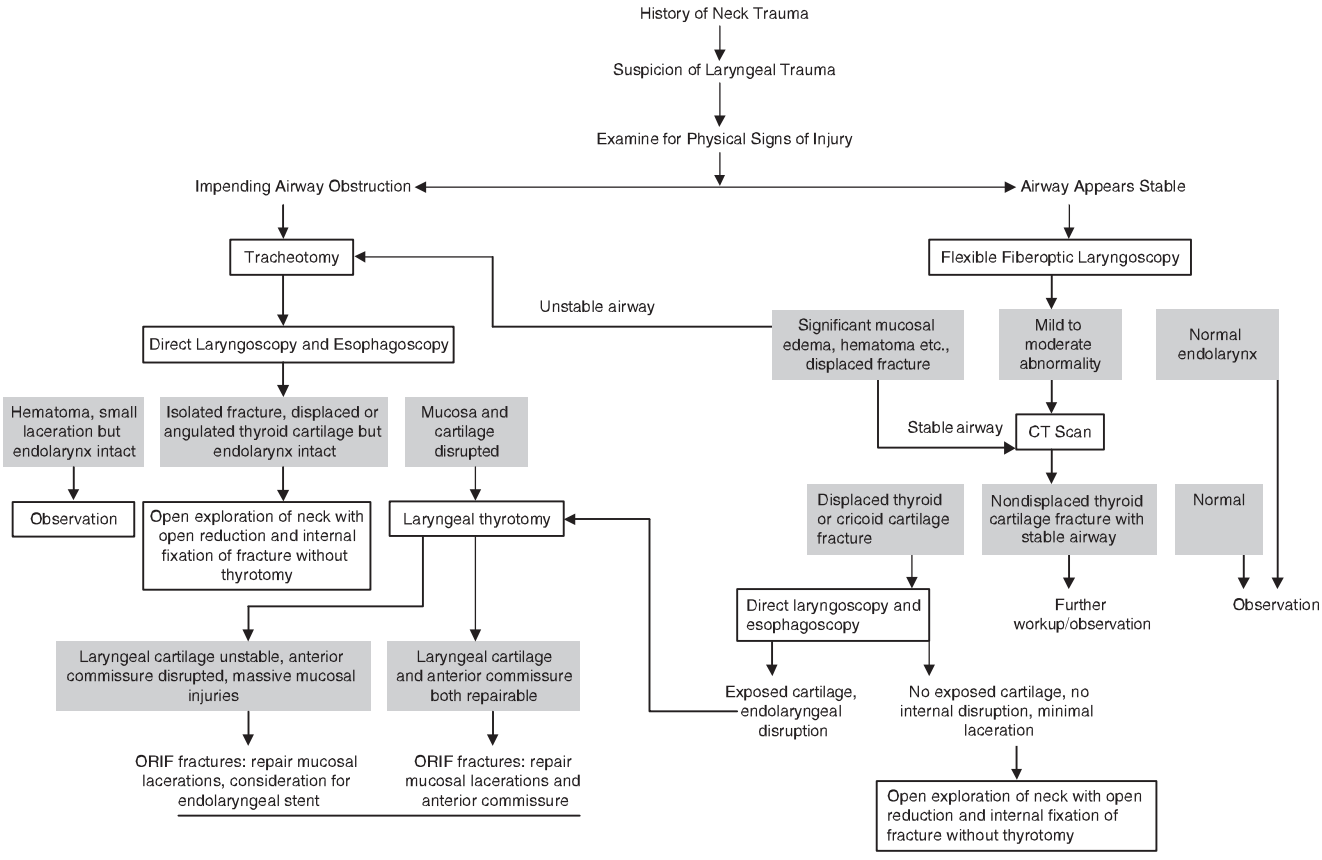

Figure 77.2 Management algorithm for suspected laryngeal injury.

TABLE 77.2 EMERGENCY CARE LARYNGEAL TRAUMA

Multisystem trauma
- Establish airway
- Cardiac resuscitation
- Control of hemorrhage
- Stabilization of spinal injuries

Adult airway
- Tracheotomy under local anesthesia or rigid bronchoscopic intubation
- Alternatively, endotracheal intubation only with:
  - Experienced personnel
  - Small-diameter endotracheal tube

Pediatric airway
- Rigid bronchoscopic intubation followed by tracheotomy

Medical
- Voice rest
- Systemic steroids
- Elevate head
- Humidified air
- Antibiotics
- Antireflux measures

Surgical
- Tracheotomy
- Endoscopy
- Exploration
- Thyrotomy
- Closure of lacerations
- Insertion of stents for disrupted anterior commissure
- Grafting for severe mucosal loss only
- Fixation of fractures

injury, documented with flexible laryngoscopy and CT, can safely undergo careful endotracheal intubation if it is needed to manage other injuries. Such intubation should be performed by a highly experienced physician to avoid further injury to the larynx.

A child with a traumatized larynx presents a special case because it usually is difficult to perform tracheotomy under local anesthesia in this situation. Inhaled anesthesia with spontaneous respirations is used to achieve bronchoscopic intubation, which allows direct visualization of laryngeal injuries and prevents additional iatrogenic injury (11,21). Some authors recommend needle cricothyroidotomy and jet insufflation for patients younger than 12 years (22). However, obtaining a needle cricothyroidotomy may be difficult with loss of laryngeal landmarks, and jet insufflation may worsen subcutaneous emphysema or pneumomediastinum (22).

Treatment Decision Making

Management is divided into medical and surgical treatment according to the extent of injury as determined at physical examination and CT (Table 77.3). The decision to treat a patient medically or surgically is determined by the likelihood that the injury will resolve without surgical intervention. The following conditions are likely to resolve spontaneously without serious sequelae: edema, small hematoma with intact mucosal coverage, small glottic or supraglottic lacerations without exposed cartilage, and single nondisplaced thyroid cartilage fractures in a stable larynx (15,16,20). Some evidence, however, suggests that the repair of even single nondisplaced angulated fractures can prevent subtle vocal changes, as shown by acoustic impedance (23). Strobovideolaryngoscopy may be useful in determining which minor injuries may cause phonatory disorders (13) Injuries likely to necessitate open laryngeal exploration and repair include lacerations involving the free margin of the vocal fold, large mucosal lacerations, exposed cartilage, multiple and displaced cartilage fractures, avulsed or dislocated arytenoid cartilages, and vocal fold immobility (15,16,20).

Injuries likely to necessitate the additional use of endolaryngeal stenting include disruption of the anterior commissure, multiple and displaced cartilage fractures, and multiple and severe endolaryngeal lacerations. In general, stenting is avoided if possible, but may be indicated in the management of these injuries to prevent loss of the normal scaphoid shape of the anterior commissure, to stabilize severely comminuted fractures or lacerations, and to prevent endolaryngeal stenosis. Penetrating trauma is more likely to necessitate open exploration than is blunt trauma.

Medical Treatment

The goals of adjuvant therapy are to eliminate further injury and to promote rapid healing. The clinical course after blunt trauma to the neck is uncertain; therefore, hospitalization in a monitored environment for at least 24 hours is recommended to observe for signs of progressive airway compromise and worsening of laryngeal edema (24,25). Preparations are made for possible emergency tracheotomy.

Bed rest with elevation of the head of the bed for several days helps resolve laryngeal edema. A period of voice rest can minimize further edema or reduce the progression of a hematoma or subcutaneous emphysema. The use of cool, humidified room air helps prevent crust formation in the presence of mucosal damage and transient ciliary paralysis. Additional oxygen is usually not needed unless there is evidence for oxygen desaturation, the advent of which should prompt further investigation.

Nebulized racemic epinephrine and systemic corticosteroids have been used sporadically in the management of laryngeal trauma in an effort to reduce edema and subsequent fibrosis, but no convincing clinical or experimental evidence supports use of this therapy. If used, they are most likely to be of benefit in the first few hours after injury. If there is evidence of a mucosal tear or laceration, antibiotics with coverage toward mixed upper aerodigestive track flora can be useful as prophylaxis against infection, although this has not been proven clinically (25).

A patient with a laryngeal injury is restricted at first to a clear liquid diet with intravenous supplementation as necessitated by other injuries. Nasogastric feedings usually are unnecessary, and passage of a nasogastric tube can worsen the injury. Prolonged use of a nasogastric tube can traumatize the posterior larynx and promote gastric acid reflux. The use of H_2-blocking agents and proton pump inhibitors can help prevent the development of reflux laryngitis, which may be important in preventing scar formation and stenosis in the presence of laryngeal mucosal injury (12,25). Patients with hypopharyngeal tears are given nothing by mouth initially, and if associated with severe laryngeal injury, may benefit from gastrostomy tube placement early on as opposed to placement of a nasogastric feeding tube.

Surgical Treatment

The optimal timing of endoscopic evaluation and surgical management of laryngeal trauma is controversial (2,15,16,20). Some reports indicate that waiting several days after trauma allows the edema to resolve so that endolaryngeal lacerations can be better identified and approximated (11). Currently, most authors agree that early exploration offers the opportunity for complete assessment of the injury and may result in a lower postoperative infection rate, quicker healing, less granulation tissue, and less scarring. Results of several large laryngeal trauma case series suggest that early surgical intervention is associated with better outcomes and is more effective in allowing accurate identification of mucous membrane, muscle, and cartilage injuries, which can then be repaired primarily (15,20,26). In practicality, some delays in treatment may be unavoidable due to associated injuries such as an unstable cervical spine or traumatic brain injury.

Endoscopy is used to ascertain the extent of injury to the larynx and adjacent aerodigestive tract when further surgical management is being considered. A thorough direct laryngoscopic examination is performed in which the entire larynx and hypopharynx are visualized. If dislocated arytenoid cartilage is found, endoscopic reduction should be performed with efforts focused on restoring proper height of the vocal process (27). Bronchoscopy also is used to evaluate the subglottis and trachea. Esophagoscopy is performed to rule out unsuspected esophageal perforation. When injuries that clearly necessitate surgical management are identified at endoscopy, open exploration is performed immediately.

The extent of injury found at endoscopy or open exploration determines the extent of surgical therapy. It may be as limited as tracheotomy to establish an airway or as extensive as open reduction and internal fixation with stenting. Endoscopic or CT evidence of laceration of the mucous membrane, exposed cartilage, immobility of the vocal folds, or displaced or comminuted fractures of cartilage are indications for open exploration. Open reduction and fixation of cartilage fractures is definitely preferable to closed reduction over a bronchoscope and subsequent placement of a stent because of the difficulty of obtaining an adequate reduction in a closed manner and because the dynamic nature of the stresses on the larynx necessitate continued fixation to provide stability. In the management of severe injuries, such as large mucosal lacerations involving the anterior commissure, comminuted cartilage fractures, and avulsion of the arytenoid cartilage, open exploration through a laryngofissure or thyrotomy with stenting is indicated (15,20).

Exploration is performed through a horizontal skin incision in a skin crease at the level of the cricothyroid membrane. Subplatysmal flaps are elevated superiorly to the level of the hyoid bone and inferiorly to just below the cricoid cartilage. The incision can be extended to explore and repair associated neural, vascular, or visceral injuries. The infrahyoid strap muscles are separated in the midline and retracted laterally to expose the laryngeal skeleton and fractures. The thyroid cartilage is incised at the midline, or a preexisting vertical fracture in close proximity to the midline can alternatively be used, and the endolarynx is entered through the cricothyroid membrane. Under direct vision, the incision is extended superiorly through the anterior commissure to the thyroid membrane. The entire endolarynx is examined to identify the extent of the injury (Figs. 77.3 and 77.4). The arytenoid cartilages are palpated to assess their position and mobility.

All mucous membrane, muscle, and cartilage with a viable blood supply are preserved and restored to their original position. Because it is the primary factor responsible for formation of granulation tissue and fibrosis, exposed cartilage must be covered primarily. Failure to do so necessitates grafting and healing by secondary intention. Lacerations are meticulously approximated with 5-0 or 6-0 absorbable suture material (Fig. 77.5). Mucosal advancement flaps may be needed to relieve tension on suture lines and to achieve complete cartilage coverage.

Cartilaginous fractures may be repaired with wire, nonabsorbable suture, resorbable miniplates, or permanent miniplates. Miniplates offer increased opportunity for reconstitution of the skeletal anatomy of the thyroid or cricoid cartilage as compared to less rigid means of fixation (28,29), and have become the mainstay of many authors' armamentarium (30–33). Resorbable plates generally resorb within 1 to 2 years and are particularly attractive due to their relative ease of adaptability (34). However, screws of both resorbable and nonresorbable type tend to pull out easily in cartilage, and an untapped, undersized drill bit

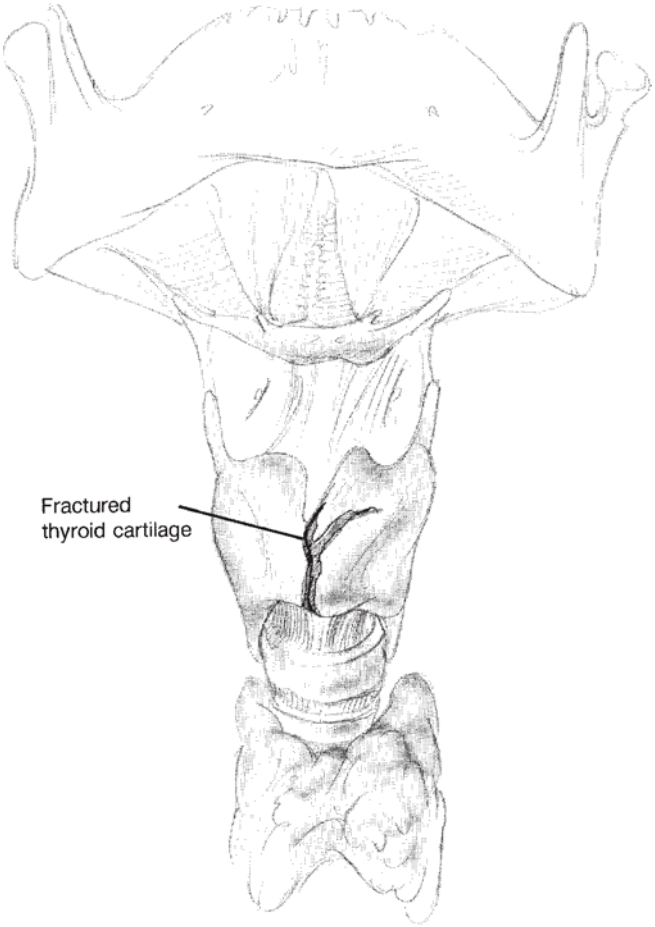

Figure 77.3 Fracture of thyroid cartilage.

should be used along with careful insertion technique in order to avoid shear failure (31,33,34). If a screw does strip, nonresorbable or long-lasting resorbable suture can still be used to secure the cartilage to the plate, while still gaining increased rigidity from the plate itself. Small fragments of cartilage with no intact perichondrium are removed to prevent chondritis. The anterior margin of each true vocal fold is sutured to the thyroid cartilage or its external perichondrium at the thyrotomy site to reconstitute the anterior commissure (Fig. 77.5). If the anterior commissure is devoid of epithelium, a preformed keel or reinforced polymeric silicone sheeting can be placed to prevent web formation. The thyrotomy is closed with wire, nonabsorbable suture, or miniplates (Fig. 77.6). If part of the anterior cricoid ring is lost, suturing the infrahyoid strap muscles into the defect can help maintain the airway and voice.

Grafting

Adhering to the principles of conservation of normal anatomic relations and immediate surgical management makes the need for a graft rare. Mucous membrane or skin grafts have been used to cover areas of exposed cartilage that cannot be closed primarily; however, these wounds must heal by second intention, which causes greater scar

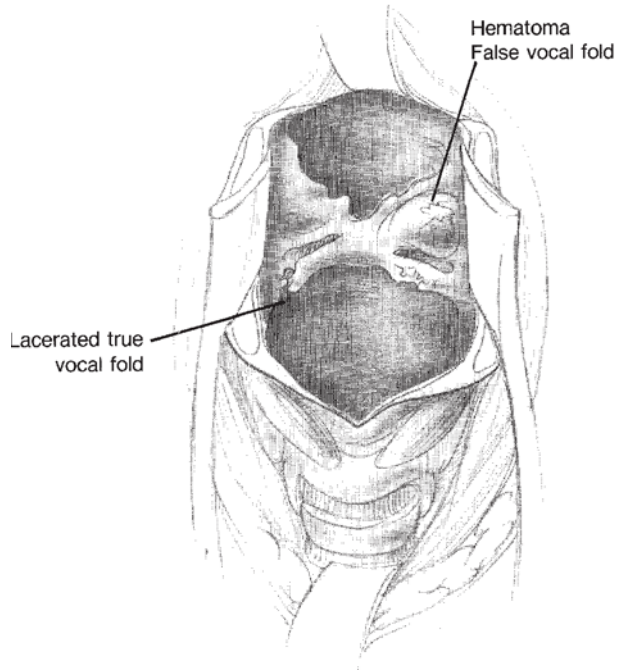

Figure 77.4 Laceration of true vocal fold and hematoma of false vocal fold.

formation than with primary closure. In the rare situation in which a graft is needed, mucous membrane, dermis, and split-thickness skin are suitable. Mucous membrane most closely resembles the normal endolaryngeal epithelium, but use of this tissue carries high donor-site morbidity and necessitates entering the oral cavity. Grafting never is a substitute for careful closure of laryngeal lacerations.

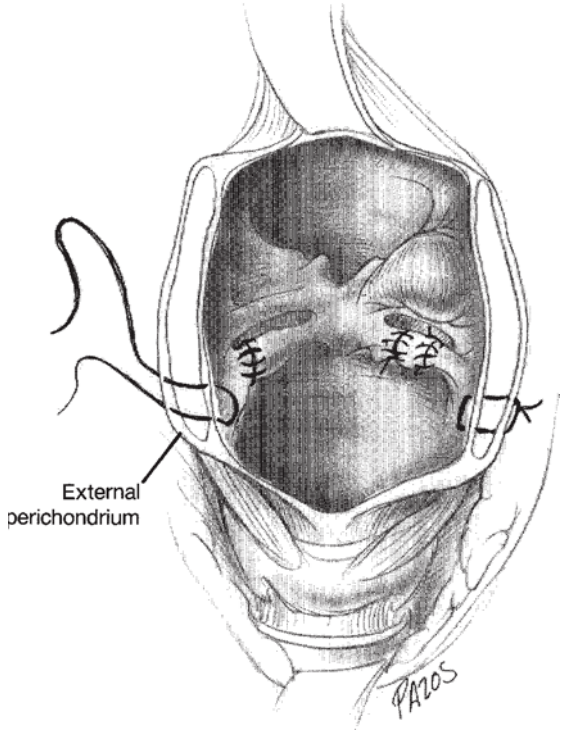

Figure 77.5 Repair of lacerations.

Stents

Laryngeal stents can be used initially for internal fixation devices and thereafter prevent endolaryngeal scarring and maintain the internal configuration of the larynx. Although the presence of a stent can increase the risk of infection and formation of granulation tissue, the clinical findings sometimes dictate stenting (35). Multiple cartilaginous fractures that cannot be stabilized adequately with open reduction and internal fixation and extensive lacerations involving the anterior commissure are specific indications for the use of stents. In the presence of a stable laryngeal skeleton with an intact anterior commissure before thyrotomy, stenting is not needed. Massive mucosal injuries may necessitate stenting to prevent mucosal adhesions (Fig. 77.7). Stents alone, however, are not a substitute for primary closure of mucosal lacerations and careful reduction and internal fixation of fractures (15,20).

The stent must be fixed in the larynx in such a way that it moves with the larynx during swallowing and can be consistently and easily recovered by means of endoscopy alone. A useful method is to pass a heavy, nonabsorbable suture through the stent and the larynx at the level of the laryngeal ventricle and another at the cricothyroid membrane. These are tied over buttons outside the skin. There is some controversy about how long to leave a stent in place. The desired laryngeal stabilization must be achieved and scar formation prevented, but the risk of infection and wound necrosis associated with prolonged stenting must be considered (36). If an analogy can be drawn with pediatric single-stage laryngotracheal reconstruction with endotracheal tube stenting, stenting for longer than 1 week does not confer any advantage (37). The stent is removed by means of direct laryngoscopy, and the operative result is assessed. Granulation tissue can be removed with conservative use of a carbon dioxide laser or laryngeal microdebrider. An association has been suggested between

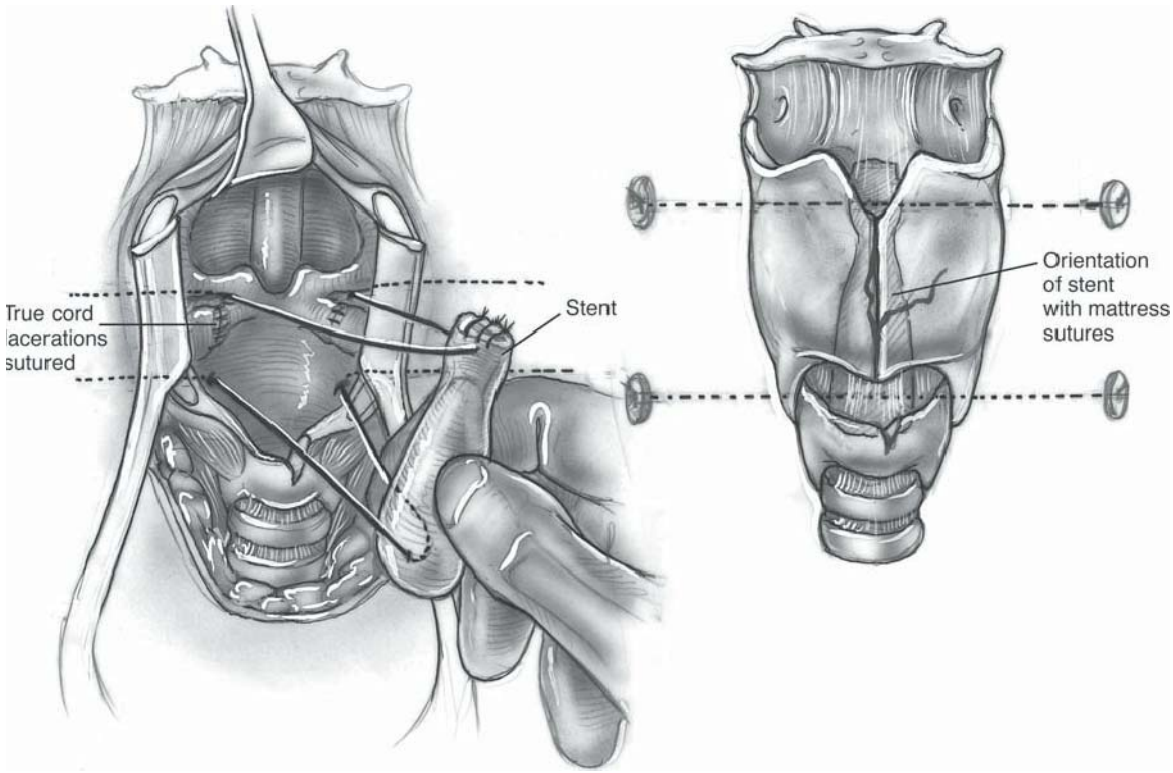

Figure 77.7 Fixation of endolaryngeal stent using nonabsorbable sutures.

the development of granulation tissue and stent colonization with *Staphylococcus aureus* and *Pseudomonas aeruginosa*, and it is recommended that prophylactic antibiotics be used (38). The need for additional endoscopic manipulation is determined with serial flexible laryngeal examinations. Decannulation is best deferred until the patient can tolerate a reasonable period of plugging of the tracheotomy tube.

Cricotracheal Separation

Cricotracheal separation is one of the more severe injuries associated with anterior cervical trauma and commonly occurs from clothesline injuries (39). Several factors unique to this injury must be considered including a precarious airway, loss of cricoid support, injury to the recurrent laryngeal nerves, and late development of subglottic stenosis. While cricotracheal transection often is associated with asphyxiation at the time of trauma, respiratory distress may not be present if prefascial tissues remain intact. Therefore, a high index of suspicion is required for diagnosis of this type of injury. The airway is best controlled by means of tracheotomy with the patient under local anesthesia. When this is impossible, tracheotomy is performed after careful passage of a ventilating bronchoscope. Intubation of the patient with laryngotracheal separation can result in loss of airway due to placement of the endotracheal tube through the mucosal laceration into the soft tissue of the neck, with disastrous consequence. If the patient has successfully been intubated before evaluation, the diagnosis may not be established until extubation. CT may aid in diagnosis of the intubated patient showing balloon overinflation or herniation (40).

If the cricoid cartilage is intact, the mucous membrane is repaired directly with absorbable suture. To distribute the tension on the wound away from the cricotracheal anastomosis, nonabsorbable sutures are placed from the superior aspect of the cricoid cartilage to the inferior aspect of the second tracheal ring. If the cricoid is fractured, the effectiveness of repair is limited by the stability of the cricoid cartilage after internal fixation. Reconstitution of the severely injured cricoid cartilage, with the assistance of internal fixation and stenting, is preferable to extensive resection of the cricoid and thyrotracheal anastomosis.

Severed Recurrent Laryngeal Nerve

Management of a severed recurrent laryngeal nerve continues to be controversial. Even with careful microscopic repair of the transected nerve, vocal fold mobility is not regained owing to the mixture of abductor and adductor fibers in the nerve (41). Additionally, vocal fold synkinesis may develop after neurorrhaphy. Nerve regeneration can prevent muscle atrophy, help maintain some strength of voice, and decrease rate of aspiration (41). Therefore, it appears that the best acute-phase management is immediate reapproximation of the nerve under an operating microscope.

COMPLICATIONS

Early recognition of laryngeal injuries and the application of consistent management principles have decreased the morbidity and mortality from laryngeal trauma (Table 77.4). Success is measured in terms of restoration of the voice, airway, and deglutition. Bent has proposed a modification of Shaefer's original grading system that may be useful in predicting successful outcomes (Table 77.5) (5,20). Among patients with edema, hematoma, or minor lacerations, excellent recovery of both voice and airway usually can be achieved without surgery or with minimal surgical intervention, such as tracheotomy or endoscopy. With severe lacerations and cartilaginous fractures, good results can be achieved with early primary repair of lacerations and internal fixation of fractures. In the two largest published series of laryngeal trauma, greater than 97% of patients were able to be decannulated using these treatment protocols (16,20). In these same series, voice quality was graded as poor in only 1 patient out of the combined total of 251 patients (16,20). If present, suboptimal voice outcome may be related to impaired lengthening of the vocal folds secondary to scarring or superior laryngeal nerve injury (42).

The most common problem in the immediately postoperative period is development of granulation tissue, which most often happens in the presence of bare cartilage. This problem often is the precursor to fibrosis and stenosis. Many techniques have been used in attempts to arrest formation of granulation tissue, including the use of systemic and intralesional corticosteroids, long-term splinting, and

TABLE 77.4 COMPLICATIONS LARYNGEAL TRAUMA[a]

Granulation tissue
Prevent by covering all exposed cartilage
Avoid stents when possible
Careful excision

Thyroplasty-type vocal fold medialization
Arytenoidectomy and vocal fold lateralization for bilateral paralysis

[a]Manifested as failure to decannulate and inadequate voice.

TABLE 77.5 INJURY GROUPS

Group 1: Minor endolaryngeal hematoma/lacerations without detectable fracture
Group 2: Edema, hematoma, minor mucosal disruption without exposed cartilage; nondisplaced fractures on CT scan
Group 3: Massive edema, mucosal tears, exposed cartilage, vocal cord immobility, displaced fractures
Group 4: Group 3 plus three or more fractures and massive mucosal damage requiring stenting
Group 5: Laryngotracheal separation

low-dose irradiation, but these methods have had little success. Probably, the most effective technique is to minimize the initial formation of granulation tissue by attempting to cover all exposed cartilage meticulously in primary closure of laryngeal lacerations. Control of reflux through the postoperative use of H_2 blockers and proton-pump inhibitors may be beneficial in decreasing the formation of granulation tissue (12). Using intraluminal stents only in highly selected cases, as described earlier, and keeping the stents in place for the minimum amount of time needed decreases the amount of granulation tissue that forms.

Despite strict adherence to proper principles of management of laryngeal trauma, fibrosis and stenosis can occur. Therapeutic measures depend to some extent on the level of stenosis. Supraglottic stenosis often can be corrected with simple excision of the scar tissue and local advancement flaps for wound coverage. Stenosis repair may be performed through an open or endoscopic approach (3). Extensive areas of stenosis may necessitate the removal of a large portion of the epiglottis or aryepiglottic fold. In rare instances, supraglottic laryngectomy may be necessary if depending on the degree of stenosis or cartilaginous injury (43). A keel or stent can be used as needed to maintain the repair.

Rehabilitation from glottic stenosis depends on the extent of the lesion. Thin anterior glottic webs can often be lysed and repaired using a microflap technique (see Chapter 68) (44). Posterior glottic webs or interarytenoid scarring may require arytenoidectomy or related procedures (see Chapter 69). Extensive glottic stenosis often necessitates a laryngofissure with direct excision of the stenotic area followed by placement of a rib cartilage graft with or without a stent.

Subglottic stenosis continues to be difficult to manage, no matter what the cause. Less extensive lesions can be managed with repeated dilation or conservative noncircumferential laser excision of the scar tissue. Balloon dilation has been shown to be safe and effective while maximizing the "radial direction of dilation" compared to standard bogie dilation (45). More serious stenosis may necessitate anterior or posterior cricoid splits with cartilage grafting to increase the size of the subglottic lumen. Stenting usually is needed as are numerous endoscopic procedures to excise granulation tissue after removal of the stent. Mitomycin C has shown promise as a topical agent to help prevent recurrent scar formation (3,46). While the exact mechanism of action of Mitomycin C is unknown, it is believed to decrease scar formation through inhibition of fibroblast migration (3). Marked tracheal stenosis in a short segment is managed by means of resecting the stenotic area and performing end-to-end tracheal anastomosis (47). Lesions up to 4 cm in length can be resected with laryngeal release techniques; however, the results with many of these techniques are disappointing, and prevention of these complications continues to be the optimal treatment (see Chapter 62).

After blunt trauma, persistent immobility of the vocal fold may be caused by recurrent laryngeal nerve injury or by cricoarytenoid joint fixation or dislocation. Differentiating these causes is essential in selecting the proper form of therapy, and is best accomplished by observing vocal fold motion with fiberoptic laryngoscopy and videostrobolaryngoscopy followed by direct palpation of the arytenoid to assess its mobility (27). Laryngeal electromyography (EMG) may be necessary to distinguish vocal fold paralysis from arytenoid dislocation (27,48). If the arytenoid cartilage is mobile, the vocal fold is observed for as long as 1 year to await the possible spontaneous return of recurrent laryngeal nerve function; however, laryngeal EMG can shorten the waiting period by providing key prognostic information regarding spontaneous recovery possibilities (see Chapter 69). If aspiration or dysphonia is severe, injecting the vocal fold with an augmenting material such as gelfoam, fat, hydroxyapatite paste, hyaluronic acid, or one of many available materials can be a temporizing measure (49–52). Persistent paralysis resulting in an inadequate voice can often be rehabilitated with appropriate laryngeal framework surgery (53,54). In the case of unilateral fixation of the arytenoid cartilage with adequate voice and airway, no treatment is needed. Bilateral arytenoid fixation or recurrent laryngeal paralysis with a compromised airway often is managed with arytenoidectomy and vocal fold lateralization (see Chapter 69).

CONCLUSION

Although each instance of laryngeal trauma presents a unique therapeutic challenge, using basic primary treatment principles greatly simplifies the management plan. When clinically possible, flexible laryngoscopy provides essential information on the nature and severity of injury, which subsequently directly factors into treatment decisions. The use of CT scans in some cases of laryngeal trauma may obviate the need for open exploration and often is helpful in diagnosis and treatment planning. Tracheotomy rather than endotracheal intubation often is the most controlled method for establishing an airway when necessary.

Immediate open exploration for serious injuries allows primary closure of all mucosal lacerations and prevents some long-term complications of laryngeal trauma. Stenting is not needed when the cartilaginous skeleton is stable after internal fixation and when mucosal coverage of the anterior commissure can be reconstituted. Use of an early primary management protocol to manage laryngeal trauma should predictably maintain laryngeal function.

HIGHLIGHTS

- A high index of suspicion is the most valuable aid to early diagnosis.
- CT is the most useful radiologic examination in the evaluation of laryngeal injury.
- Management is determined by the findings at flexible laryngoscopy and CT.
- Hematoma, small lacerations, and edema are likely to resolve with medical therapy alone.
- Cartilage fractures, large lacerations with exposed cartilage, disruption of the anterior commissure, and arytenoid injuries necessitate surgical repair.
- Tracheotomy is the most controlled method for establishing an airway with an injured larynx.
- Mucosal repair is best accomplished immediately.
- Primary mucosal coverage of exposed cartilage most effectively prevents development of granulation tissue.
- Grafts are used for coverage of exposed cartilage only when primary mucosal coverage is impossible.
- Stents are used only in the presence of anterior commissure injuries or cartilage fractures that are unable to be adequately stabilized.

78 Principles in Rigid Fixation of the Facial Skeleton

Robert M. Kellman *Sherard A. Tatum*

In this age of rapid transportation and increasing urban violence, severe facial trauma is an entity that the otolaryngologist–head and neck surgeon is likely to encounter. Complex facial trauma may refer to blunt and/or penetrating trauma resulting in multiple facial fractures and varying degrees of soft tissue injury or loss.

Skeletal facial trauma is frequently subdivided into fractures of the frontal sinus, nasoethmoid complex, zygomaticomaxillary complex, midface, dentoalveolar structures, mandible, and other unusual fracture patterns. Complex facial trauma can then refer to either the multiplicity of areas involved (i.e., panfacial fractures) or the degree of severity of involvement of a given area. For purposes of this chapter, massive facial trauma refers to high-energy blunt or penetrating trauma leading to severe bony displacement, comminution or frank bone loss, and/or involvement of multiple anatomic areas and reducing the availability of anatomic reference points for fracture reduction. These injuries may be associated with severe soft tissue lacerations, avulsions, or globe or central nervous system injuries. Regardless of the precise definition of massive facial trauma, it is our contention that these injuries can be managed successfully by adherence to the same basic principles that lead to successful outcomes from less complex trauma.

BONE HEALING

Bone is a complex tissue made up of a collagen matrix mineralized with calcium phosphate (hydroxyapatite) crystals. Interspersed within bone are cellular components that mediate bone resorption, deposition, and metabolism. Thicker areas of bone typically involve two structural components: an outer cortical or dense bone layer and an inner cancellous or spongy bone layer. Thinner sections of bone are lamellar and lack significant cancellous bone or marrow space. Nutrition is supplied to bone through the outer layer of periosteum and inner open circulation of the marrow space (1).

Fracture results in disruption of the bone matrix, surrounding soft tissue and, if applicable, marrow space. This disruption allows blood and inflammatory cells to flood the area. A hematoma forms, which matures through granulation tissue, fibrous tissue, cartilage, and then bone or directly from fibrous tissue to bone depending on the embryologic origin. This callous formation allows indirect healing to occur when the edges of the bone are not approximated. Mineralization eventually occurs if motion is not excessive. If not anatomically reduced, segments heal in a new position, which may lead to deformity and dysfunction (2).

If the distance between bone fragments is decreased by anatomic reduction of the fracture, then healing will occur with less callous formation and diminished alteration of anatomy. Areas of the fracture that are abutted and compressed will heal by contact healing or direct osseous formation without significant callous formation. Direct osseous healing is not likely to occur along the full length of a fracture even if it is well reduced. Microgaps heal by callous formation or gap healing in which bone is laid down directly perpendicular to its normal orientation followed by remodeling to change this orientation. Regardless, the fragments heal in anatomic position (3).

Problems with the bone-healing mechanism can lead to clinical complications of fractures. Delayed union refers to reduced or absent mineralization of a fracture line 8 to 12 weeks after immobilization. Malunion occurs when a fracture heals by osseous union with segments in nonanatomic position. Fibrous union occurs when progression of indirect healing to ossification does not occur. A nonunion can refer to fibrous union, although it typically connotes a wider gap with very poor function, whereas fibrous unions may not result in a functional deficit. Pseudoarthrosis refers to a fibrous union that is mobile enough to function

like a joint. This phenomenon might be a desirable result for a subcondylar fracture that has resulted in temporomandibular joint ankylosis. Otherwise the mobility leads to dysfunction and pain. Inadequate stabilization and infection are major causes of these healing problems (4).

FRACTURE PATHOPHYSIOLOGY AND CLASSIFICATION

Fractures occur when forces are applied that exceed the stress capabilities of bone, leading to a disruption of the mineralized matrix with additional disruption of the associated soft tissue. Fractures may be simple, involving a single disruption between two bone segments, or comminuted, meaning multiple bony fragments exist in the separation between bone segments. Displacement refers to the alteration in anatomic relationships of bony segments. This alteration can occur as a result of the energy of the blow itself or because of unopposed muscle pull. Angulation is the change in angle of the long axis of the bone across the fracture. Distraction refers to the distance between bone segments across a fracture, and rotation is the orientation alteration of bone segments along their long axis. A fracture is considered favorable if it is oriented such that muscle pull vectors act to compress the fracture. An unfavorable fracture is one oriented such that muscle pull vectors act to displace the fragments (Fig. 78.1).

The concept of open or compound fractures relates to the exposure of fractured bone outside the soft tissue, leading to bacterial contamination. This idea is a little confusing in the face because of the oral, nasal, and sinus cavities. Certainly, fractures involving gross lacerations of facial skin or oral mucosa exposing bone are open fractures. Typically, fractures involving tooth-bearing bone even without mucosal laceration are considered open because of exposure to the oral flora through the periodontal tissue. Fractures through the nasal cavity involving mucosal lacerations are likewise exposed to nasal flora. Fractures through an uninfected sinus cavity may not initially involve bacterial contamination; however, a blood-filled sinus is likely to become colonized fairly quickly. Therefore, few facial fractures would not be considered open. Isolated mandibular ramus or subcondylar fractures and zygomatic arch fractures are among these.

The amount of energy associated with the injury tends to affect the characteristics of the injury. Low-energy impacts such as fist blows tend to lead to less comminuted and less displaced fractures. High-energy impacts are more typically associated with comminution, greater displacement, and a greater degree of soft tissue injury. The rate of energy dissipation into the tissue is the true determinant. A hard object striking the face is more likely to lead to comminution than a fist striking with the same energy because the energy of the blow is transferred to the tissue more quickly. The kinetic energy of the object may be greater as well. Penetrating trauma is similar, with low-energy missiles creating less injury than high-energy missiles. However, missile design comes into consideration. A high-energy missile with a hard surface may exit the body fairly quickly, not dissipating all its energy into the body. A lower-energy missile designed to expand, spiral, or tumble and dissipate most of its energy before exit can be more damaging. However, the amount of shock wave energy from the missile impact determines the degree of collateral tissue damage. Point-blank gunshot wounds have the added soft tissue injury of the expanding propellant gases. This blast injury can lead to poor healing, infection, and fibrosis. Ballistics information is helpful, but wound evaluation is still the best guide (5).

RATIONALE FOR RIGID FIXATION

Regardless of the etiology or classification of the fracture, the healing mechanism can be assisted with reapproximation of the fragments followed by fixation to create stability and reduce movement of the bone fragments. Decreasing

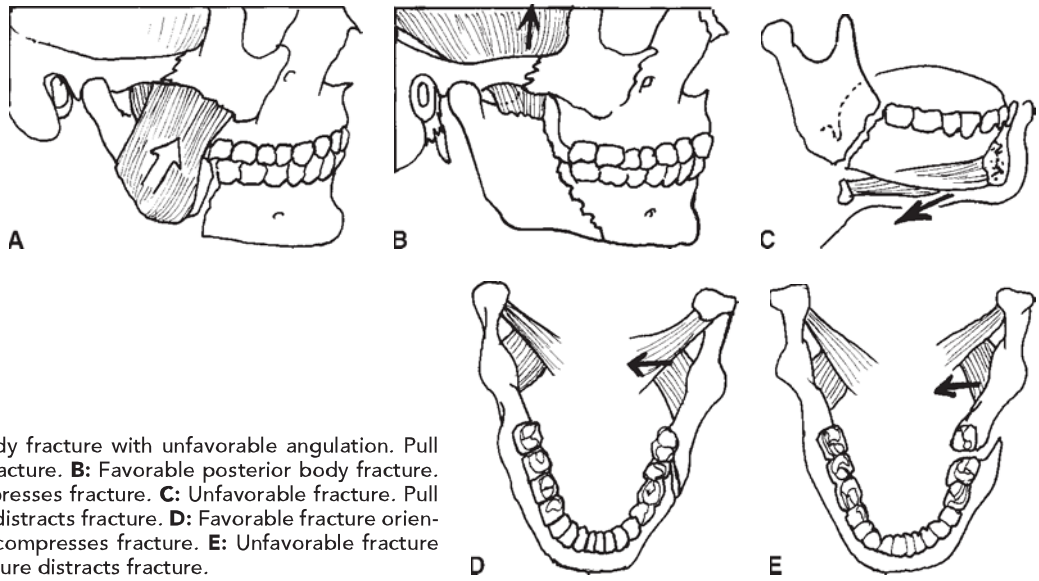

Figure 78.1 **A:** Posterior body fracture with unfavorable angulation. Pull of masseter muscle distracts fracture. **B:** Favorable posterior body fracture. Pull of temporalis muscle compresses fracture. **C:** Unfavorable fracture. Pull of hyomandibular musculature distracts fracture. **D:** Favorable fracture orientation. movement of the bone fragments enhances ossification and the progression to a bony union. Reestablishment of blood supply to devascularized bone fragments or bone grafts is also enhanced by immobility. This lack of movement or stability requires overcoming the biomechanical forces acting on the bone fragments. Varying degrees of stability are imparted by different fixation techniques. Rigid fixation of fractures with plates and screws is thought to provide superior stability by overcoming functional forces applied by the musculoskeletal system across a fracture (6). This concept is not universally accepted, however. Enhancements in imaging capabilities and surgical exposure techniques and a greater interest in maxillofacial trauma have paralleled the development of plating technology. These developments may account for improved trauma outcomes. Additionally, plates have been criticized for being palpable, occasionally being visible, causing temperature sensitivity, inhibiting growth, and weakening bone by stress shielding. Some of these criticisms are more theoretic than others, but absorbable plating systems promise to alleviate most of these problems. To obtain comparable strength, characteristics of absorbable plating systems currently require larger plates and screws than their metal counterparts, so they are not suitable for every indication. However, newer reinforced materials may alleviate this problem (7,8).

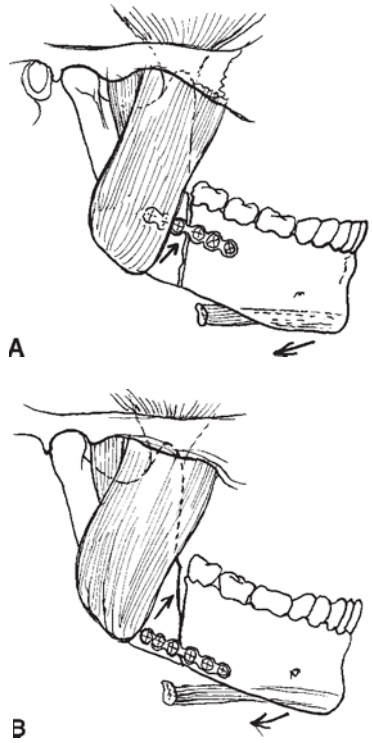

Figure 78.2 Muscle pull distracts superior border of fracture and compresses inferior border of fracture. Plate placement in (**A**) prevents superior distraction. Plate placement in (**B**) does not.

BASIC PRINCIPLES OF RIGID FIXATION

The central concept of rigid fixation is to return skeletal fragments to their anatomic position and rigidly fixate them in that position with an implantable device that provides sufficient strength across the fracture to maintain the reduction against musculoskeletal forces. Fixation plates are designed to span a fracture and provide stress shielding and fracture stability. The plates are fixed to the bone with screws. Each screw placed in the bone is a fixation point. Larger plates made of stiffer material provide greater stress shielding and stability. Large screws provide stronger fixation than small screws. Bicortical screws provide greater stability than monocortical screws, and increasing the number of screws or fixation points anchoring a plate to a bone segment increases stability. Compression or loading of the bone across the fracture enhances stability by increasing the friction between the fracture edges (9). Additionally, plate location relative to bone thickness and the many complex forces acting on the bone are important. Generally speaking, greater bone thickness is found when the forces acting on the bone are greater; however, more bone thickness allows for longer screws, providing increased stability. Forces acting to angulate a fracture distract one end of a fracture and compress the other. A plate placed closer to the end being distracted is more likely to overcome those forces than a plate located at the end being compressed because of mechanical advantage related to the lever principle (Fig. 78.2).

The previous statements are true within certain limitations. The more rigid a plate is, the more precise the bending of the plate has to be to conform to the surface contours of the bone where it is to be applied. Otherwise, as the screws are tightened, the bone may be pulled toward the plate, creating distraction (Fig. 78.3). To overcome this problem, locking-screw plates have been developed. These allow the threaded screw head to lock into a corresponding threaded plate hole, so the screw head locks to plate. This obviates the need for the preciseness of the bend, because the bone will not be pulled to the plate. In mandibular repair, monocortical miniplates have been found to be adequate to replace a heavy bicortical plate so long as they are properly positioned to overcome the distracting forces that occur during function (10). Additional fixation points (i.e., screws) provide additional stability; however, the incremental increase in stability decreases as the number of fixation points increases (11). The increase in stability must be weighed against the additional exposure required and higher bulk of the larger implant. Increasing screw diameter must be weighed against the weakening of the residual bony buttress created by increasing the screw hole size. Increasing screw length into cancellous bone adds little additional strength unless a second cortex is engaged. Screw length beyond the applicable bone thickness certainly adds no strength, and damage to underlying structures such as tooth roots could occur.

FIXATION DEVICE CLASSIFICATION AND TERMINOLOGY

The terminology applied to plating systems is confusing and nonuniform, because it is applied differently by different manufacturers. Plating systems are usually identified

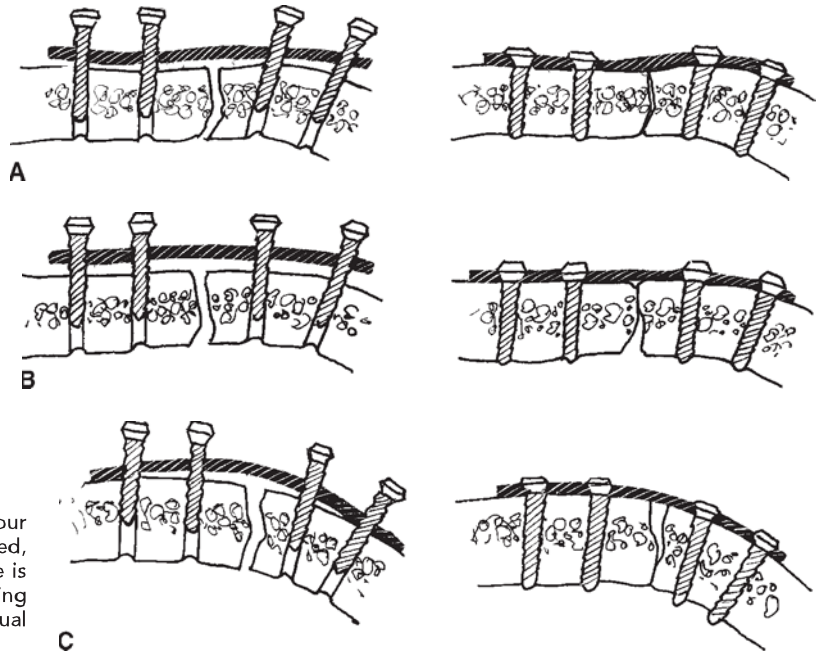

Figure 78.3 **A:** Plate is bent to appropriate contour with bony cortex so that when screws are tightened, lingual and buccal cortices are approximated. **B:** Plate is underbent, approximating buccal cortex but distracting lingual cortex. **C:** Plate is overbent, approximating lingual cortex but distracting buccal cortex.

either by their dimensions or by their application. The term *miniplate* typically refers to plates designed for screws in the 1.2- to 2.5-mm range. The term *microplate* refers to plates designed for screw diameters around 1 mm. There are several intermediate sizes and now modular systems with multiple plate and screw dimensions. Larger systems are designed specifically for the mandible with screw diameters up to 2.4 mm or more and greater lengths for bicortical applications, including lengths up to 40 mm for lag screw applications. Usually, as screw size increases, so does plate thickness. So-called three-dimensional (3-D) plates are available in mini and micro sizes. These plates have added strength due to a lattice design (12).

Plating systems are sometimes designated according to their proposed function, such as maxillary or zygomatic miniplates or mandibular miniplates. Although screw dimensions may be the same, mandibular miniplates are thicker than maxillary and zygomatic miniplates. Mandibular miniplates are typically 1 mm thick. Mandibular systems are further delineated as trauma sets or reconstruction sets, with the reconstruction sets offering the thickest (3 mm or more) stiffest plates in the greatest lengths and with the largest screws. Condylar prostheses may be included. Specialty plates also exist that are prebent for orthognathic surgery or with special configurations useful for microvascular reconstruction of the mandible. Various mesh designs are used to replace defect areas in non–load-bearing areas such as the orbital floor. Newer orbital floor plares have been designed from human models to mimic the anatomical contours (convexities and concavities) of the orbital floor and medial wall providing for more precise repairs.

Dynamic compression plates are designed to push fracture fragments together as the screws are driven. The plate holes are ovoid, and the edges of the hole are slanted. The holes for the screws are drilled eccentrically within the plate holes so that when the screw is tightened, the head slides down the slant, bringing the bone with it. The plate hole orientation determines the direction of movement and compression. Standard dynamic compression plates compress parallel to the plate across the fracture. Eccentric dynamic compression plates have holes on the end that are oriented to provide angular compression for the superior border of the mandible. Today, compression plates are used less frequently than in the past, and eccentric dynamic compression plates are rarely used.

Absorbable plates and screws can be used as well, though to obtain strengths similar to titanium, larger implants are required (13).

PRINCIPLES OF SCREW APPLICATION

For a screw placed in bone to serve as a stable fixation point, the threads of the screw must engage or grip the bone around the drill hole. Factors leading to inherent bone weakness such as osteoporosis or osteitis are beyond the surgeon's control. Adherence to good surgical technique, however, will enhance the stability of the screw in the bone. The drill hole must match the inner screw shaft diameter. If the hole is too small, excessive friction and stress will result. This excess can lead to shearing of the screw head or local bone ischemia and resorption. The screw is held by a functional sleeve of bone around the drill hole that is the thickness of the screw threads (Fig. 78.4). This thickness varies from screw to screw but is typically on the order of 0.1 to 1.0 mm. Any imprecision in drilling can lead to reduction of this sleeve of bone and a larger than desired drill hole. High-speed drill chatter, bent drill bits, drill angulation

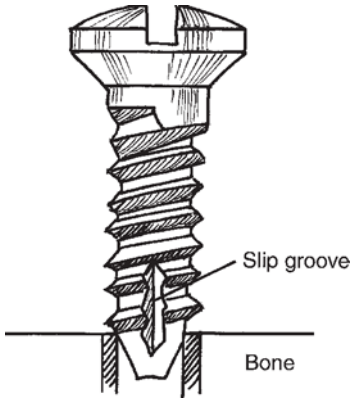

Figure 78.4 Detail of fixation screw in bone. The diameter of the hole in the bone matches the inner core diameter of the screw, not the outer thread diameter of the screw.

change (i.e., hand movement), or continued drilling once the hole is complete can lead to attrition of the bone around the drill hole. Excessive heat leads to delayed attrition from osteocyte death. Therefore, ideal drilling is achieved with a sharp straight drill bit, a low-speed drill, a drill guide, a steady hand, and copious irrigation. The diameter of the drill bit should match the diameter of the screw shaft without threads, not the diameter with threads. If a drill bit's diameter matches the screw's outer diameter with threads, then the screw can be pushed or pulled through the drill hole without turning the screw. This situation is termed *gliding* and is desirable only in lag screwing.

Tapping refers to the cutting of screw threads in the drill hole. Most systems now have self-tapping screws that have flutes beginning at the tip of the screw and extending several threads up the screw to allow for the cutting of the bone into a thread pattern. Residual bone dust from the drilling should be irrigated away from the hole before screw application. The act of tapping itself creates additional bone dust as the threads are cut. This material can lead to binding and excessive wear of the threads. The bone dust should be released by intermittent back turns while tapping and irrigated away. Some systems require or offer as an option tapping as a separate step. The tap thread must match the screw threads exactly, and the subsequent screw must be placed carefully to avoid cross-threading. If inadequate bone exists around the drill hole to hold the screw, then it will fail to tighten as it is screwed into the bone and will begin to slip. Overtightening of the screw can lead to microfracture or stripping of the bone threads as well. Because this is a fairly frequent occurrence, most plating systems contain emergency (rescue) screws, which are screws with the same shaft diameter but a greater thread diameter to allow for bone engagement beyond the stripped portion of the hole. If the emergency screw fails to engage, then another fixation site must be sought. If the plate has extra holes beyond what is needed for adequate fixation, the stripped screw or "spinner" may still be useful. That screw can be left in to anchor the reduction and plate position until the other screws are placed. Then it should be removed and when possible replaced with a larger screw. An advance in screw design eliminates the need for drilling. The tip of the screw is like a drill bit, and the screw is driven directly into the bone. Self-drilling screws allow placement of the screws directly into the bone, avoiding drilling altogether. These are especially helpful in thin bone.

LAG SCREW APPLICATION

A lag screw presses two pieces of bone together by compressing the first piece of bone between the second piece in which the tip of the screw is engaged and the head of the screw (Fig. 78.5). In this situation, a hole is drilled relatively perpendicular to a fracture line traversing the fracture. The hole is double drilled such that the part of the hole on the screw head side of the fracture matches the diameter of the screw with threads, allowing the screw to glide or to be pushed through the hole to the fracture. On the other side of the fracture, the hole diameter is drilled to match the screw shaft diameter without threads. This allows the screw threads to engage the bone on the other side of the fracture. As the screw is tightened, the top fragment is compressed between the head of the screw and the second fragment in which the threads are engaging on the other side of the fracture. An enhancement of this technique has occurred through the development of a tapered drill bit. This bit allows a single drilling motion to provide a larger gliding hole on the screw head side of this fracture and a smaller engaging hole on the other side of the fracture. Because of the often near-tangential angulation of the screw relative to the cortical surface, a countersink hole is drilled to allow the screw head to seat better. Sometimes, drilling the countersink hole first facilitates drilling for the lag screw. The countersink hole should not be too deep or the screw head as it is tightened will pull through the residual cortex into the marrow space and will not be stable.

It is very important to distinguish a lag screw from a positioning screw. A positioning screw is used in very specific circumstances such as fixation of a mandibular sagittal split osteotomy. There, lag screw compression may overcompress the mandibular neurovascular bundle or overtorque the condyle. When a position screw is desired, the drill holes on either side of the fracture or osteotomy are of the screw shaft diameter without thread. The screw threads then engage the bone on either side, making compression across the fracture impossible. The bone segments are fixated into position relative to each other, but a gap exists between them, and there is no compression.

PLATE APPLICATION

A myriad of plate dimensions and shapes exists that conform to multiple anatomic applications (14) (Table 78.1). The variety allows the surgeon to maximize the number

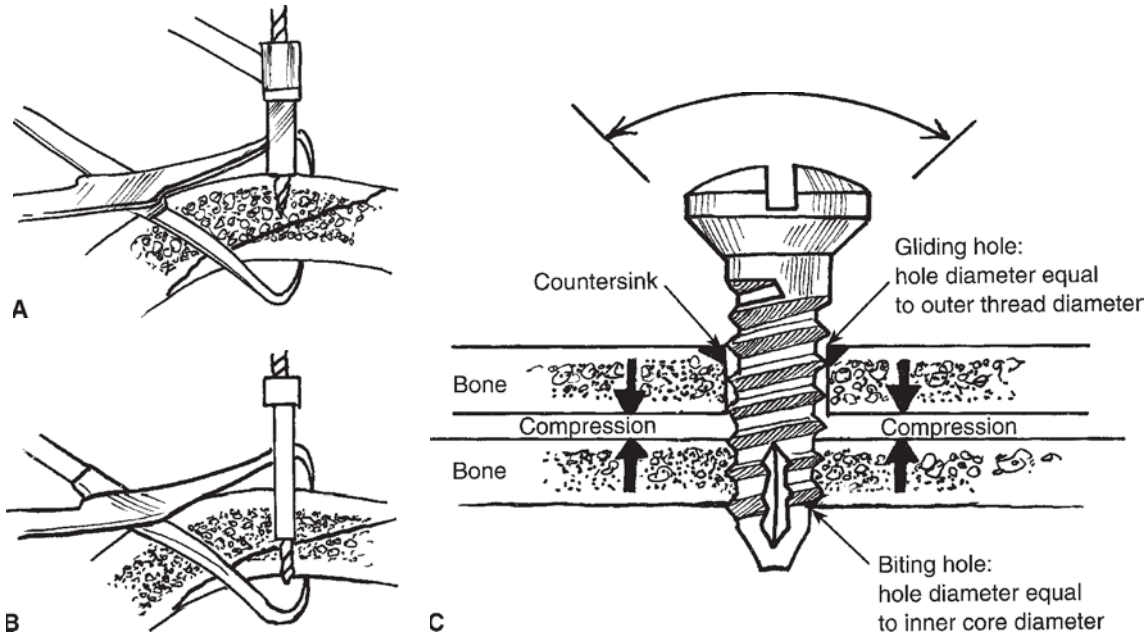

Figure 78.5 **A:** Drilling gliding hole for lag screw placement. The diameter matches the outer screw thread diameter. **B:** Drilling biting hole for lag screw placement. The drill bit diameter matches the inner core diameter of screw. **C:** Detail of lag screw. Diameter of bone hole closest to the head of the screw matches the outer diameter of the threads of the screw, allowing the screw to be pushed through or glide through the first hole without being turned. Diameter of the hole closest to the tip of the screw matches the inner core diameter of the screw. When the screw is tightened, the two pieces of bone are compressed together.

of fixation points in solid bone while minimizing potential injury to underlying structures and working through sometimes difficult exposures. At least two fixation points, one on either side of a fracture, are required for a plate to function as a tension band (resisting distraction forces only). However, there is no rotational stability with two points of fixation. Three points of fixation, two screws on one side of the fracture and one on the other, will prevent plate rotation. However, the fragment with only one point of fixation would still have rotational instability. Four points of fixation, two on either side of the fracture, should be the minimum goal for providing stability of the plate and both fragments. Additional fixation points up to five or six on either side of the fracture may be desirable when bony defects are bridged or healing complications are present. Compression or loading of the bony segments across a fracture, as mentioned before, increases stability. This compression can be provided before plate application by compressing the segments together with a forceps such as a modified towel clip or by the plate itself.

TABLE 78.1 RECOMMENDED PLATE APPLICATIONS

Location[a]	Plate Size
Skull/frontal sinus/supraorbital rims/nasoethmoid complex	Microplates/3-D microplates
Lateral orbital rim	Microplates or low-profile miniplates
Inferior orbital rim	Microplates
Piriform aperture	Low-profile, standard, or 3-D maxillary miniplates or 3-D microplates
Posterior maxillary buttress	Standard or 3-D maxillary miniplates or 3-D microplates
Mandible	Mandibular (thicker than maxillary) miniplates, standard mandibular plates (DCP or EDCP), 3-D mandibular miniplates
Mandible with comminution, infection, or defect	Reconstruction plates

[a]In any location, depending on the situation, wires, heavy sutures, or no fixation at all may be appropriate.
DCP, dynamic compression plate; EDCP, eccentric dynamic compression plate.

INSTRUMENTATION

Application of plates and screws to bone requires specialized instrumentation. Typically, plating systems are self-contained in that they provide all the specialized instrumentation needed for application of the plates. Standard instrumentation for obtaining exposure of the fracture site, however, is not included. Scalpels, scissors, clamps, retractors, and periosteal elevators typically must be supplied in addition to the plating set.

The plating set itself has drill bits that are precisely matched to the screw size. As previously mentioned, a

hole that is too large will prevent the screw from engaging the bone. A hole that is too small may prevent adequate driving of the screw or, in the case of microsystems, cause shearing of the head off of the screw shaft as it is being driven. Typically, there is only one appropriate drill bit diameter for a given screw diameter, and it is usually the size of the screw shaft (i.e., the screw without its threads). An exception to this is found in some microplating systems where drill bits of two different diameters are appropriate for one particular screw diameter. The larger drill bit is used in areas where the bone is harder and thicker to reduce screw head shearing. A smaller bit is used where the bone is thinner or softer, particularly in pediatric cases, to increase screw thread hold. Drill bits with stop collars allow for drilling of a hole to a predetermined depth. The collar prevents overpenetration of the bit, protecting underlying structures.

Drill guides serve several purposes. They protect the surrounding soft tissue from injury by the rotating drill bit and allow for percutaneous drilling. The guide also serves to stabilize the rotating bit, allowing a more precise drill hole. Additionally, guides provide for more precise placement of a drill hole relative to a plate hole. Concentric drill guides place the drill hole in the center of the plate hole. Eccentric guides place the drill hole off center, allowing for compression as the screw head seats in the center of the plate hole. An addition is a guide with a curved extension that points to the drill bit exit site for through-and-through drilling. This extension allows more predictable drilling.

Depth gauges allow precise selection of an appropriate screw length for a given application. When bicortical fixation screws or lag screws are placed, the screw should be long enough to engage the inner cortex without protruding more than a millimeter or two beyond the cortex. When monocortical screws are being placed, the surgeon should have a general idea of the appropriate depth before drilling to avoid damage to underlying structures before a screw is ever placed. For example, monocortical screws being placed over tooth roots should not be longer than 3 to 5 mm depending on location, and the drill hole should not be drilled any deeper than this. Drill bits with collared stops predetermine the drill hole depth and allow appropriate screw length selection without a depth gauge. When tapping is a separate step, the depth gauge should be used before tapping to avoid damage to the threads in the bone.

Some systems contain bone reduction forceps that allow fracture reduction and/or temporary fixation while plates are being bent and applied. Some of these devices are designed to apply compression across the fracture. These devices are useful because they make it possible to avoid having to continually rereduce the fracture for testing of plate contour, which may result in a less precise final reduction and fixation. The bulkier devices require an extraoral approach. Towel, Kelley, or Kocher clamps often will suffice. Drilling of small holes flanking a fracture will sometimes improve the purchase of reduction clamps. Wires can be passed through drill holes on either side of the fracture away from the area needed for plating and used for temporary reduction. Incompletely driven screws can be placed on either side of the fracture and wired or clamped together for temporary reduction.

Various screwdriver tip and screw head configurations exist, and the interface between the two is the important factor. Ideally, the interface provides sufficient strength (i.e., resistance to stripping) so that appropriate torque can be applied to drive the screw into the bone. The interface should also allow retention of the screw on the tip of the driver while it is being brought into position. This retention is achieved in several ways. One is through friction at the interface. The other is for a clamping mechanism that slides down the screwdriver shaft and grips the edges of the screw head. This clamp device can be too bulky for working through percutaneous instrumentation and in other tight locations. Bone wax on the tip of the screwdriver is a third option when the clamp is too bulky and interface friction is inadequate for screw retention. Additionally, the interface affects how quickly the screw can be mounted on the driver, an important factor in dealing with multiple fractures and long repair procedures. It is also important to know what screw type is present when removing hardware so the appropriate screwdriver can be available. Some manufacturers now have screwdriver sets containing all of the common types.

FRACTURE REDUCTION

The structure of the facial skeleton can be viewed as a lattice framework of thick bony buttresses that impart the 3-D strength necessary to withstand the functional forces of mastication (Fig. 78.6). The intervening thin bone adds little additional strength but serves as a partition separating various facial components such as the sinuses, orbits, pharynx, and nasal and cranial cavities. Reestablishment of the anatomic position and continuity of these buttresses is the key to fracture reduction (15). Although of secondary importance, anatomic reduction of the intervening thin bone should be obtained as well, particularly when that bone forms one of the walls of the orbit. Otherwise, orbital contents will sag through the defect into an adjacent cavity, resulting in globe malposition.

Anatomic reduction predisposes a frame of reference that guides the replacement of a malaligned bony fragment into an aligned position. With massive facial trauma, anatomic reference points may be further away and more difficult to expose and/or they may be so comminuted that they cannot provide a reliable indication of the proper reduction. For example, in a simple zygomaticomaxillary complex fracture, the medial aspect of the infraorbital rim, the superior aspect of the lateral orbital rim, the zygomatico-sphenoid relationship in the lateral orbit, and the posterior maxillomalar buttress provide adequate reference points for anatomic reduction. Panfacial fractures resulting in comminution or mobility of these reference points may

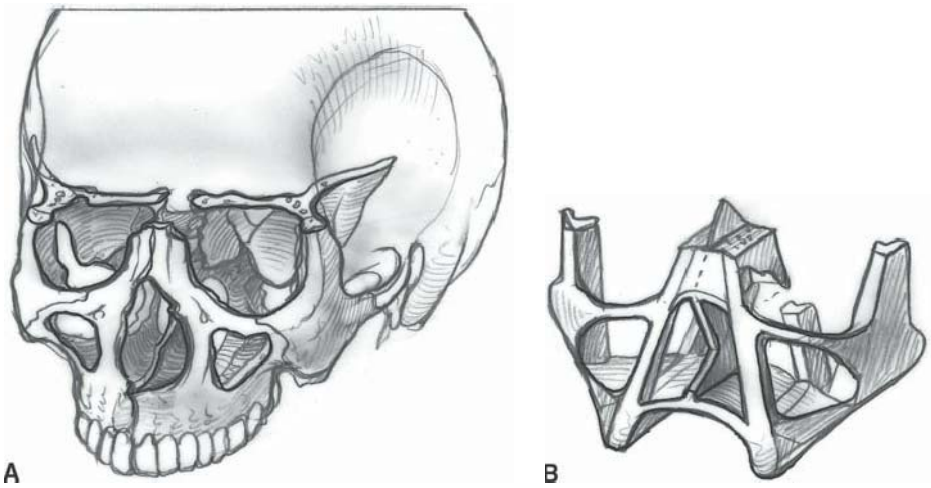

Figure 78.6 **A:** Facial skeleton showing bony buttresses with removal of intervening bone. **B:** Representation of structural buttressing of the midface.

necessitate exposure of the root of the zygomatic arch as another reference point for appropriate placement of the zygomaticomaxillary complex (16). Preoperative virtual surgical planning systems and intraoperative 3-D positioning systems offer some promise in aiding with this problem (17–22).

High-energy injuries may lead to severe comminution or even pulverization of intervening segments of bone. In this case, bony structure is reduced to its anatomic position based on existing reference points, and intervening gaps in the buttresses are bone grafted. Reestablishing bony continuity of the buttresses is imperative because they must ultimately transmit the forces of mastication to the skull base. Sometimes, a bony fragment from a less crucial area can be borrowed and reoriented to establish buttress continuity. Frequently, additional bone is required, however, and outer table calvarial bone is our preferred source for bone grafting because of its reliability and proximity to the injury site (Fig. 78.7). Minimal donor site morbidity and frequent preexisting exposure due to use of the coronal approach to the face are benefits. Other relatively popular donor sites include the ilium and ribs. Hydroxyapatite cement offers promise for dealing with bony defects without attendant donor site morbidity particularly when fiber reinforced (23).

OCCLUSION

For the masticatory apparatus to function properly, stable reproducible occlusion must exist. For occlusion to occur, the cusps of the maxillary dentition must fit into the grooves of the mandibular dentition and vice versa (Fig. 78.8). This is termed intercuspation. Wear facets of opposing teeth should contact each other. The wear patterns may be the only reference when preinjury occlusion is abnormal. Normal molar occlusion in the anteroposterior (AP) dimension is defined as intercuspation of the mesial buccal cusp of the maxillary first molar with the buccal groove of the mandibular first molar. This description does not address transverse molar relationships or anterior dental relationships. A normal transverse relationship exists when the buccal cusps of the mandibular molars are between the buccal and palatal cusps of the maxillary molars. Normal anterior dental relationship occurs when the maxillary anterior dentition is 1 to 3 mm anterior to the mandibular anterior dentition with central incisal overlap of 1 to 3 mm. Increased distance horizontally between the incisors is overjet. Increased vertical distance is overbite or deep bite. Anterior crossbite and anterior open bite are the respective converse conditions.

Because preinjury occlusion is frequently not normal as defined previously, it is useful to question the patient or family about the preinjury occlusion. Dental records are also quite helpful. In the absence of this information, wear facets are the main occlusal guide. When the preinjury occlusion is unclear, then anatomic reduction of the fractures before interdental fixation may be more accurate. There should be no reluctance to open interdental fixation if it is preventing anatomic reduction of bone segments. The interdental fixation and skeletal reduction should correlate. If they do not, a preexisting malocclusion should be suspected.

INCISIONS AND EXPOSURE

Adequate anatomic reduction requires wide exposure to view fractures from several angles. Lacerations may provide some exposure, but frequently more is needed. The entire craniofacial skeleton can be exposed through a combination of hidden or well-camouflaged incisions (24) (Fig. 78.9). The entire mandible except for the condyles can be exposed through intraoral vestibular sulcus incisions (25) (Fig. 78.10), and now, with the addition of endoscopic techniques, even the condylar area can be adequately exposed transorally for endoscopic-assisted repair (26). Small stab incisions through the cheek may be necessary for plating posterior fractures and subcondylar fractures; however, angulated instrumentation promises to reduce the need for even these incisions. Pitfalls associated with the mandibular vestibular sulcus incision include damage to the mental nerve, failure to achieve a watertight closure of the incision, and failure to resuspend the mentalis muscle if the chin is degloved. Intraoral incisions for the mandible are not recommended with comminuted fractures, severe periodontal disease, or hygiene problems. Because of the tangential view achieved when approaching posterior fractures transorally, it can be very difficult to contour a heavy plate to the outer cortex. It is our recommendation that any situation requiring a heavy plate placed posteriorly on the mandible should be approached extraorally through a Risdon and/or submandibular neck incision. Low subcondylar fractures needing repair can be approached transorally, but this requires specialized equipment. Unless endoscopic techniques can be utilized, high subcondylar fractures needing repair will require either a Risdon, retromandibular, or a preauricular incision (27–29).

The inferior maxilla can be exposed through a superior circumvestibular incision. The superior exposure can be extended by elevating the nasal floor mucosa between the inferior turbinate root and maxillary crest. Even further superior exposure can be obtained by incising the nasal mucosa along the cephalic border of the lower lateral cartilage and piriform aperture in a full midface degloving approach. Pitfalls include damage to the infraorbital nerve, nostril stenosis, and leaving inadequate oral vestibular mucosa for wound closure.

Upper facial access can be obtained through a coronal incision elevated in the subgaleal or subperiosteal plane. This incision provides access to the medial, superior, and lateral walls of the orbit; the zygomatic arch; and the bony pyramid of the nose. It additionally uncovers donor sites for cranial bone grafting. Pitfalls include damage to cutaneous sensory innervation and motor innervation to the

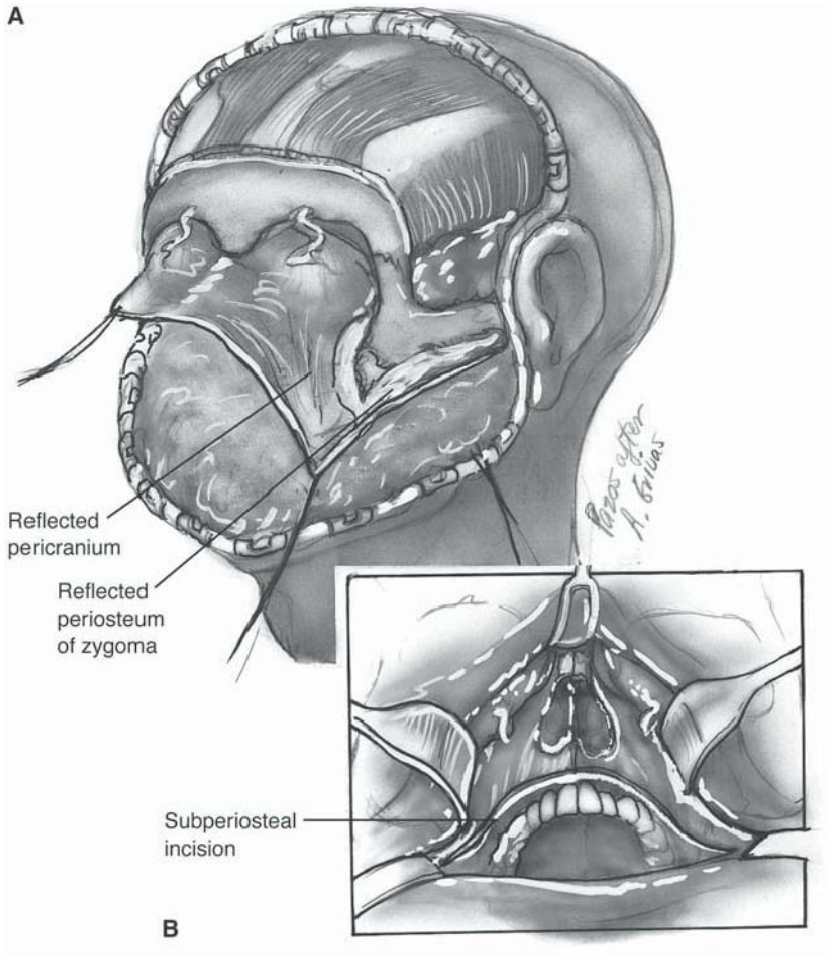

Figure 78.9 **A:** Cranioorbital exposure through bicoronal flap. **B:** Midface exposure through circumvestibular incision.

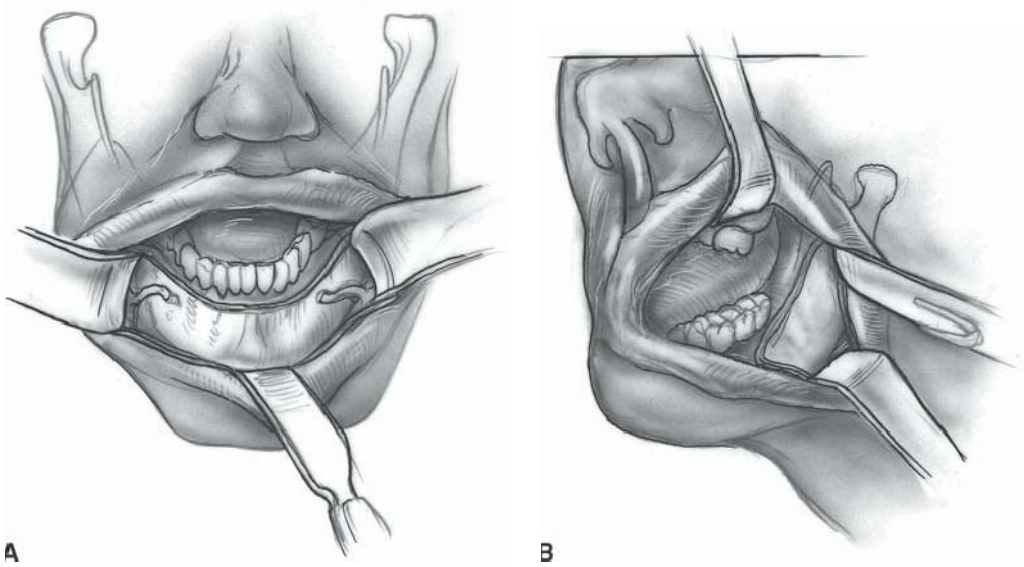

Figure 78.10 **A:** Intraoral approach to the anterior mandible. **B:** Intraoral approach to the angle of the mandible.

frontalis muscle or inadequate closure of the galea, both of which can lead to brow ptosis.

Infraorbital rim and orbital floor exposure is still limited, however, and a lower lid incision is required for that exposure. We prefer either a subciliary incision or a transconjunctival incision with or without a lateral canthotomy and inferior cantholysis for increased exposure when necessary. Inferior lid crease and rim incisions are other options in this area, although they are rarely used today. Careful closure of these incisions and canthal repair are critical to reduce lid complications of entropion or ectropion.

If a coronal incision is not performed, then access to the frontozygomatic region can be obtained through a lateral brow incision or a superior lid crease incision (12). Medial orbital wall and nasoethmoid exposure can be obtained through a broken external ethmoid-type incision. Some people use a gull-wing incision, but the scar can sometimes be quite unacceptable. If the nasal dorsal skin between the incisions is sufficiently elevated and mobilized, then adequate exposure can usually be obtained by retracting the skin without having to make the transverse incision across the nasal dorsum. A transcaruncular incision may provide adequate access to the medial orbit (30).

APPROACH TO PANFACIAL FRACTURES

Severe and complex facial disruptions represent difficult challenges for the craniomaxillofacial surgeon, because usually few reference points are available to help the surgeon determine how to reposition the multiply fractured fragments. Nonetheless, the principles of repair remain the same, and careful attention to the procedures described previously will lead to the best possible outcomes.

Emergencies related to massive facial trauma must be attended to first (Table 73.2). The airway can be threatened by anatomic obstruction, blood, or both and must be secured. Gross hemorrhage must be controlled, preferably with direct pressure. Definitive control should be obtained in the operating room to prevent damage to important nonvascular structures. Occasionally, partial reduction of severely displaced fractures is necessary to aid in the control of hemorrhage. A few interdental wires can be placed emergently to stabilize this gross reduction and alleviate some of the pain associated with mobility of the fractures. Soft tissue injuries should be irrigated and repaired if the patient is not planned for immediate fracture repair in the operating room. Dental avulsions and fractures through the pulp cavity should be treated urgently if the damaged teeth are to be salvaged, and other dental injuries should be identified and appropriate consultations obtained (31). Preoperative antibiotics have been shown to reduce infectious complications (32). Tetanus should be considered in grossly contaminated wounds.

History and physical examination can provide some initial indication of the extent of facial injuries. Historical information such as mechanism of injury and energy of impact is useful in assessing the extent of the injury. Ecchymosis patterns including raccoon eyes and Battles' sign can be indicative of skull base fractures. Other soft tissue findings such as the bowstring lid test can indicate canthal detachments. Palpation of bone surfaces will allow detection of step-offs and mobility. Documentation of cranial nerve function is critical to distinguish injury-associated deficits from iatrogenic deficits occurring after fracture repair. Other factors such as neurologic and visual function are frequently impaired with panfacial fractures. Neurologic and ophthalmologic assessments are necessary (33).

TABLE 78.2 EMERGENCIES FACIAL TRAUMA

Situation	Intervention
Airway obstruction	Intubation, tracheotomy, bronchoscopy
Hemorrhage	Fluid resuscitation, direct pressure, temporary reduction of severely displaced fractures, control in operating room, fluid resuscitation
Central nervous system injury	
Cervical spine	Immobilize
Brain	Neurosurgery evaluation
Reimplantable avulsions	
Tooth	Reimplant and stabilize
Large areas of soft tissue	Reimplant ± microvascular reanastomosis ± hyperbaric oxygen treatment
Globe rupture	Ophthalmology evaluation, repair or enucleation
Optic nerve compression	Medical management Surgical decompression

Radiologic evaluation is key to the full assessment of massive facial trauma (34,35). In our institution, axial computed tomography (CT) is obtained as part of the initial trauma protocol when head and facial injuries are present. Because of cervical spine clearance issues, acute direct coronal CTs are rarely obtained. If complex periorbital fractures are present, then when the patient's condition permits, direct coronal CT is obtained. The mandible is separately evaluated with plain radiographs and panoramic radiography if the patient's condition permits. CT evaluation of the mandible provides additional information as well (36). With severe injury, 3-D reconstructions may be helpful.

With severe craniofacial injuries, there is a high risk that injuries may involve the eyes, dura, and neural structures of the skull base and cervical spine. It is essential that the surgeon be attuned to these possibilities, because failure to recognize these associated injuries could have dire consequences for the patient. Globe injuries must be evaluated by ophthalmology. Ruptured globes often require enucleation, although occasionally minor ruptures may be repaired, and this situation may mandate postponement of the repair of the orbital/periorbital fractures. Similarly, a retinal detachment may require a period of healing before surgical manipulation of the surrounding bones.

It is critically important to identify optic nerve compression, because rapid and aggressive management of this injury may preserve or even salvage vision. When optic nerve compression is associated with frontonasal fractures of the anterior skull base, the subcranial approach as advocated by Raveh et al. (37,38) provides excellent access to the optic nerve canal(s) for decompression. In the subcranial approach, the nasal bones and front wall of the frontal sinus are removed en bloc and saved for later replacement. The posterior wall is then opened, allowing full visualization of the anterior cranial fossa without olfactory compromise or significant brain retraction. This approach also allows for the repair of associated skeletal injuries in the anterior skull base, medial orbits, frontal area, and nose. Rigid fixation allows for the dependable repositioning of the bone fragments and thereby makes the subcranial approach possible. Without rigid repair of the completely removed nasofrontal bone fragments, there would be a high probability of malposition and/or resorption of the bone. Most authors advocate a trial of very high-dose steroids before optic nerve decompression is attempted (39). An eye that shows no light perception from the moment of impact is probably irretrievable, and the value of decompression in this situation is controversial at best. On the other hand, if a patient has progressive visual loss or if a seeing eye progresses to no light perception after trauma to the area of the posterior orbit and/or anterior skull base, and if steroids are not effective in restoring vision within 24 to 48 hours, then most authors would agree that the potential benefit of optic nerve decompression probably outweighs the risks. If the subcranial approach is not appropriate (or desired), then the optic canal can be approached endoscopically through the sinuses or from above via an intracranial approach (40). Recently, some periorbital endoscopic approaches have been described that show promise.

When the floor of the anterior fossa is disrupted, then it is convenient to perform the repair at the time of facial fracture reduction. Here again, the subcranial approach provides excellent access to this area (38). It allows for repair of the anterior fossa dura with a fascial patch or a pericranial flap, without the need to significantly elevate or retract the frontal lobes. This is a very desirable feature of the technique. In most of these panfacial fracture cases, the brain has been injured and is likely to be swollen.

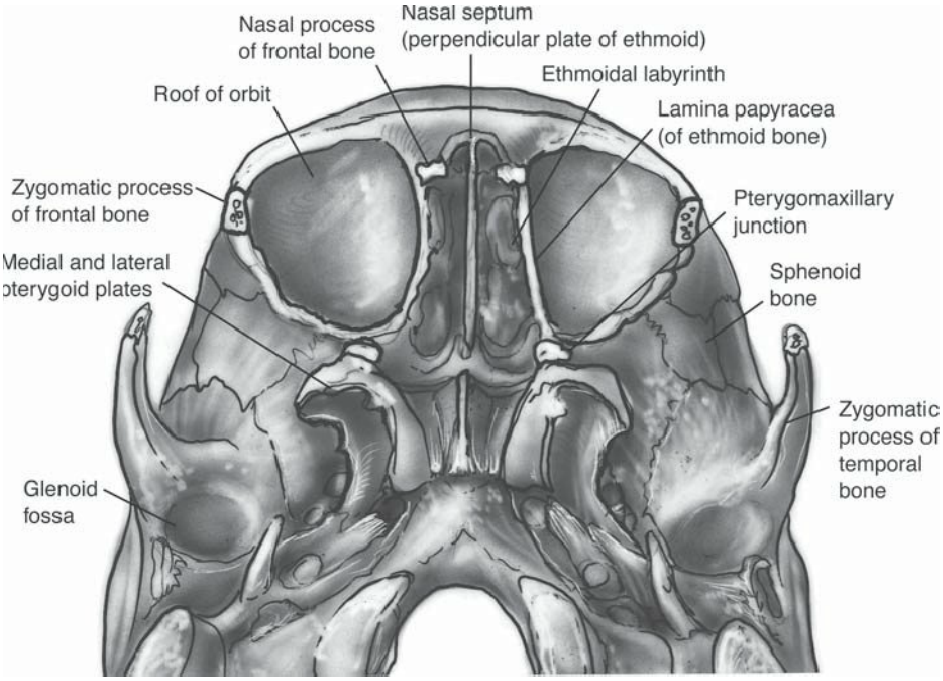

Figure 78.11 Skull base detail showing major areas of attachment of the facial skeleton to the cranial skeleton. These include the nasal and zygomatic processes of the frontal bone, the zygomatic process of the temporal bone, the nasal septum, and the pterygomaxillary junction.

Therefore, acute repair should be considered to decrease the likelihood of cerebrospinal fluid leakage and thereby decrease the risk of later development of meningitis. The subcranial approach avoids brain retraction due to the inferior and direct angle of approach, making early intervention a feasible option in this circumstance.

With regard to timing of repair of fractures, unless a patient's overall condition prevents it, immediate repair has been advocated as the best approach (41). Immediate repair allows visualization of facial structures before the full development of injury edema, which generally occurs 24 to 48 hours after the injury. However, associated injuries frequently require several days for stabilization of the patient (42). Delaying repair may lead to increased bacterial contamination and therefore increased risk of infection. With further delay, the soft tissue envelope around the fractured skeleton begins to fibrose and contract, increasing resistance to anatomic reduction. With increased delay, callus formation and resorption of some of the fine detail of the fracture edges increases the difficulty of mobilization and reduces the ability to achieve an accurate reduction.

As previously stated, one of the major problems with massive facial trauma is a lack of reference points for anatomic reduction. Approaches yielding wide exposure are preferred (43) although there has been a recent trend toward less invasive approaches (44–47). With maximal exposure of the facial skeleton, repair should begin at the periphery, including recreating the contours of the skull and the mandible. The ultimate reference for facial skeletal position is the skull base (Fig. 78.11). For the mandible, this reference is through the condyles. Therefore, the importance of open reduction of subcondylar fractures in this situation cannot be overemphasized. For the middle and upper face, the vertical reference points are the lateral and medial orbital rims, the nasal radix, the piriform apertures, and the posterior maxillary buttresses. Often underutilized is the important horizontal AP reference along the zygomatic arches. Anterior skull fractures can obscure some of these reference points, but then, the next higher point of skeletal stability becomes the new reference point. Once anterior skull fractures are repaired, facial fracture repair can proceed. A systematic approach working from areas of stability toward areas of instability is required. All fractures that are to be repaired should be exposed and reduced before any final fixation. Vertical, horizontal, and sagittal facial dimensions must be restored (Fig. 78.12). We often prereduce complex fractures with wires or sutures initially, withholding more rigid fixation until all fractures have been adequately reduced. Maxillomandibular interdental fixation should be achieved before skeletal fixation as well. Release of maxillomandibular fixation may be required to effect anatomic reduction of bony segments, particularly when preinjury occlusion does not appear to have been normal. Cutting an arch bar over an area where a fracture proceeds between teeth may also be required to achieve anatomic bony reduction. The split arch bar is then repaired once reduction is obtained.

Typically, fracture fixation proceeds centripetally toward the nasal region (centripetally) (Fig. 78.13), although some advocate starting with the nasoorbitoethmoid region (centrifugally). Skull fractures, frontal sinus fractures, and any intracranial injuries are addressed first. A subcranial approach as previously mentioned through the nasofrontal region is our preferred method to access the anterior cranial fossa and medial orbits when the anterior skull base is involved. The mandible should be repaired, and

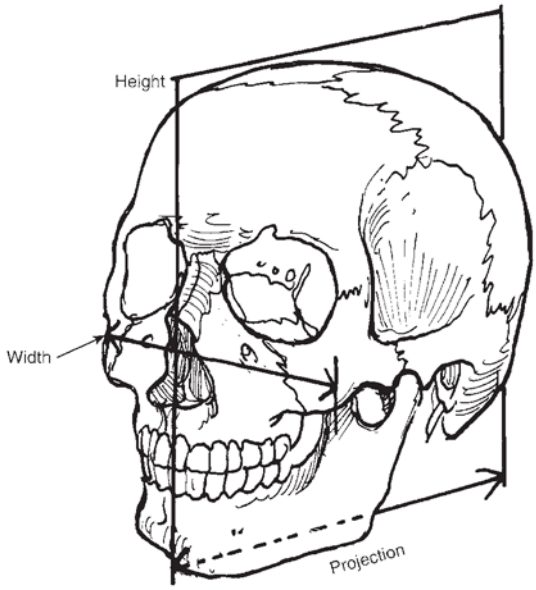

Figure 78.12 Important dimensions of the facial skeleton to be reestablished during reconstructive efforts.

if necessary defects should be bridged with reconstruction plates. Whether the mandible is severely comminuted or partially absent, the occlusal relationship remains the priority concern and the best indication of the premorbid shape. When the dentition is lost or absent, occlusion becomes less critical and obviously unusable as a landmark. Mandibular height should be reconstituted, using a costochondral graft to reestablish the condylar position if the condylar head has been lost. In the case of bilateral displaced subcondylar fractures and midface fractures, at least one of the subcondylar fractures will need to be opened and internally fixated to provide a reference for lower third facial height. If necessary, zygomatic arch fractures are then fixated to provide an AP reference for the malar eminence (48). Arch repair is performed using wires whenever possible, because even small plates on the arch may create some broadening of the cheek. If plate fixation is needed, the smallest (thinnest) plates available should be used. In rare cases, this may require bone grafting of one or both malar eminences to reestablish the proper facial projection. The maxilla and its dentition can then be suspended rigidly from the zygomas, using plates and/or bone grafts to ensure fixation and bony continuity. Lateral maxillary buttress, piriform aperture, and lateral orbital rim fractures are then repaired. Then the orbital rim contours are reconstructed, trying to recreate the natural shape of the orbits with bone grafts or implants while making sure that the globes are returned to their proper position with a 2- to 3-mm overcorrection to allow retropositioning as swelling decreases. Note that the vertical position of the globe should not be overcorrected. Any buttresses with segmental defects after appropriate reduction of the skeletal structures are bone grafted. The bone grafts are stabilized and positioned with bridging plates and/or screws. Once buttress continuity has been reestablished, remaining lamellar bone defects are addressed as needed. The bimalar diameter can usually be reestablished based on the posterior buttresses after occlusal relationships have been reestablished. With severe comminution, however, repair of the nasoethmoidal complex provides additional reference information for restoration of the bimalar diameter. Recent advances include the use of rapid prototyping, which allows for the use of prefabricated implants (49), and the use of a sterilized skull model to allow for plate adaptation (50). In addition, the advent of image guidance systems has allowed for careful planning and carrying out of complex facial repairs (17). Surgical planning can be carried out at a workstation preoperatively, and then a wand can be used at surgery to identify the positioning of bone fragments and grafts relative to the desired positions (17).

Orbital floor continuity must be reestablished. We prefer autogenous bone for this repair, although some prefer

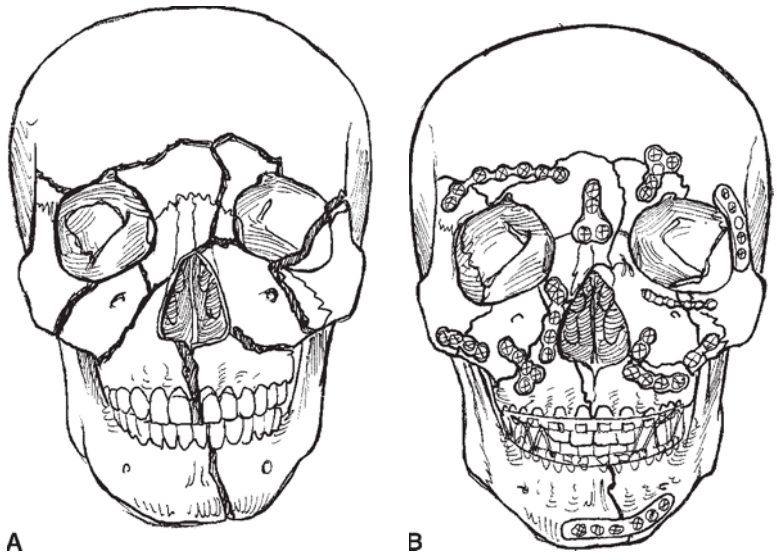

Figure 78.13 **A:** Panfacial fractures. **B:** Repair of fractures with rigid fixation. Fractures are typically repaired centripetally, working from the skull base and the mandible toward the midface and working from the lateral midface toward the medial midface.

alloplastic implants for this location; this is clearly a controversial issue. The previously mentioned titanium anatomic orbital plates and titanium polyethylene composite plates are becoming popular. Perpendicular plate of ethmoid and/or septal cartilage, if not severely fractured, can be used to replace the orbital floor, walls, or roof. Cranial bone or the nonfractured anterior face of the maxilla also do well here. Very small defects can be covered with absorbable plates, gelatin film, or homograft dura. The superior, medial, and lateral orbital walls need to be repaired if they are displaced enough to impinge on orbital contents or significantly alter orbital volume. A defect greater than 2 to 3 cm in diameter of the anterior face of the maxilla itself may need to be repaired; otherwise, facial soft tissue will collapse into the sinus, creating a subtle but noticeable deformity of the melolabial region.

Finally, the nasoethmoid complex is addressed. The typical telescoping collapse must be reduced and reprojected. Frequently, the lamina papyracea needs to be replaced with bone grafts to support forward projection and prevent the herniation of periorbita into the ethmoid sinuses. It is also important to create a structure against which the medial canthal ligament can reattach after fixation. The projection of the nose is reestablished by cantilevering off the frontal bone and/or fixation of the medial orbital region. If the nasal dorsum is deficient, a primary bone graft should be placed.

Once complete fracture reduction has been achieved, certain soft tissue structures that were detached traumatically or to provide exposure must be resuspended. The medial and lateral canthi should be suspended from the adjacent bone slightly posterior and superior to their original insertion sites either with wires or heavy nonabsorbable sutures. For medial canthal suspension, a permanent suture may be utilized. It is placed through the ligament; passed through the nasal septum, lamina papyracea, and/or drill holes in the medial orbital wall bone grafts; and positioned so that the ligament is pulled posteriorly and superiorly. The medial tension is then adjusted using the suture, which is fixed to the contralateral frontal bone using a plate hole, a screw, or a hole drilled through the medial supraorbital rim.

As previously mentioned, the mentalis muscle should be suspended from drill holes in the menton. Soft tissue of the midface might need to be resuspended too if it was significantly dissected. The lacrimal ducts should be cannulated if they are interrupted or do not flow freely when irrigated. Access incisions must be closed meticulously to prevent complications. Failure to close the galea in the bicoronal incision can lead to brow ptosis. Failure to obtain watertight closure of intraoral incisions can lead to dehiscence and plate exposure. Particular attention should be paid to the lower lid incision closure to prevent entropion or ectropion. A Frost stitch should be placed through the lower lid and fixed under tension to the forehead (with tape). This is left in place for 24 to 72 hours, to stretch the lower lid.

SOFT TISSUE LOSS

The acute repair of soft tissue loss remains controversial when dealing with facial injuries. Of course, whenever it is feasible, it is preferable to repair soft tissue loss and bone loss simultaneously. In years past, early attention was directed at restoring the soft tissues, with the belief that the primary repair of the facial skeleton could not be successfully performed in the absence of adequate soft tissue coverage. Unfortunately, in the absence of proper skeletal support, reconstructed soft tissues often shrank and retracted, leading to the development of contractures that frequently interfered with the ultimate hard-tissue reconstruction, and a satisfactory outcome was less likely to result.

The advent of rigid skeletal fixation has allowed for a rethinking of this approach, because rigidly fixed bony structures will generally survive even in the absence of adequate soft tissue coverage. This has proved particularly helpful in shotgun-blast injuries, which can be very destructive to both skeletal and soft tissues. An example is shown of the case of a stainless steel mandibular reconstruction plate that was placed across a shotgun-blast defect of the anterior mandible (Fig. 78.14). The defect extended from midbody to midbody. Deltopectoral skin was used to incompletely cover the steel plate. (Note that this approach could not have been considered before the introduction of rigid fixation techniques, because mobile exposed bone fragments often become infected and necrosed.) Ultimately, after release of the flap and closure of the soft tissue defect, the space (which had been maintained by the reconstruction plate) was reconstructed with an iliac corticocancellous graft that was fixed to the plate. The graft took completely, and the plate was later removed, leaving fully recontoured mandible.

The same principles have been similarly applied to midfacial defects. The availability of microvascular free tissue transfer has made it possible to perform immediate soft tissue and/or skeletal reconstruction of large defects when the patient's condition is appropriate. Restoration of the skeletal framework (or its shape) should be accomplished as acutely as possible. Although the soft tissue reconstruction is now generally performed acutely when possible, it can be delayed if necessary due to the needs of the individual patient and/or the techniques available for repair.

COMPLICATIONS AND REVISIONS

With severe injuries, it is not uncommon to obtain a less than perfect result, though an excellent reconstruction is often acceptable to patients who appreciate the severity of their initial injuries. Still, selective revision surgery can enhance an outcome and convert an acceptable result to an excellent one. The judicious use of bone grafts or alloplastic implants may be necessary to build up deficient areas or reposition a globe. Occasionally, a malunion may

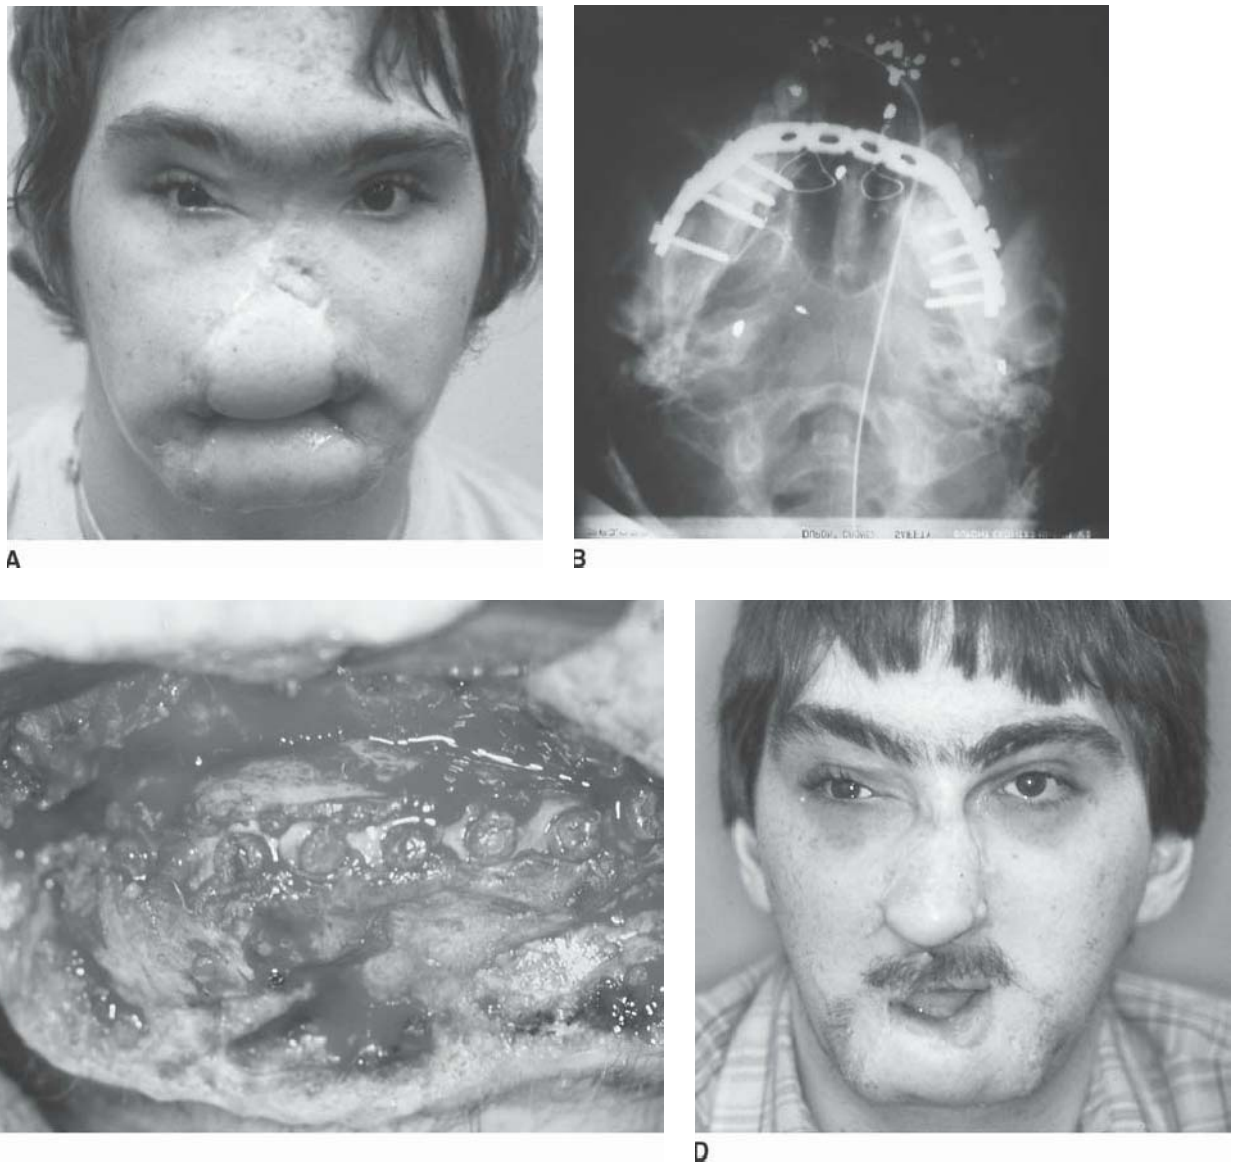

Figure 78.14 **A:** Patient with midfacial shotgun-blast injury after soft tissue repair. **B:** Initial maintenance of mandibular spacing with reconstruction plate. **C:** Bony continuity reestablished with graft, and plate removed. **D:** Result after additional soft tissue surgery.

result, and one of the options available is the remobilization of facial bones via osteotomy followed by repositioning and refixation with bone grafts as needed. The techniques for this are beyond the scope of this chapter, but it is important to offer this option to a patient with a residual deformity.

It is not uncommon for craniomaxillofacial surgeons in tertiary care centers to receive referrals of patients who have already undergone initial and sometimes subsequent repairs. Occasionally, patients have not been repaired at all for a variety of reasons. It is important for the tertiary surgeon to avoid judgmental commentary and focus on what can be offered to the patient. These are challenging cases both technically and emotionally, and they should be approached with the utmost skill and diplomacy.

A host of complications may be seen, including ectropion, entropion, facial scarring, epiphora, numbness, facial nerve injuries, diplopia, malocclusion, facial asymmetry, and temporomandibular joint dysfunction (Table 73.3). Familiarity with the multiplicity of problems and outcomes that can result will make it possible for the facial plastic surgeon to offer the patient the widest variety of options for care.

TABLE 78.3 COMPLICATIONS FACIAL TRAUMA

Type	Management
Osseous	
Osteitis	Intravenous antibiotics
Delayed union	Observation, prolonged interdental fixation
Osteomyelitis	Intravenous antibiotics ± hyperbaric oxygen, debride and revise
Nonunion	Debride and revise
Malunion/malocclusion	Osteotomize and reposition
Fibrous union with poor function	Debride and revise
Bone loss	Free bone graft ± revascularized
Temporomandibular joint dysfunction	Etiology specific
Soft tissue	
Deficiency	Local/regional/distant tissue transfer
Scarring	Scar revision, laser resurfacing, etc.
Ptosis	Etiology-specific ptosis repair
Lagophthalmos	Scar revision, weights, springs
Entropion	Lid revision, free grafts
Ectropion	Lid revision, free grafts
Nasal obstruction	Septoplasty, lysis of synechiae, valve surgery
Neurosplanchnic	
Brain injury	Per neurosurgery
Globe injury	Per ophthalmology
Globe malposition	Orbital bone grafts/repositioning
Cerebrospinal fluid leak	Endoscopic or open repair
Meningocele/encephalocele	Surgical repair
Cranial nerve dysfunction	Compensatory procedures
Glandular dysfunction	Artificial tears/saliva Punctal plugs

HIGHLIGHTS

- Management of massive or complex injuries follows the same principles used for less severe injuries.
- Anatomic reduction of fractures offers the best chance of return to preinjury function and appearance.
- Rigid internal fixation stabilizes and shields a reduced fracture from biomechanical forces that would act to displace the fracture until bone healing can occur.
- Fracture repair is best achieved as early after the injury as possible with the following being considered: the patient's overall condition takes priority and maximal soft tissue swelling occurs 24 to 48 hours after the injury.
- Within limits, the stability of an internal fixation system increases with the rigidity and thickness of the material, the size and number of screws, the thickness of the underlying bone, and compression of the fracture edges.
- Application of a screw to be a successful fixation point for a plate requires maintenance of a healthy cylinder of bone lining the drill hole that "hugs" the inner shaft of the screw as it or a tap cuts threads in the bone.
- Plate type and location selection is made to provide adequate stability to a fracture while minimizing application difficulty, hardware load, and prominence through the soft tissue.
- The 3-D skeletal buttress structure and continuity must be reestablished to restore facial appearance and the ability to withstand biomechanical forces.
- Resuspension of key soft tissue structures such as the medial and lateral canthi and the mentalis muscle is necessary to obtain the best result from treatment of massive trauma.
- Minor complications are not uncommon and can usually be managed with minor revisions. Major complications from tissue loss or malposition are best prevented, but major reconstructive procedures with osteotomies and bone grafting can provide satisfactory final results.

Surgical Approaches to the Craniofacial Skeleton

79

John F. Hoffmann

There have been three principal advances that have revolutionized the management of craniofacial trauma over the last several decades. These are advanced imaging, sophisticated internal fixation technology, and aesthetic surgical approaches. Modern computed tomography scanning allows for visualization of the craniofacial skeleton in multiple perspectives as well as in three dimensions. This enables the clinician to precisely identify fracture patterns and anatomy. Sophisticated internal fixation plating systems have evolved to allow the surgeon to precisely and rigidly fixate craniofacial fractures so that normal anatomy can be restored and stabilized against the forces of mastication. Contemporary surgical approaches to the craniofacial skeleton have also advanced to allow one to expose facial fractures in a way that provides optimal visualization for fracture reduction and placement of fixation hardware while minimizing soft tissue damage and scarring. In some instances, surgical incisions for aesthetic facial surgery have been adapted to the exposure of the craniofacial skeleton. An example would be the lateral upper lid crease incision that has been adapted from blepharoplasty procedures. The surgeon should be familiar with the relaxed skin tension lines of the face and neck and place elective incisions within these whenever possible, thereby minimizing the visibility of the final scar. Meticulous and gentle soft tissue handling techniques are paramount to obtaining rapid healing with minimal scarring. Similarly, the use of electrocautery should be judicious especially in areas of thin soft tissues and around hair follicles. Intimate knowledge of the location and course of critical nerves—such as the facial and trigeminal nerves—is essential. This chapter discusses the various options for exposing the craniofacial skeleton from the frontal sinus to the mandible. Endoscopic approaches have gained some popularity in the management of orbital, frontal sinus, zygomatic arch, and mandibular condyle fractures. These techniques are beyond the scope of this chapter, however.

UPPER FACIAL SKELETON AND FRONTAL SINUS

The workhorse approach for the upper facial skeleton is the hemicoronal or full coronal incision. This classic surgical approach enables the surgeon to expose the upper frontal and parietal skull all the way inferiorly to the superior orbital rims, orbital roof, and nasoethmoid region as well as the entire zygomatic arches (1). The coronal approach also can be employed in those instances in which cranial bone grafts will need to be harvested. In cases of unilateral fracture, a hemicoronal approach extending from the midline down to the ipsilateral pinna may be considered. It must be remembered, however, that a hemicoronal flap will have more limited inferior exposure compared to a full coronal flap due to the reduced inferior rotation of the flap. Coronal flaps typically have robust blood supplies and can be designed to include pericranial tissues as well. In the instances where the posterior table of the frontal sinus is fractured and the risk of cerebrospinal fluid (CSF) leakage is high, the surgeon should be very careful to preserve the vascularity of the pericranial tissue as a pericranial flap may be very helpful in these cases to repair dural injuries.

The coronal incision has classically been described as a straight-line incision extending from just above the pinna, coursing several centimeters behind the anterior hairline across to the contralateral side as needed. Typically, the incision is made several centimeters behind the hairline (Fig. 79.1). In men, one may need to locate the incision more posteriorly to accommodate male pattern baldness. One disadvantage of the straight-line incision, however, is that it may be more visible. This is particularly true when the hair is wet as it may part away from the incision making it very visible (Fig. 79.2). Alternatives to the straight-line incision include a curvilinear incision or a "sawtooth" design (Fig. 79.3) (2). These modifications are intended to help camouflage the parietal portion of the

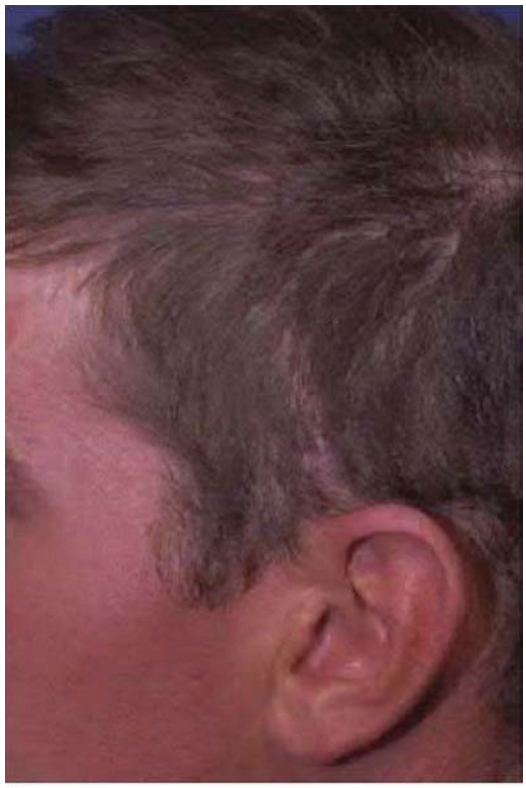

Figure 79.1 Typical coronal incision location for women and men with no significant baldness. In men with baldness, the incision is moved posteriorly as needed. (From Ellis E, Zide MF. *Surgical approaches to the facial skeleton*, 2nd ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2006, with permission.)

coronal incision. As these incisions are more irregular, wet hair will be far less likely to part away from the incision in a straight line and thereby make it less visible. A sawtooth design, however, may predispose the points of the sawtooth to some alopecia, thereby making the incision more visible. Regardless of which incision design is selected, the incision should be made parallel to the hair follicles, thereby minimizing the risk of injuring the follicles. It is also advisable to minimize the use of electrocautery along the incision line as this also may widen the area of alopecia and potentially lead to more hypertrophic scarring. Raney clips or compression sutures may be used along the

Figure 79.2 Coronal incision scarring. **A:** Highly visible strait scar, especially noticeable when the hair is wet and falls away from the scar. **B:** Intraoperative design of a curvilinear coronal incision.

C

edges of the incision to aid hemostasis, but these also may lead to more alopecia due to pressure injury of the follicles. The lateral extent of the incision is normally at the apex of the ear. In cases where exposure of the zygomatic arch is anticipated, the incision may be extended inferiorly in a preauricular crease down to the tragus. Centrally, the flap may be elevated in a subgaleal or in a subperiosteal plane. If the flap is raised initially in the subgaleal plane, then a transition will need to be made through the pericranium above the fracture site itself. The surgeon must anticipate the potential need for a pericranial flap early in the flap design and plan accordingly. A pericranial flap may be developed separately or dissected off of the galea once the flap has been raised (Fig. 79.4). In the parietal and temporal aspects of the flap, the typical dissection plane is in the loose areolar tissue beneath the temporoparietal fascia and just superficial to the deep temporalis muscle fascia. Blunt dissection over the temporalis fascia allows for rapid inferior elevation of the flap in a relatively bloodless plane. One must, however, sharply release the fascia along the anterior temporal line as it is firmly affixed to the periosteum here. As will be discussed below, the lateral blunt dissection must be stopped several centimeters above the zygomatic arch in order to avoid injury to the frontotemporal branches of the facial nerve.

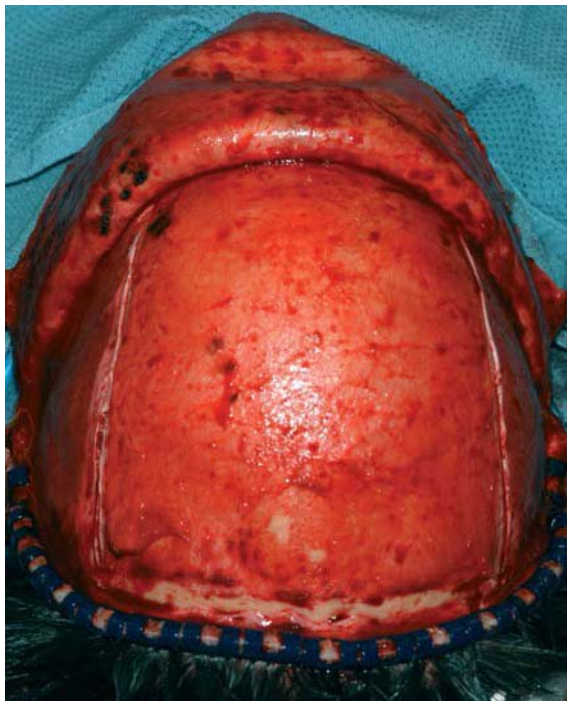

Figure 79.3 Sawtooth design alternative for a coronal incision. This may lead to alopecia at the tips of the triangular incision points.

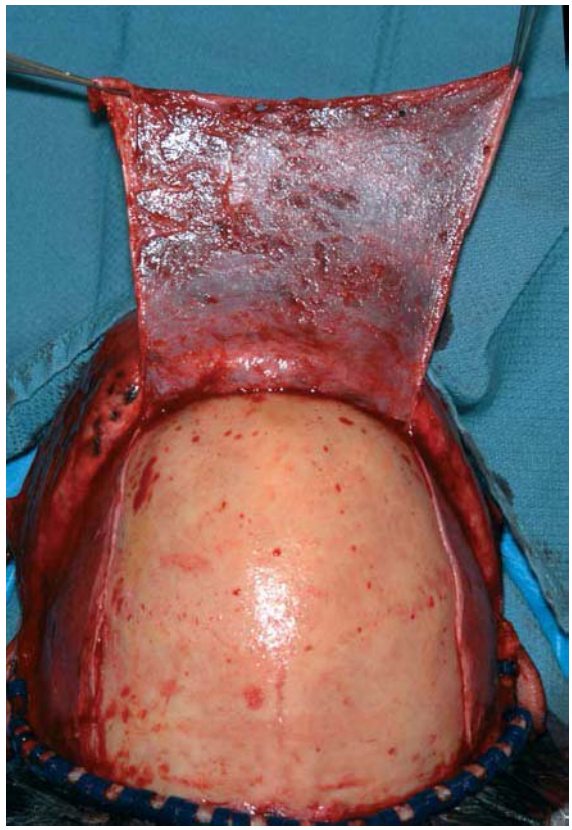
As the flap elevation proceeds inferiorly, the surgeon should carefully identify and preserve the supraorbital neurovascular bundles. The supraorbital structures may emerge from the orbit via a notch in the superior orbital rim or from a complete bony foramen usually at the junction of the medial and central thirds of the orbital rim (3). In order to fully visualize the superior orbital rim and to extend dissection into the nasoethmoid region or the orbital roof, the supraorbital structures must be mobilized. If the flap has been raised in a subgaleal plane, then a transition through the pericranium is made several centimeters above the supraorbital rims. If the supraorbital bundles are within a notch, then the careful subperiosteal elevation will release them. If, however, these structures exit through a foramen, then an osteotomy may be necessary to fully mobilize them (Fig. 79.5). Once the supraorbital structures are released, the dissection can proceed inferiorly to expose the nasal root, the medial canthal region, the nasal ethmoid complex, and the orbital roof. The surgeon should be careful during exposure of the medial orbital wall and nasoethmoid region to not detach the medial canthal tendon from the bone as this would lead to soft tissue telecanthus, which can be quite difficult to correct. The coronal incisions will also provide excellent exposure of the lateral orbital rim and the frontozygomatic junction, a site frequently involved in facial fractures. Again one should be cautious to not detach the lateral canthal tendon during subperiosteal dissection as well to prevent postoperative malposition of the lateral canthus.



The coronal approach also provides an ideal surgical exposure of the zygomatic arches (4). Exposure of the arches may be necessary either in severely comminuted and displaced zygomaticomaxillary–orbital fractures or in LeFort III fractures. With exposure of the arches, however, the surgeon must alter his dissection plane in order to avoid injury to the frontotemporal branches of the facial nerve. Below the level of the zygomatic arch, the facial nerve travels beneath the superficial musculoaponeurotic system (SMAS) layer. At the level of the zygomatic arch, however, the fascial planes coalesce and the facial nerve branches pass over the zygomatic arch where they are quite

vulnerable to surgical injury. Once above the zygomatic arch, the facial nerve lies within the temporoparietal fascia on its way to the corrugator and frontalis muscles. In order to avoid injury to the facial nerve as it passes over the zygomatic arch, the surgical dissection plane must change. If dissection were to continue along the surface of the deep temporalis muscle fascia, then the facial nerve would be damaged at the level of the arch. To avoid this, the dissection plane should change several centimeters above the zygomatic arch (Fig. 79.6). An incision should be made through the superficial layer of the deep temporalis fascia, and then dissection should continue inferiorly on the undersurface of this fascia. This space contains the temporal fat pad, and one should minimize disruption of the fat pad during dissection to help minimize postoperative atrophy. Atrophy of this fat pad can lead to hollowing within the temporal fossa, which is aesthetically displeasing and is difficult to correct. The zygomatic arch should be approached along its superior border at which point the periosteum is incised and elevated. The facial nerve branches will then be contained within the soft tissues of the flap. The arch can then be exposed along its entire length from its origin at the temporal bone to its attachment to the malar eminence (Fig. 79.7). At the conclusion of the procedure, it is critical to resuspend the soft tissues to avoid ptosis of the malar tissues (5). This is typically done by suturing the mobilized fascia back to the temporalis fascia, taking care while placing the sutures to not injure the facial nerve.

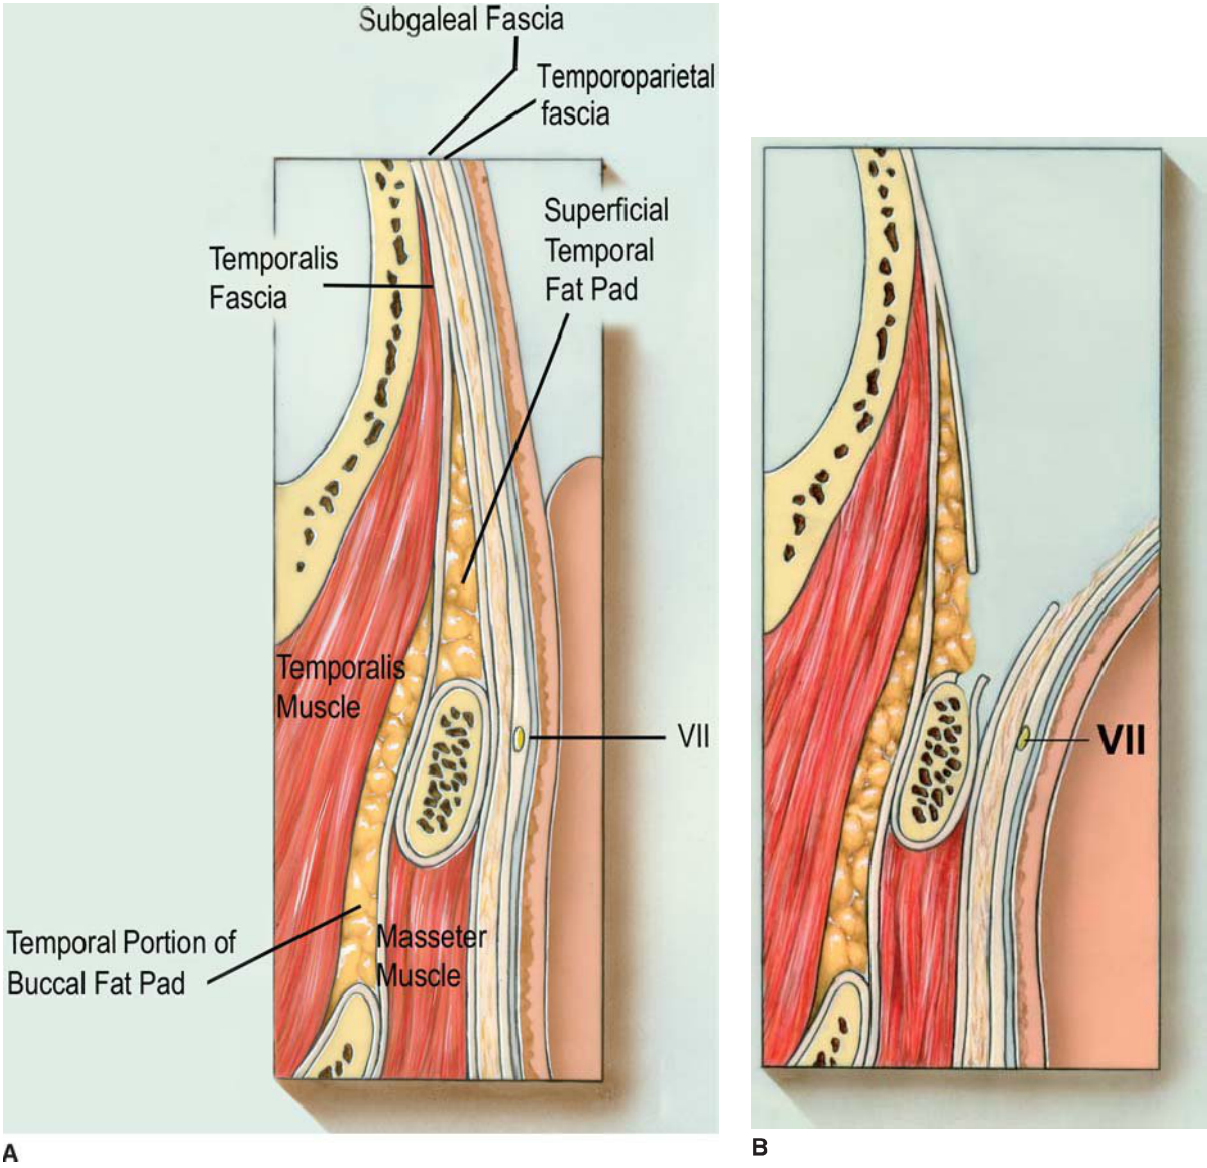

Figure 79.6 Exposure and dissection planes in temporal region and zygomatic arch. **A:** Tissue planes and location of frontal branch of facial nerve over the zygomatic arch. **B:** Dissection plane over zygomatic arch to avoid injury to the facial nerve branches. Above the arch the plane of dissection passes through the deep temporal fascia into the temporal fat pad. The periosteum in incised along the superior border of the arch and is elevated deep to the facial nerve. (From Ellis E, Zide MF. *Surgical approaches to the facial skeleton*, 2nd ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2006, with permission.)

A suction drain may or may not be required and can be used at the surgeon's discretion. The scalp incision is then carefully closed in a layered fashion. All tension on the wound should be borne by sutures placed within the galeal layer, and cutaneous closure should only be done to realign the epithelium correctly. Excessive skin closure tension will possibly lead to increased scarring and alopecia. Complications of the coronal approach include bleeding or hematoma, temporary or permanent numbness of the forehead tissues, injury to the frontal branches of the facial nerve, and excessive scarring or alopecia. Patient should be counseled that some degree of numbness is inevitable posterior to the incision.

Another alternative for exposure of fractures of the upper facial skeleton exists when there is a large laceration. This most commonly occurs in fractures of the frontal sinus as direct blows to this region will often cause lacerations. Another common location of lacerations is along the lateral brow, and occasionally these can be used to expose the frontozygomatic area and the lateral orbital wall. One should be cautioned, however, to avoid significantly lengthening a laceration to obtain appropriate

Figure 79.7 Intraoperative exposure and plating of zygomatic arch in a LeFort III fracture. Temporalis muscle is retracted to the right of the picture.

exposure of fractures. This could easily lead to unsightly scarring or possible nerve injury. In general, one should avoid the historical eyebrow or "gullwing" incision. This routinely leads to unsightly scarring and a deformity of the eyebrows (Fig. 79.8). There is significant propensity for chronic edema in this dependent flap as well as extensive numbness of the forehead. For these reasons, a coronal flap should be employed as it provides unparalleled access and a far more pleasing aesthetic result. This is true even in patients with baldness.

Figure 79.8 "Gullwing" brow incision. Note chronic edema of flap above the incision and the highly visible scar.

MIDFACIAL SKELETON

Orbit

The lateral orbital wall and frontozygomatic area can be easily approached via upper eye lid crease incisions. In essence, this type of incision is a limited lateral blepharoplasty incision. Historically, incisions adjacent to or within the lateral brow were advocated. However, these incisions frequently leave unsightly scars or may cause permanent hair loss in the eyebrow and do not offer any exposure advantage over the lid crease incisions (Fig. 79.9). Instead, placing the incision within the lateral upper eyelid crease is far more preferable aesthetically and also provides improved exposure of the lateral orbital rim and medial aspect of the lateral orbital wall. The technique is very straightforward (Fig. 79.10). The lateral aspect of the lid crease is marked prior to the injection of local anesthetic. The incision is made through the skin and the underlying orbicularis fibers are bluntly separated. The periosteum of the lateral rim is incised and elevated as needed for fracture exposure and implant placement. It is frequently beneficial to extend the subperiosteal exposure posteriorly along the lateral orbital wall. This allows the surgeon to visualize the displaced fractures and provides another perspective to evaluate accurate anatomic reduction of fracture segments. Following fracture repair, the periosteum is closed and the incision is closed in a layered fashion. It is not typically necessary to drain this incision. Although one may see some temporary orbicularis weakness postoperatively, permanent lagophthalmos should be very rare. Healing is usually rapid with an excellent aesthetic result (Fig. 79.10D).

Figure 79.9 Left lateral brow incision. This scar can be very visible and cause permanent loss of eyebrow hairs and has more limited exposure of the lateral orbit and should be avoided.

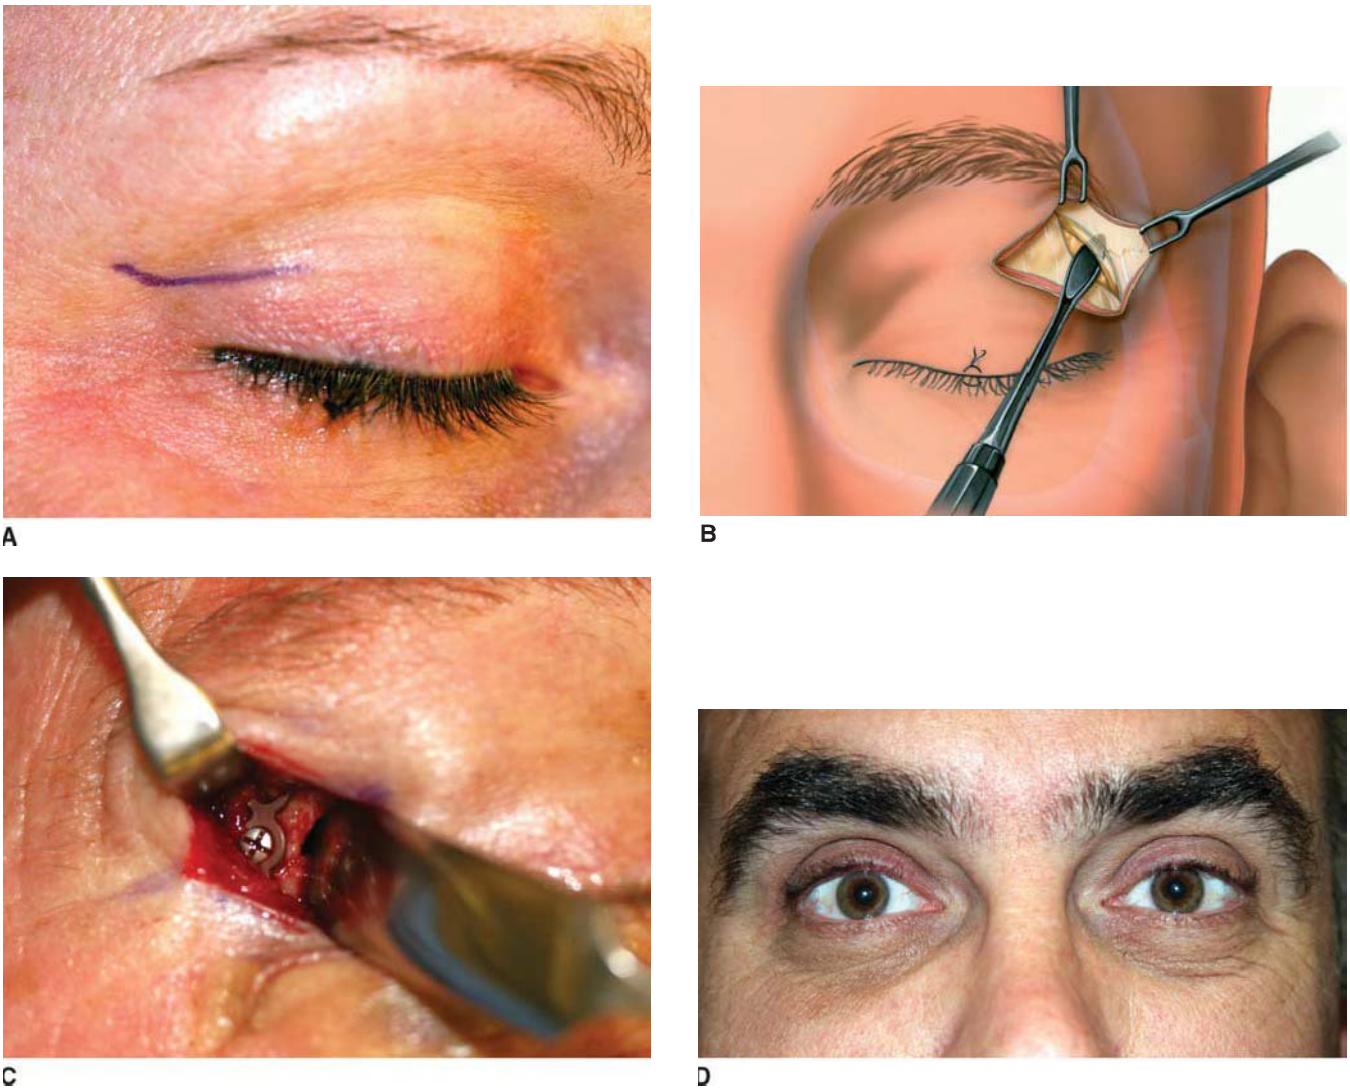

Figure 79.10 Lateral lid crease (upper blepharoplasty) approach. **A:** Incision is placed in natural supratarsal lid crease as shown and extended laterally within the crease as needed. **B:** Periosteum of lateral wall is incised and elevated to expose bone above and below the fracture to allow reduction and fixation hardware placement. (Part B From Ellis E, Zide MF. *Surgical approaches to the facial skeleton*, 2nd ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2006, with permission.)

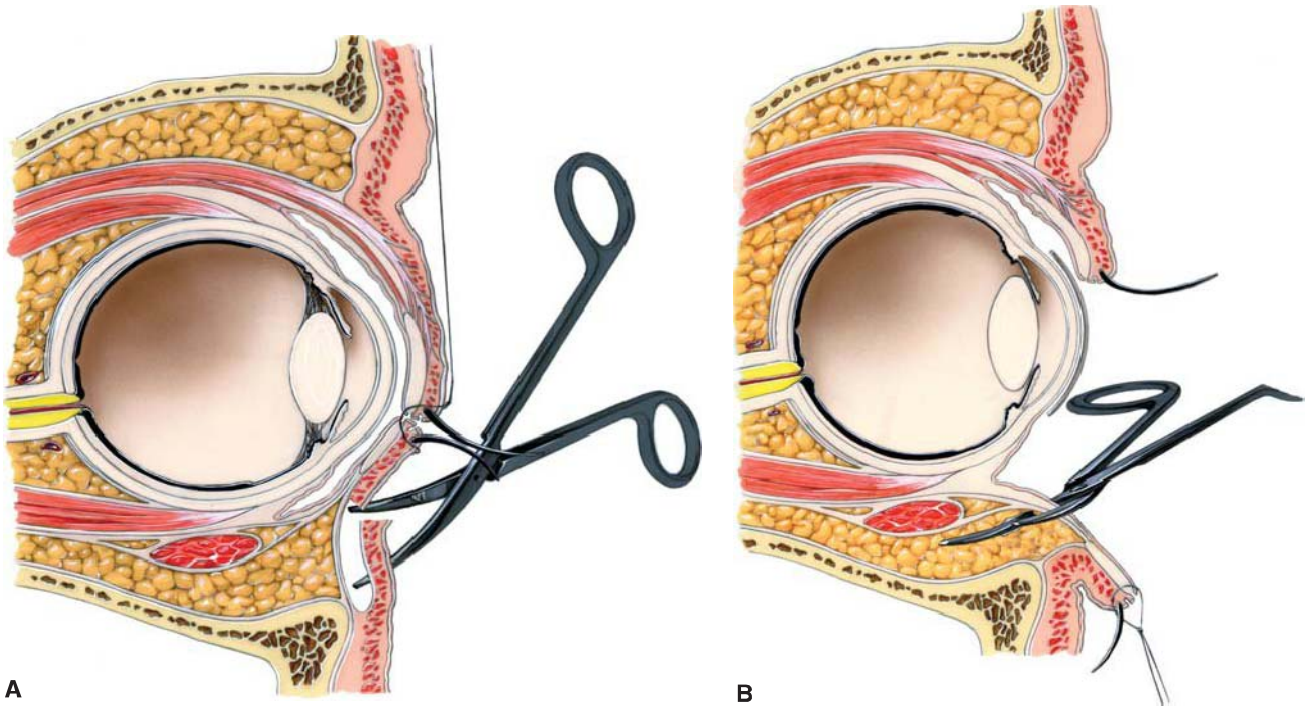
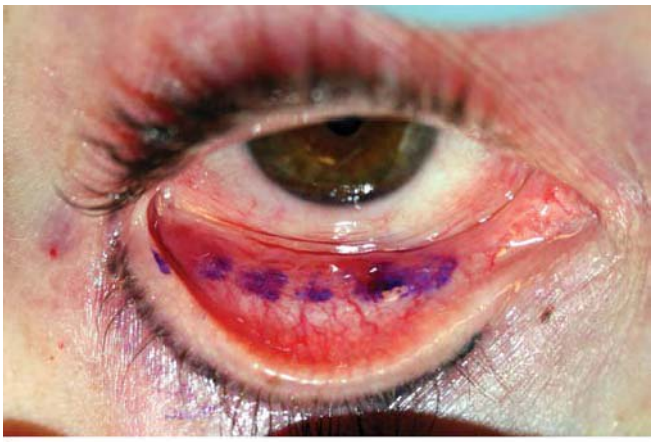
Inferior Orbital Rim, Floor, and Medial Wall

The inferior orbital rim, orbital floor, and medial orbital wall are most commonly approached through the various lower eyelid incisions. These incisions may either be transcutaneous or transconjunctival (Fig. 79.11). Both of these approaches have been long advocated in the literature, and when carefully designed and executed, both approaches will yield excellent results (6). Transconjunctival approaches have several potential advantages, however (7). Obviously, there is no visible scar unless a short lateral canthotomy incision is incorporated. A transconjunctival approach lends itself very well to extended medial exposure for fractures involving the medial orbital wall. In addition, transconjunctival approaches are completely posterior to the orbicularis muscle of the lower eyelid and therefore preserve an important structural support of the lower lid. As a result, postoperative lower lid malposition or ectropion may be less common with a transconjunctival approach (8,9). Furthermore, a transconjunctival approach can be done in some cases without any division of the lateral canthal structures and thus weaken lower lid support even less.

Transconjunctival Lower Lid Approaches

The lower eyelid transconjunctival approach is begun with an incision placed in the inferior fornix. A corneal shield can be employed if desired but may impede exposure somewhat. If a shield is used for a long case, such as a complex nasoethmoid or LeFort fracture, one should





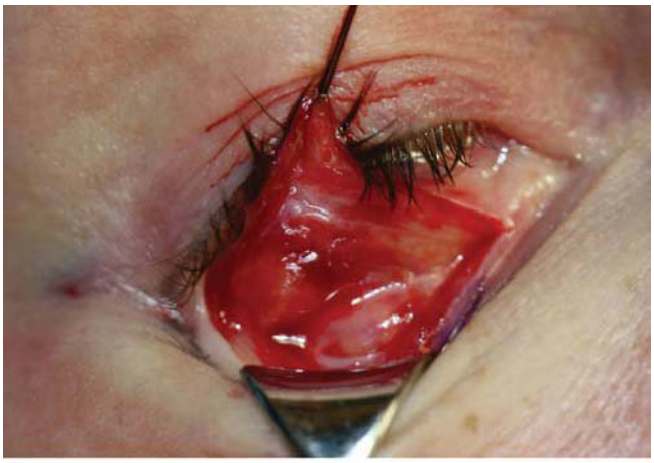


Figure 79.11 Transcutaneous and transconjunctival approaches to the orbital floor. **A:** Cross-section of eyelids demonstrating surgical planes for transcutaneous (subciliary or lid crease) approach. **B:** Cross-section of eyelids demonstrating transconjunctival approach. Following the incision in the inferior fornix, the dissection can proceed either anterior or posterior to the orbital septum (see Text and Figure 79.13).

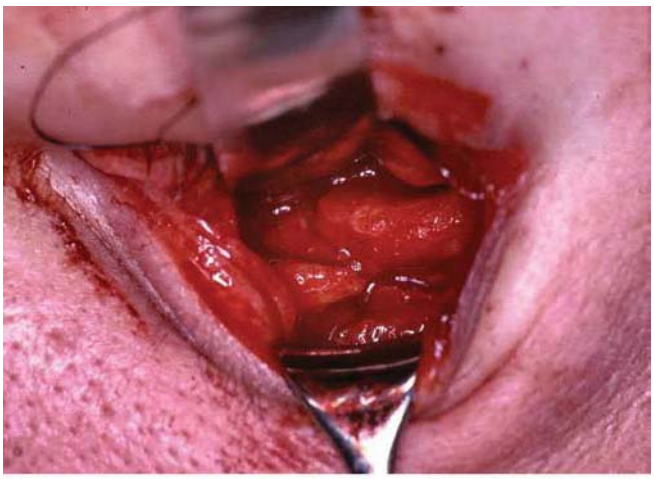

remove the shield periodically and reapply ocular lubricant to reduce the risk of corneal compromise or abrasion. Initially, the lower lid is retracted gently, and the incision is typically made several millimeters below the tarsal plate. Limited orbital floor fractures may be repaired with this incision alone without any lateral canthotomy incision. One should try and avoid a lateral canthotomy if possible as these approaches heal with the lowest incidence of lid malposition (7). If, however, the orbital floor fracture is large, the lid has little laxity, or if one anticipates the need to explore the medial orbit, a lateral canthotomy and cantholysis may be necessary (Fig. 79.14). The lateral canthotomy incision is made directly through the lateral canthus and typically extends only a few millimeters. Extending the cutaneous incision beyond this will not enhance exposure and will make the incision more visible. The lateral canthal tendon is then divided with a cantholysis, which is typically performed with small tenotomy scissors angled obliquely downward under the conjunctiva. The canthal tendon fibers are fully divided so that full mobilization of the lower lid is obtained. The conjunctival incision is then extended along the inferior fornix a few millimeters below the inferior border of the tarsus. A flap of conjunctiva and lower lid retractors is created and retracted superiorly with a traction suture (Fig. 79.12B). This provides coverage of the cornea and often eliminates the need for a corneal protector. Tension on this flap will also provide countertraction, which will aid the inferior dissection toward the rim. At this point, there are two options for surgical dissection: preseptal or post (retro) septal (Fig. 79.13). Preseptal dissection is typically done with blunt instruments in the loose areolar tissue between the orbicularis muscle and the orbital septum inferiorly until the infraorbital rim is encountered. An advantage of this approach is that the orbital fat is largely contained by the septum and therefore does not obscure visualization. A potential disadvantage is that scar contracture could occur along the orbital septum leading to some postoperative displacement or malposition of the lower lid. This may result in inferior displacement of the lower lid leading to increased scleral show or perhaps some entropion (10,11). Retroseptal dissection is also blunt but is behind the orbital septum and traverses the orbital fat. A principal disadvantage of this approach is that visualization may be more difficult as the orbital fat will protrude into the surgeon's view, and there is a somewhat greater potential for injury to the inferior oblique muscle as it is adjacent to the plane of dissection. Advocates of this approach, however, feel that the risk of lower lid malposition is largely eliminated as there is no contracture along the orbital septum. In either approach, the orbital rim is quickly and widely exposed (Fig. 79.14). The periosteum of the rim is then incised, and wide subperiosteal dissection is performed as dictated by the fracture. It is essential that the dissection along the orbital floor be complete and be carried out to fully expose the intact bony shelves along the lateral orbital floor, medial orbital floor, and especially

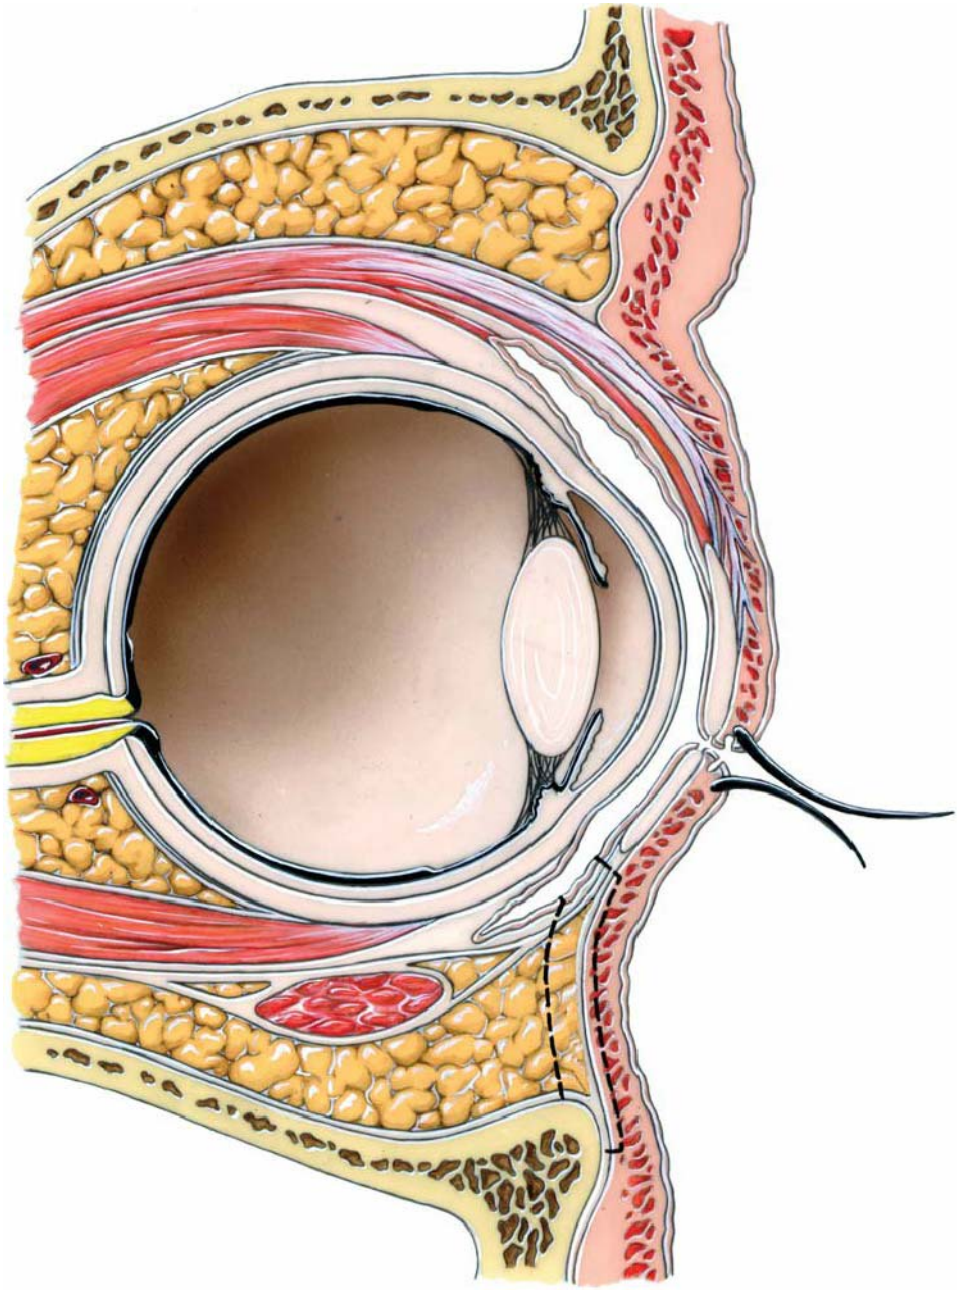

Figure 79.13 Sagittal view of orbit demonstrating preseptal versus retroseptal planes of dissection. (From Ellis E, Zide MF. *Surgical approaches to the facial skeleton*, 2nd ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2006 with permission.)

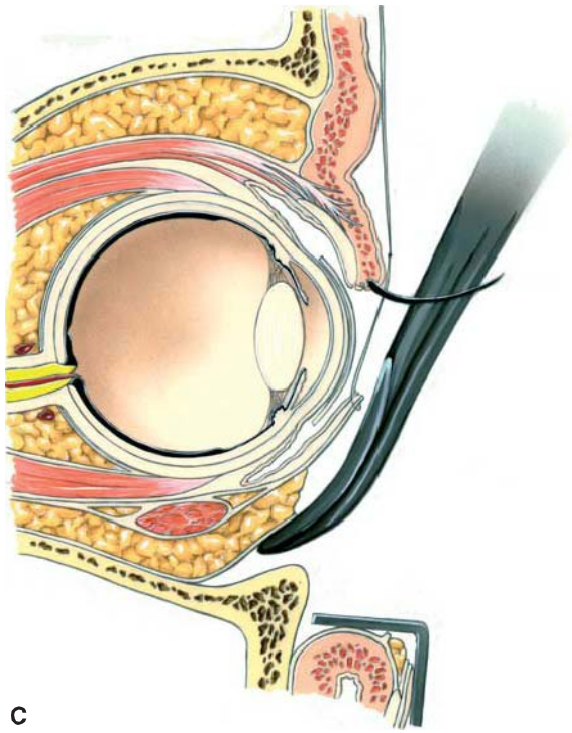
back to the posterior orbital bony shelf. Care is taken during floor dissection to bluntly identify the infraorbital nerve and separate it from the orbital soft tissues. Repair of the fracture is then performed using the implant or graft preferred by the surgeon. At the conclusion of the repair, it is important to repair the periosteum along the infraorbital rim. This is particularly true if there has been wide elevation of the periosteum off of the face of the maxilla or malar eminence as in a malar complex or LeFort fracture repair. In those cases, closure of the periosteum will help prevent inferior displacement or ptosis of the midface soft tissues. It is not necessary to close the conjunctiva although a few sutures to realign the edges may be helpful. There is some wisdom to not closing the conjunctiva tightly as this will allow blood and serous fluid to escape from the orbit postoperatively. If a canthotomy and cantholysis have been performed, then the lateral canthal tendon segments are carefully reapproximated, and precise closure of the lateral canthus is essential. Failure to close the lateral canthus precisely could lead to rounding or webbing in this area.



A medial extension of the transconjunctival approach provides an opportunity to fully expose the medial orbital wall as well. This is done with an extension through the caruncular area (Fig. 79.15) (12,13). The caruncle is the soft

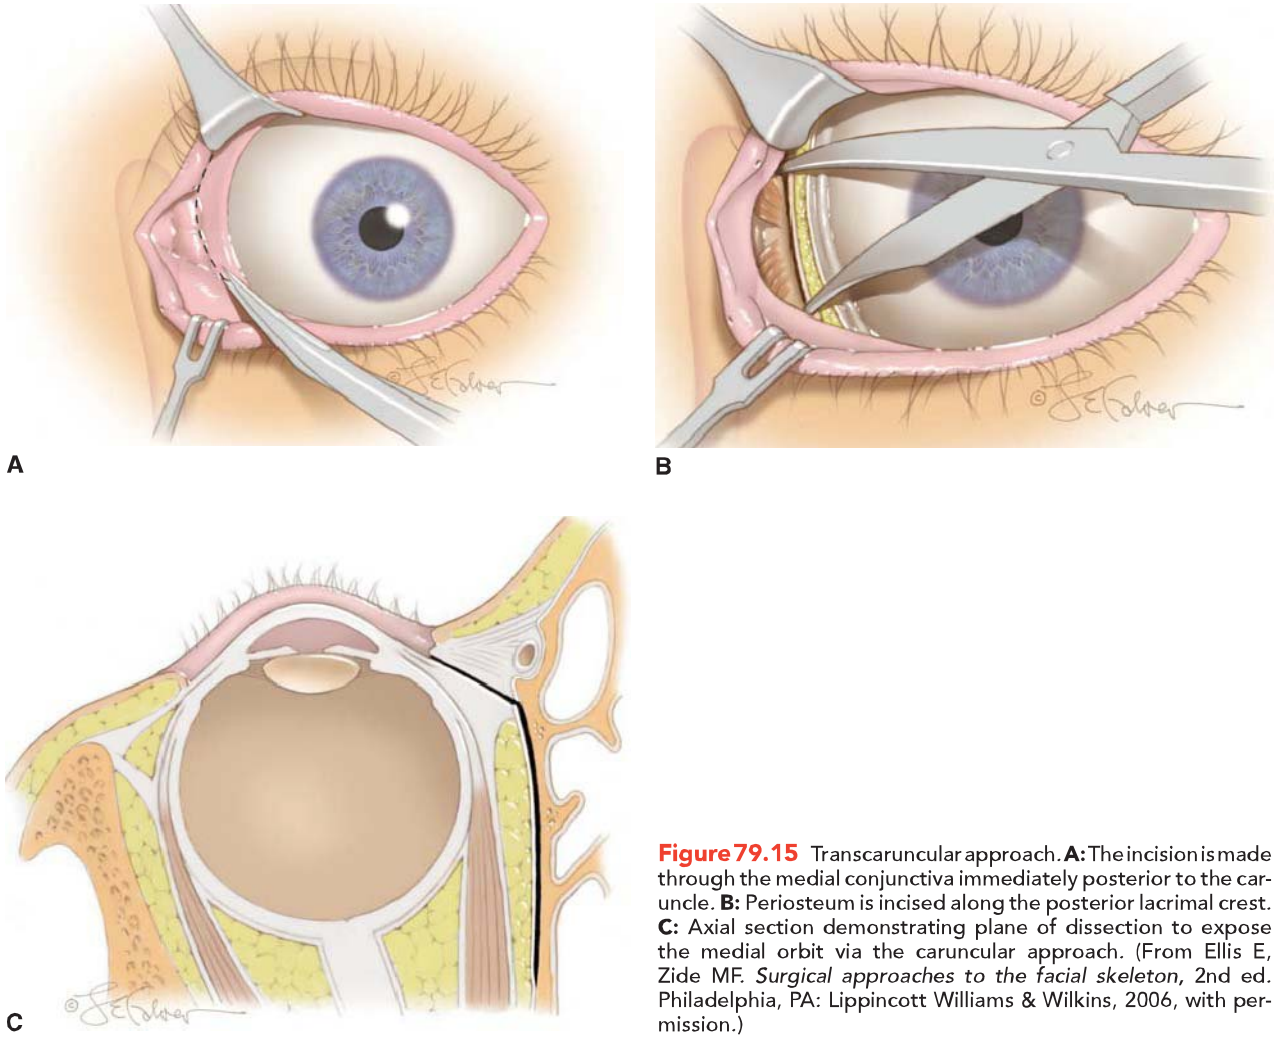
The canthal tendon fibers are divided either through the conjunctiva or submucosally but never through the skin. The tendon fibers can usually be palpated with the scissor tip as a "bowstring." **C:** Artist's depiction of cantholysis. **D:** Complete lid mobilization is apparent after the tendon fibers are divided. **E:** Postoperative view following repair of left orbital floor fracture with canthotomy/cantholysis and transconjunctival approach. (Part C from Ellis E, Zide MF. *Surgical approaches to the facial skeleton*, 2nd ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2006, with permission.)

tissue collection in the conjunctiva, which lies posterior and lateral to the medial canthus and just anterior to the semilunar fold of the conjunctiva. Deep to the caruncle are the attachments of the medial orbital septum and Horner muscle and portions of the medial canthal tendon. The common canaliculus is immediately medial to the caruncle as well. The caruncular approach can be performed as an isolated incision to gain access to the medial orbital structures as in an isolated medial wall fracture. More often, it is combined with the lower lid transconjunctival approach to provide wide access for the entire inferior and medial orbital structures. Typically, the lower lid portion is executed first and the dissection is then extended medially. A lateral canthotomy and cantholysis, as discussed above, may facilitate better exposure in this instance. Orbital retractors are employed to retract the globe laterally and the medial canthus medially.



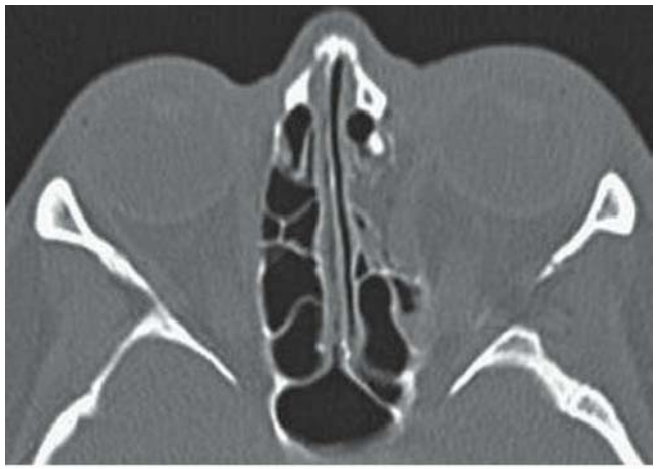


Figure 79.15 Transcaruncular approach. **A:** The incision is made through the medial conjunctiva immediately posterior to the caruncle. **B:** Periosteum is incised along the posterior lacrimal crest. **C:** Axial section demonstrating plane of dissection to expose the medial orbit via the caruncular approach. (From Ellis E, Zide MF. *Surgical approaches to the facial skeleton*, 2nd ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2006, with permission.)

The incision is made between the caruncle and the semilunar fold of the conjunctiva. Dissection with a small tenotomy scissor or periosteal elevator extends posteriorly until the posterior lacrimal crest is palpated. The periosteum is incised along or just posterior to the posterior lacrimal crest, and the exposure is extended posteriorly and superiorly as indicated. It is essential to only dissect posterior to the lacrimal fossa in order to avoid damaging the lacrimal sac and canaliculi. This transcaruncular approach will allow visualization from the lacrimal fossa up to the frontoethmoid suture and the ethmoid arteries and even the medial orbital roof. When more extensive superior exposure is required, the ethmoid arteries can be cauterized or ligated and divided while remaining cognizant of the nearby optic nerve location. Once the surgical repair is complete, the conjunctiva is closed near the junction of the wall and floor boundary as this will help to prevent webbing between the medial wall and lower lid conjunctiva. The patient may have some chemosis and edema postoperatively, but the healing is rapid and the final result is aesthetically excellent and far superior to the transcutaneous medial wall, "Lynch," incisions that often heal with unsightly scarring that is hard to camouflage (Fig. 79.16). The Lynch incision is simple to execute, and the dissection is direct to the medial orbital wall. However, the inferior dissection is limited by the lacrimal structures, and there is more risk of detaching the medial canthal tendon. More importantly though is the fact that the scar is potentially quite visible and somewhat prone to webbing as it heals and contracts. If one insists on using a transcutaneous medial orbital incision, a Z-plasty should be incorporated into the design of the incision to minimize webbing of the scar as it heals, and this will help to camouflage the final scar. Overall, the caruncular approach through the conjunctiva is far superior and it is strongly recommended.

In general, transconjunctival approaches heal predictably well (6,8,9,11). Prolonged chemosis may occasionally occur. Eyelid malpositions are uncommon and may result either in increased scleral show from vertical contracture or perhaps entropion if there is contracture of the posterior lamellar tissues (10). Most of these will improve with time and massage but occasionally will require corrective surgery with scar release and perhaps mucosal grafting to the posterior lamella. If there is significant lateral canthal webbing or scarring, then secondary canthoplasty may be needed.

Note the highly visible scar as well as a visible subciliary incision on the left.

Transcutaneous Lower Lid Approaches

There are several options for cutaneous incisions in the lower lid (Fig. 79.17). The subciliary incision is perhaps the most commonly employed and is typically placed 2 to 3 mL below the eyelashes. A good alternative is to place the incision within a natural lower lid crease (subtarsal), which is below the subciliary line (8,14). Placing the incision directly over the infraorbital rim should usually be avoided as this location is more prone to visible scarring and may lead to prolonged lower lid edema above the incision and sits in thicker cheek skin (Fig. 79.18). With transcutaneous approaches, corneal protection is provided by placing a temporary tarsorrhaphy suture from the lower lid up to the upper lid, taking care that the suture does not penetrate the conjunctiva (Fig. 79.20A). If one chooses the subciliary approach, the incision is made through the skin only a few millimeters below the lashes and typically stair-stepped preserving a cuff of orbicularis muscle along the tarsus as this helps to support the lower lid position while healing. Below the tarsus, the orbicularis is penetrated and the skin–muscle flap is then bluntly raised off of the underlying orbital septum down to the infraorbital rim (Fig. 79.19). If a lower lid crease (subtarsal) is chosen for the incision, then a skin–muscle flap is immediately developed as the crease is typically below the level of

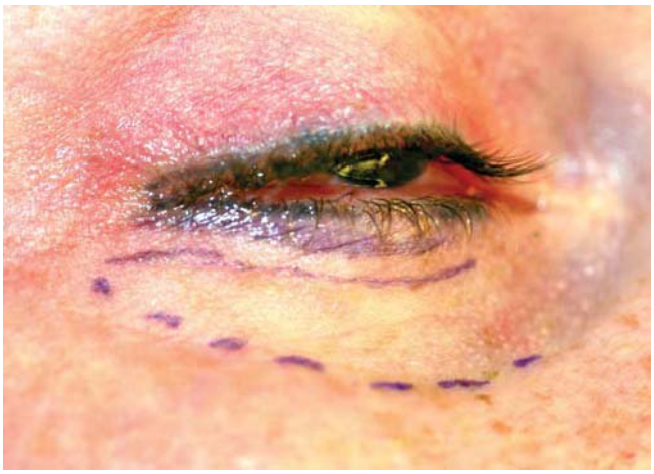

Figure 79.17 Transcutaneous lower eyelid incision. From superior to inferior: subciliary, lid crease, and infraorbital rim.

Figure 79.18 Postoperative appearance of an inferior rim incision. Note the visibility of the scar, the chronic edema, and the lower lid malposition.

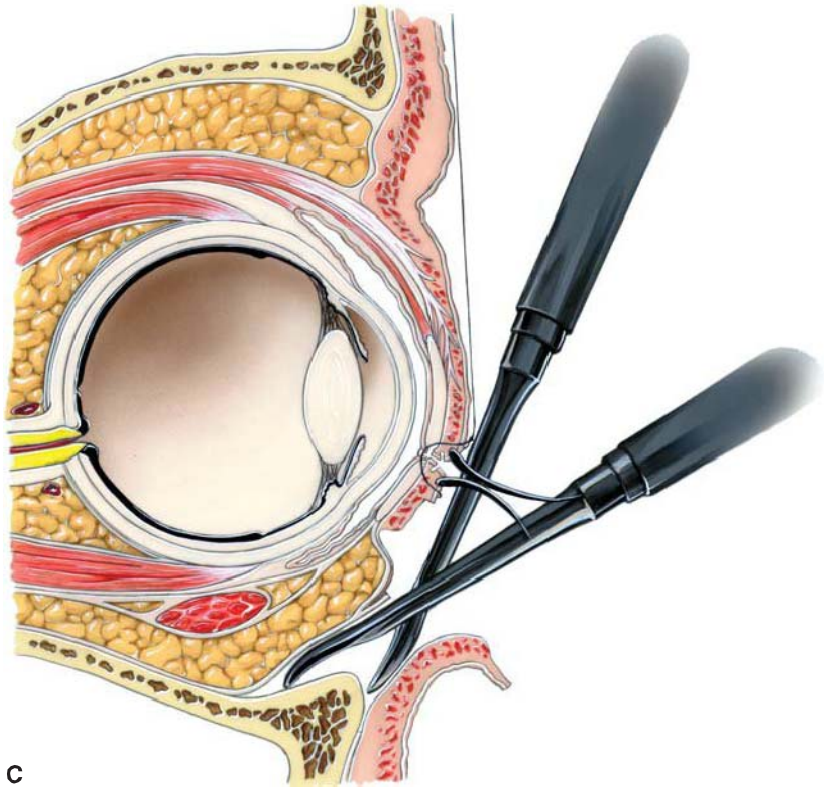
the tarsus. Dissection is again between the orbicularis and orbital septum. The infraorbital rim is exposed and the periosteum is incised, and dissection continues along the floor as needed for fracture repair (Fig. 79.20). At the conclusion of the repair, it is important to close the periosteum along the rim to help suspend the elevated premaxillary soft tissues and to provide soft tissue coverage over the fixation hardware. During closure of the skin–muscle flap, it is critical that the flap be resuspended to the periosteum of the lateral orbital rim near the lateral canthus. This is important because the skin–muscle flap weakens the support of the lower lid by dividing and partially denervating the orbicularis muscle, which is a critical support of the lower lid. The suspension suture, typically a 5-0 slowly resorbing suture material, is placed from the orbicularis of the flap to the lateral orbital rim periosteum. The suspension suture should be tightened so that the skin edges are brought together with no tension along the incision line. If the periosteum is lacking or has been elevated during fracture repair, then one can drill a small hole in the bone of the lateral rim and pass the suture through that. Elderly patients frequently have some preexisting laxity of the lower lid, and in these patients, some tightening of the lateral canthal structures at the time of wound closure will help prevent lid malposition.



A major criticism of the transcutaneous approach—particularly the subciliary approach—is that it is potentially more prone to cause malposition of the lower lid, particularly ectropion (Fig. 79.21) (6,8,9). This is thought to be due to contracture along the orbital septum or anterior lamella (i.e., skin and orbicularis) combined with weakening of the lower

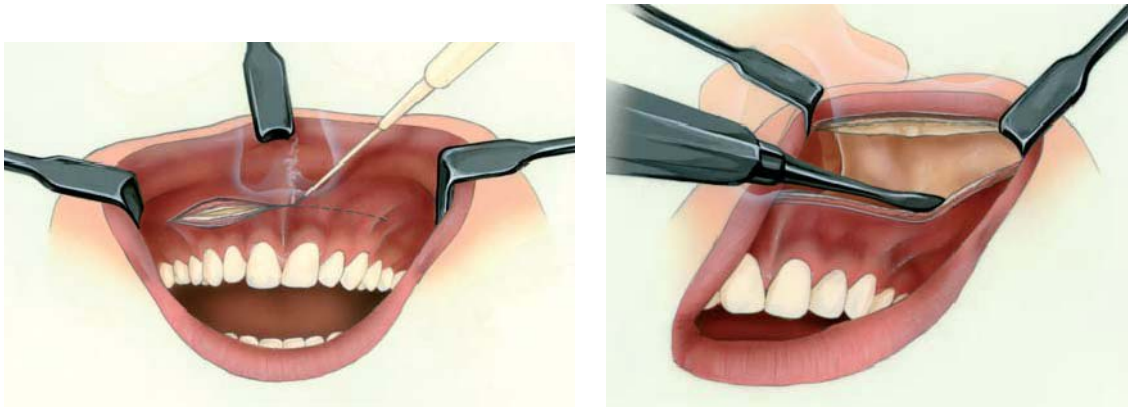
A temporary tarsorrhaphy suture has been placed to provide corneal protection. **B:** Sagittal view of dissection planes with orbital floor and rim exposure. **C:** Exposed orbital floor with hardware in place. **D:** Postoperative view of patient following repair of left malar complex and orbital fractures with a subciliary approach and lateral upper lid crease incision. It is critical to resuspend the skin–muscle flap to the lateral orbital rim periosteum to prevent lower lid malposition. (From Ellis E, Zide MF. *Surgical approaches to the facial skeleton*, 2nd ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2006, with permission.)

Figure 79.21 Malposition of right lower eyelid following repair of right orbital fracture through a transcutaneous approach. This may be due to unrecognized lid laxity, failure to resuspend the skin–muscle flap, or excessive scar contracture.

lid orbicularis. It has been suggested that a lower lid crease, or subtarsal, incision may have a lower incidence of malposition presumably because the pretarsal orbicularis sling is not traumatized (6,15). Lower lid malposition can lead to corneal exposure, epiphora from a displaced puncta, and aesthetic deformity, which may need complicated surgical repair. If an ectropion is seen in the early postoperative period, one should initially treat it with massage and perhaps judicious corticosteroid injections. On occasion, corrective surgery with scar release, skin or mucosal grafting, and lateral canthal tightening may be necessary. Proper suspension of the skin–muscle flap as described and closure of the incision under no tension will help to limit this outcome and can allow for excellent aesthetic and functional results (Fig. 79.20).

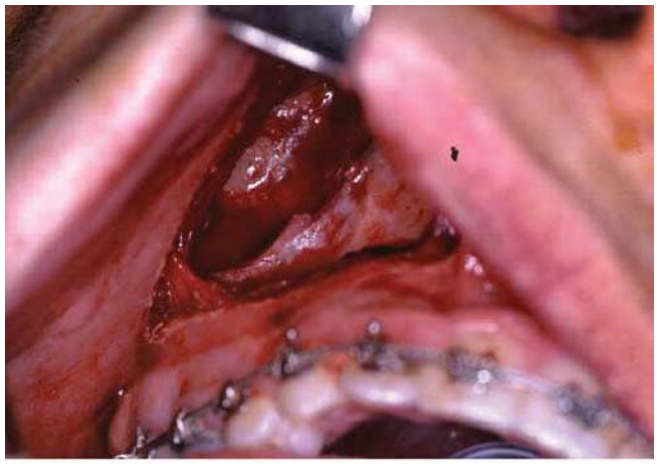
LOWER MIDFACE AND MAXILLA



The upper labial sulcus approach provides for exposure of the lower midface including the pyriform aperture, medial maxillary buttresses, and lateral maxillary buttresses (Fig. 79.22). This approach allows the surgeon to visualize the midface from the maxillary alveolus up to the infraorbital rim and from the malar eminence to the nasal bones (16). The incision is placed 5 to 10 mL above the gingiva and extended from the midline to as far lateral as needed based on the needs of the fracture exposure. One must be certain to place the incision high enough to not devitalize the gingiva around the teeth. The incision is made sharply down through the periosteum and subperiosteal elevation is begun. The infraorbital nerve must be identified early and carefully preserved. Release along the pyriform aperture can be done taking care to avoid perforation into the nasal cavity. Laterally, the periosteum is firmly adherent to the bone where the masseter muscle attaches to the lateral maxilla and malar eminence, and this will need to be sharply released in order to visualize the superior lateral buttress and medial zygoma. The dissection can continue upward to expose the infraorbital rim as needed. If the labial sulcus approach is needed bilaterally, one should try to maintain some of the soft tissue attachments of the alar bases as these will tend to lateralize if fully released and may cause some flaring of the nostrils. If wide release is needed across the midline, then this flaring should be corrected at the time of closure with cinching sutures (Fig. 79.23). Once the repair is complete, the incision is closed with interrupted resorbable sutures taking care to incorporate the periosteum to help prevent wound dehiscence.

Complications of the sublabial approach are uncommon. They include wound dehiscence and implant exposure. This is most likely to occur laterally over the lateral maxillary buttress hardware. If the incision is placed too low, then some necrosis of the gingiva can occur leading to periodontal disease. Injury to the infraorbital nerve can result in permanent facial and dental anesthesia as well as prolonged facial pain. Careful incision placement, careful dissection around the infraorbital foramen, and meticulous wound closure should minimize these problems.

Mandibular Exposure



Transoral Approaches

The majority of mandibular fractures can be exposed through the oral mucosa. This includes symphyseal and parasymphyseal fractures, noncomminuted body fractures,

A B

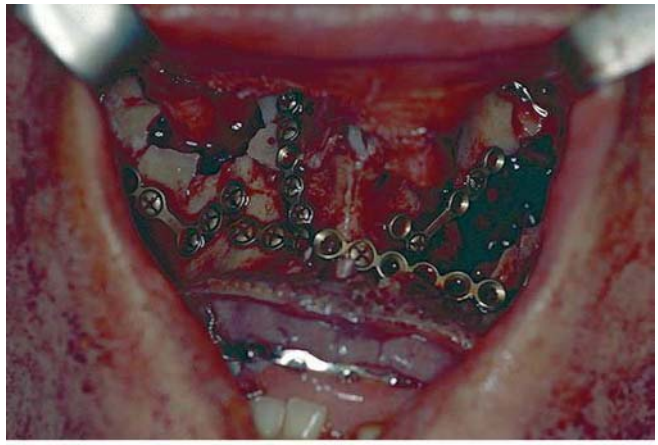


Figure 79.22 Upper labial sulcus approach. **A:** The incision is made leaving a cuff of gingival above the teeth. **B:** Subperiosteal elevation is performed to widely expose the fracture, taking care to identify and preserve the infraorbital nerve.

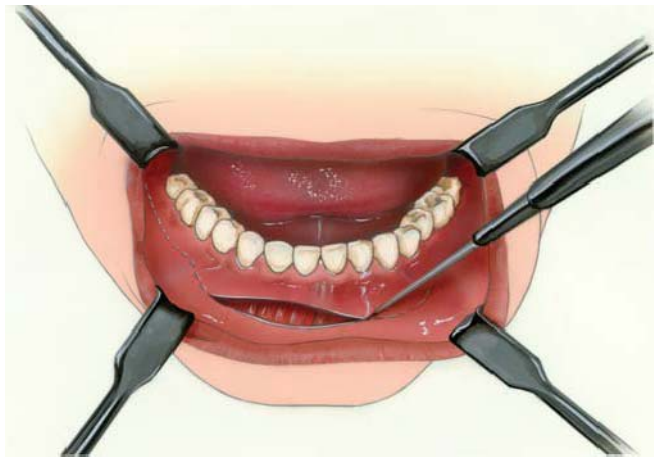
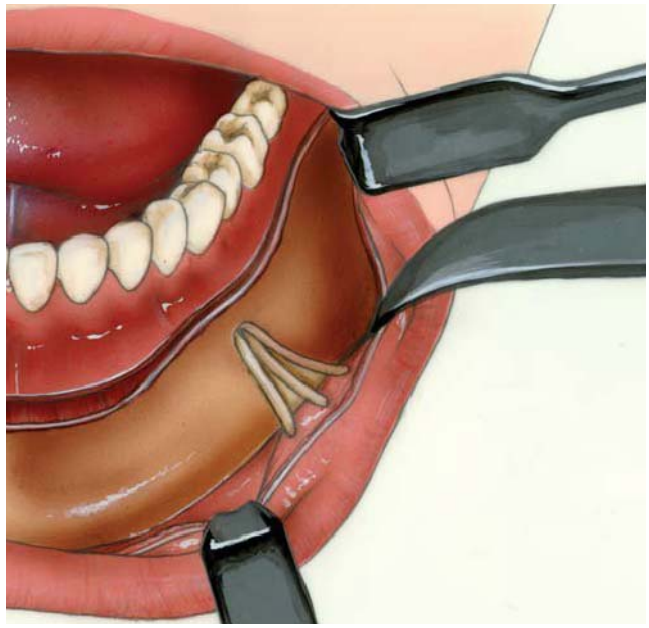
ramus and subcondylar fractures, and some condylar fractures. A transoral incision eliminates a visible scar, allows identification and preservation of the inferior alveolar nerve, and provides wide exposure of the fractures. A major disadvantage of intraoral incisions is that the lingual cortex is not easily seen, and thus, three-dimensionally accurate reduction of fractures may not occur since this cortex is not visualized. This is particularly true in the case of symphyseal and parasymphyseal fractures that are prone to lateral splaying. If the lingual cortex is not fully reduced, then posterior widening of the mandible may occur. In addition, since most fixation plates are placed along the inferior border of the mandible, the alveolar nerve may be at more somewhat greater risk as the dissection is from above and must extend below and around the nerve.



Most intraoral incisions are made in the labial sulcus and should preserve a viable cuff of gingiva. Sharp dissection extends under the periosteum and is extended as need to fully expose the fracture and to allow room for placement of the fixation hardware (Fig. 79.24). The alveolar nerve is carefully identified and preserved. In the symphyseal region, the dissection can extend under the inferior border of the mentum to allow some visualization of



the inner cortex reduction. Following the fracture reduction and hardware placement, the incision is closed with interrupted resorbable sutures that should include the periosteum for strength.

In the region of the angle and ramus, the incision is placed along the anterior border of the ramus (Fig. 79.25). Subperiosteal elevation is done as needed and can be done on both the inner and outer surfaces to allow visualization for accurate fracture reduction. This approach can also be combined with endoscopic visualization, which can assist reduction and fixation of subcondylar fractures (17,18).

Transcutaneous Approaches to the Mandible

Some mandibular fractures may be better approached through the neck or facial skin rather than transorally. Severely comminuted fractures may require large reconstruction hardware and primary bone grafting and are usually best treated through a cutaneous approach. This is especially

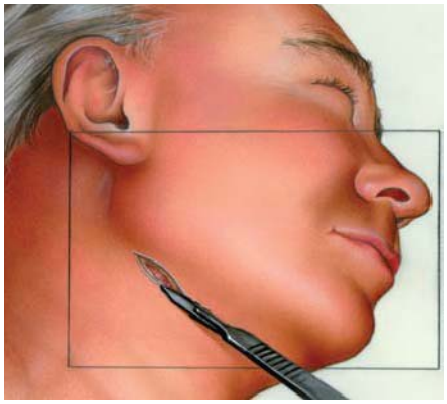
true in the body and angle regions. On occasion, a large laceration may be employed for exposure. However, one should avoid the temptation to significantly enlarge existing lacerations unless they are optimally located and extension will not endanger nerves or worsen the cosmetic outcome.

The symphysis can be approached through an extended submental incision placed in the submental crease. This is similar to that used in chin augmentation but typically is longer as wider exposure is needed. Sharp dissection is carried down to the bone and subperiosteal dissection is extended as needed. This is quite straightforward with few risks except for potential injury to the alveolar nerve. The principle advantage compared to an intraoral approach is that the inner cortex can be well visualized from below and that may assist accurate fracture reduction. The majority of symphyseal and parasymphyseal fractures are well managed with the intraoral approach.



The course of the marginal mandibular nerve must be well understood to perform transcutaneous exposure of the mandible. After the marginal mandibular branches of the facial nerve exit the substance of the parotid, they course anteriorly where they innervate the lower lip depressor muscles. Early anatomic studies (19) demonstrated that the marginal branch dropped below the inferior border of the mandible behind the facial artery in less than 20% of people. More recent studies have found, however, that in approximately half of people, the nerve dips up to 1.2 cm below the mandible until it crosses over the facial artery (20). In front of the facial artery, however, the marginal nerve is virtually always above the inferior border. Injury to the nerve will denervate the lower lip depressors resulting in elevation of the affected side with animation (Fig. 79.26). This deformity is permanent and very difficult to correct or camouflage. For this reason, most have advocated placing the incision at least 1.5 cm, or approximately two fingerbreadths, below the inferior border of the mandible usually following a natural skin crease

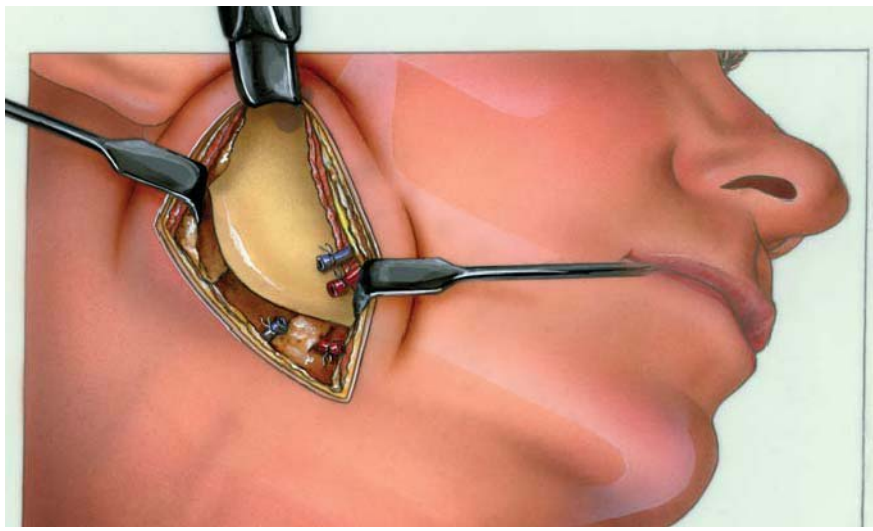


Figure 79.26 Clinical example of deformity caused by injury to the right marginal mandibular nerve. This injury weakens the depressor muscles of the lower lip, which causes the lower lip to rise leading to a crooked smile.

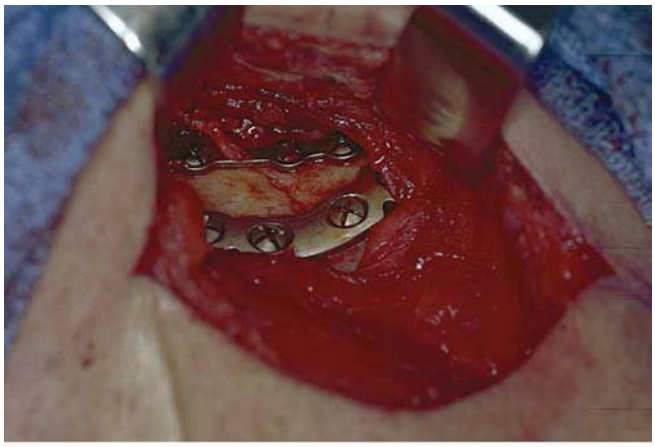
(Fig. 79.27). Dissection is carried through the skin, the subcutaneous fat, and the platysma. Blunt dissection under the platysma muscle extends up to the inferior border of the mandible, and if needed, the facial artery and vein can be ligated and divided for exposure. The cervical fascia is opened at least 1.5 cm below the inferior border of the mandible especially posterior to the mandibular notch again to avoid injuring the marginal nerves. The submandibular gland will usually be seen and is gently retracted inferiorly. The periosteum is opened and elevated, and the masseteric fibers are released as needed for exposure of the angle and ramus. This approach will allow exposure from the posterior ramus, across the angle and up to the anterior body. This approach can also be extended across the midline to the contralateral side in those unusual cases where complete exposure of the mandible is needed. Following the repair, the wound is closed in layers including the fascia and platysma. A passive drain can be placed if desired, but suction drains should be avoided as they can pull oral contaminants down into the wound and may encourage the development of oral–cutaneous fistulae.



A retromandibular or preauricular approach can also be employed for extended exposure of the mandibular ramus and condylar region (Fig. 79.28) (21–23). The retromandibular approach typically employs a vertical incision placed directly over the posterior border of the ramus below the ear. The preauricular approach employs a curvilinear incision along the preauricular crease, around the lobule, and

extending up the postauricular sulcus as one would use in a face-lift or rhytidectomy. The advantage of the face-lift incision is that it leaves a more aesthetically pleasing scar. However, the subcutaneous dissection is more extensive and closure is more involved. The incision extends through the skin and subcutaneous tissues and flaps are raised as needed. Dissection continues down through the SMAS and the parotid fascia. At this point, dissection is done with purely blunt technique with spreading of the parotid tissues toward the posterior border of the ramus of the mandible. The marginal nerve branches may be seen and should be meticulously protected with gentle retraction either superiorly or inferiorly as needed. The retromandibular vein is identified and ligated as needed. The masseter muscle fibers are incised and elevated to gain exposure of the posterior border of the ramus, and then subperiosteal dissection is extended as dictated by the fracture repair. The greatest concerns of this approach are the risks to the facial nerve and the potential for a salivary fistula from the divided parotid tissues. The marginal nerve is at greatest risk, but typically the marginal nerve can be identified and protected. Temporary paresis or weakness of the marginal nerve is common and likely is due to retraction of the nerve during exposure during the fracture repair. Closure is done in layers including the periosteum, masseteric fibers, SMAS, and skin. A passive drain may be used, but again active suction drains should be avoided.

SUMMARY

Contemporary management of facial skeletal trauma demands that the surgeon carefully diagnose, expose, and repair the facial skeleton with precision and anatomic accuracy. Surgical exposure should be performed with careful soft tissue handling techniques and with aesthetic surgical concepts in mind. The incisions should be carefully designed and placed and should follow relaxed skin tension lines whenever feasible. Dissection should follow proper anatomic planes. The surgeon should have a thorough understanding of the anatomy of the facial and trigeminal nerves and carefully avoid and protect them. Meticulous wound closure and tissue resuspension should minimize postoperative soft tissue deformities. If these basic concepts are observed, the facial trauma victim can expect an excellent recovery—hopefully with few long-term soft tissue consequences and minimally visible incisions.

HIGHLIGHTS

- Thoroughly counsel patients preoperatively regarding the exact location of all planned incisions, the risks of each approach, and postoperative care and the possible need for future scar revision.
- Incisions should be planned with relaxed skin tension lines and natural skin creases in mind.
- Gentle soft tissue handling and judicious electrocautery will minimize scarring and hair follicle damage.
- The surgeon must be intimately familiar with the location, course, and depth of the facial and trigeminal nerves.
- Consider camouflaging the scalp coronal incision with curvilinear design in the parietal regions and bevel incisions parallel to the hair follicles.
- Preserve or enhance lower eyelid support and utilize techniques that will suspend the lower lid tissues during healing to prevent lower lid malposition and ectropion. Transconjunctival approaches may be less prone to postoperative lid malposition.
- Preserve an adequate cuff of viable gingival tissue when making intraoral incision to expose the maxilla or mandible. Identify and preserve the mental nerve.
- Consider transoral approaches for all mandible fractures except those that have severe comminution that will require extensive hardware or bone grafting.
- Be cognizant of the anatomy of the marginal mandibular nerve with all transcutaneous approaches to the mandible.
- Endoscopic visualization may assist the repair of orbital floor, frontal sinus, zygomatic arch, and mandibular condylar fractures.

Mandibular Fractures

80

Brett A. Miles *Jesse E. Smith*

Mandibular fractures represent common injuries and are second only to nasal fractures with regard to frequency. The central role of the mandible in mastication, swallowing, and speech makes the surgical management and rehabilitation of mandibular fractures challenging. In addition, complications related to the management of mandibular fractures, while seldom life threatening, often result in significant morbidity for patients with these injuries. Therefore, accurate assessment of the injury and the appropriate application of the priniciples of the management of mandibular fractures is critical for sucessful outcomes.

ANATOMY

The mandible articulates with the skull base at the paired temporomandibular joints (TMJs) and is suspended by a complex ligamentous and neuromuscular apparatus. Because of this unique, bilateral articulation with the skull base and the vector of forces contributing to mandibular trauma, a bilateral fracture pattern is commonly observed. The anatomic components of the mandible include the symphysis, parasymphysis, body, angle, ramus, coronoid process, condyle, and alveolus (Fig. 80.1). Anatomic locations with an increased propensity for fracture include the third molar area (especially if the third molar is impacted), the mental foramen region, and the condylar neck. Edentulous, atrophic mandibles are inherently susceptible to fracture in multiple anatomic locations. Additionally, pediatric patients in the deciduous phase of dentition are prone to mandibular fracture, the result of weakening of the mandible due to the presence of unerupted teeth.

Knowledge of dental occlusion is integral to the diagnosis and management of all facial fractures. In the Angle classification of occlusion, the mesiobuccal cusp of the maxillary first molar is used as a reference (Fig. 80.2). Class I occlusion is the most commonly observed pattern. Class II represents retrognathism, and class III represents prognathism. Cognizance of the three classes of occlusion and careful examination of the cuspal interdigitation and wear facets allow accurate restoration of the patient's preinjury occlusion. Restoration of the patient's occlusion is the primary goal during the surgical management of mandibular fractures as well as during postoperative rehabilitation. The universal dental numbering system is useful in describing the location of mandibular fractures and reporting associated dental injuries (Fig. 80.3).

BIOMECHANICS OF THE MANDIBLE

Biomechanically, the mandible can be considered a cantilever beam. The beam is suspended at two points, which represent the TMJ attachments. In the mandibular body and angle, occlusal forces produce zones of relative tension along the superior border and compression along the inferior border. Mandibular tension–compression stress distribution is complex, and stress distribution can vary dramatically, depending on the magnitude and point of force application. In the symphyseal area, the situation is more complicated when the mandible is viewed and tested as a three-dimensional model. Compression is produced at the upper border, and tension and torsional forces exist along the lower border. These three-dimensional stress relationships are important to understand, because tension and compression forces dictate the type of fixation applicable to a particular fracture.

Angle and body fractures can be classified as either vertically or horizontally favorable or unfavorable (Fig. 80.4). Fractures are classified as favorable when muscles tend to draw the fragments toward each other, thus, reducing the fracture. Fractures are described as unfavorable when the

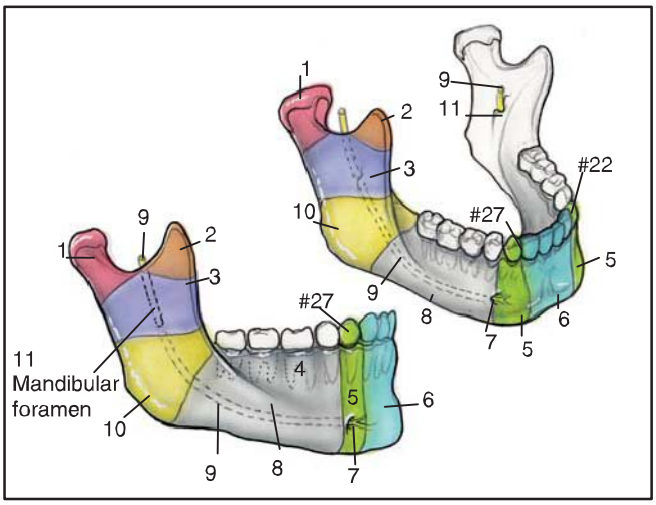

Figure 80.1 The anatomic components of the mandible include the symphysis, parasymphysis, body, angle, ramus, coronoid process, condyle, and alveolus. *1*, Condylar process; *2*, Coronoid process; *3*, Ramus; *4*, Alveolar process; *5*, Parasymphysis; *6*, Symphysis; *7*, Mental foramen; *8*, Body; *9*, Inferior alveolar nerve; *10*, Angle.

fragments tend to be displaced by muscular forces. The majority of mandibular angle fractures are horizontally unfavorable as the masseter, medial pterygoid, and temporalis muscles contribute to the superior and medial displacement of the proximal segment. Vertically unfavorable angle fractures result in medial displacement of the proximal segment by the pterygoid musculature. Vertically unfavorable fractures of the body of the mandible are distracted by the mylohyoid and suprahyoid musculature. A careful assessment of the biomechanical pattern of the fracture is paramount to guide surgical management in order to prevent displacement of fragments due to inadequate fixation techniques.

EVALUATION AND DIAGNOSIS

History

Pain and malocclusion after a blow to the lower face strongly suggest mandibular fracture. Additional symptoms include anesthesia or paresthesia of the lower lip and chin caused by trauma to the inferior alveolar nerve as it courses through the mandibular canal (Table 80.1).

Physical Examination

Fractures of the symphysis–parasymphysis and body can be accompanied by malocclusion, palpable tenderness, altered sensation, gingival lacerations/dental trauma, hematoma in the floor of the mouth, or loss of normal facial contours. Mobility of fractures in these locations is often identified with manipulation. Trismus is a relatively common finding with mandibular fractures, but it also occurs after zygomaticomaxillary complex fractures and with facial contusions without evidence of fracture. The maximal interincisal opening (MIO) of a patient with a mandibular fracture can be markedly reduced secondary to pain, muscle splinting, or impinging fragments. The normal MIO in a healthy adult is approximately 40 to 50 mm.

Fractures of the condyle and condylar neck are associated with impaired translational movement of the condyle along the articular eminence. Although limited rotation may also occur, this lack of translation produces a characteristic deviation of the chin toward the side of such a fracture when opening as well as reduced interincisal distance (Fig. 80.5). Fractures of the neck of the condyle tend to be displaced anteromedially in response to the action of the lateral pterygoid muscle. This displacement produces a loss in the functional height of the ramus, resulting in

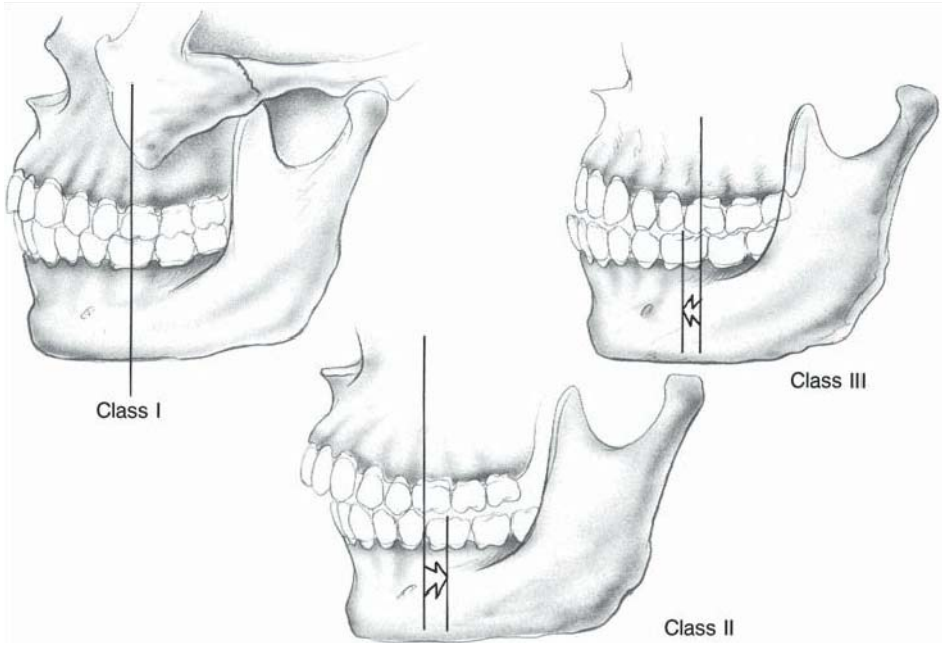

Figure 80.2 The Angle classification of occlusion is based on the relation of the mesiobuccal cusp of the maxillary first molar to the buccal groove of the mandibular first molar.

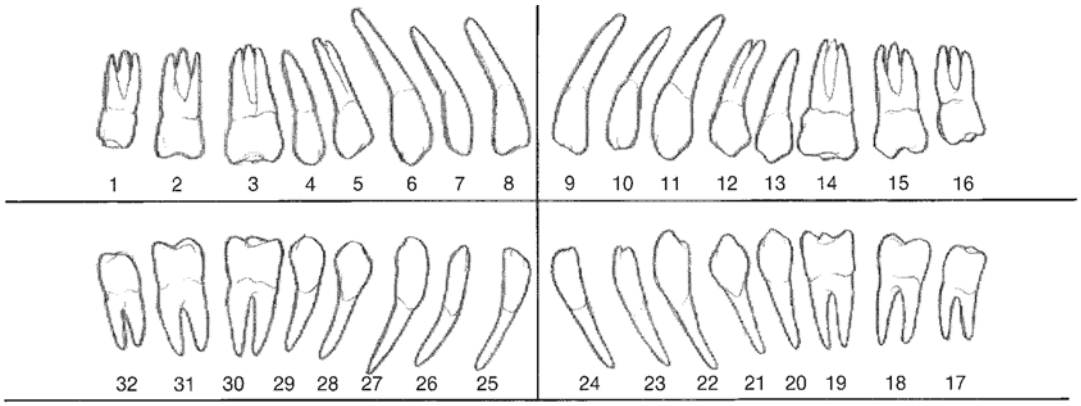

Figure 80.3 The universal numbering system for the permanent dentition begins with the maxillary right third molar. Similarly, the 20 teeth of the deciduous dentition are lettered from *A* to *T*, beginning with the maxillary right second deciduous molar.

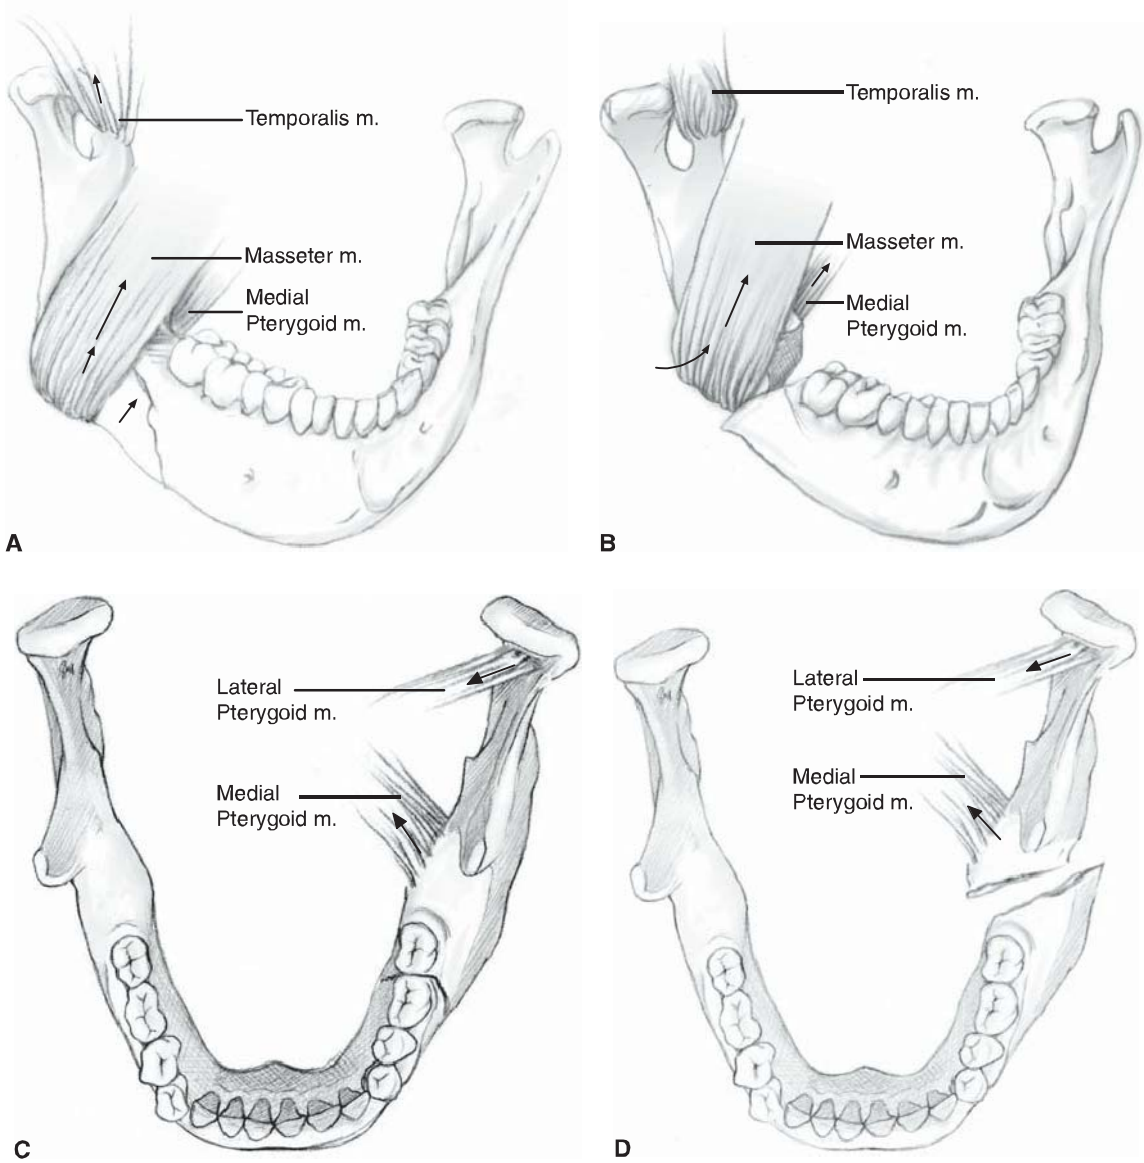

Figure 80.4 **A:** Horizontally favorable fracture. **B:** Horizontally unfavorable; the masseter, medial pterygoid, and temporalis muscles contribute to the superior and medial displacement of the proximal segment. **C:** Vertically favorable fracture. **D:** Vertically unfavorable angle fractures result in medial displacement of the proximal segment by the medial and lateral pterygoids.

TABLE 80.1 DIAGNOSIS MANDIBULAR FRACTURE

Malocclusion

premature contact of the ipsilateral molar teeth. The point of contact acts as a fulcrum and produces a characteristic open bite on the side opposite the fracture (Fig. 80.6). Bilateral condylar/subcondylar fractures often produce a symmetric anterior open bite due to the loss of vertical height of the posterior mandible.

Radiographic Evaluation

The single best radiograph for evaluation of mandibular fractures is the panoramic view (Fig. 80.7A–C). Historically, mandibular series of plane radiographs (posteroanterior view, a Townes anteroposterior axial view, and bilateral oblique views) were used to provide additional information; however, presently, computed tomography (CT) is used in many centers (Fig. 80.7D and E). CT scans, while not required, have become standard in the evaluation of mandibular fractures due to increased accuracy, and are useful in determining the fragment location and size, degree of displacement, as well as undiscovered associated fractures. Helical CT scans have been shown to accurately diagnose 100% of mandibular fractures, whereas initial panoramic imaging was sensitive in 86% of cases (1). Cone-beam technology offers extremely high-resolution, three-dimensional images of the mandible for the diagnosis of mandibular fractures as well as for evaluation of postoperative results (2,3).

MANAGEMENT

General

The primary goals when treating mandibular fractures are to establish and maintain the preinjury occlusion and provide appropriate stabilization for bone healing. Surgical management of mandibular fractures varies based on the location of the fracture and severity of the injury. In general, fractures involving the tooth-bearing portion of the mandible with communication to the oral cavity are considered open. Displacement of jaw fragments is uncomfortable, impairs oral hygiene and alimentation, and contaminates exposed bone with bacterial flora from the oral cavity. These features warrant antibiotic prophylaxis starting as soon as possible after the injury as well as intraoperatively; however, the benefit of perioperative antibiotics has been questioned recently (4). Postoperative antibiotics are unnecessary in the majority of cases (5). Topical chlorhexidine rinse may also help minimize the bacterial contamination of the fracture site. Temporary partial reduction via the use of wire fixation may alleviate some mobility at the fracture site in severely displaced fractures, prior to surgical management. Although delay of fracture repair for a short duration does not markedly increase the infection or complication rate, consideration of patient comfort and prolonged environmental exposure warrants timely intervention. It should also be noted that nonmobile, nondisplaced, or incomplete fractures may be treated with careful observation and soft diet, provided the occlusion is stable and there is no mobility at the fracture site.

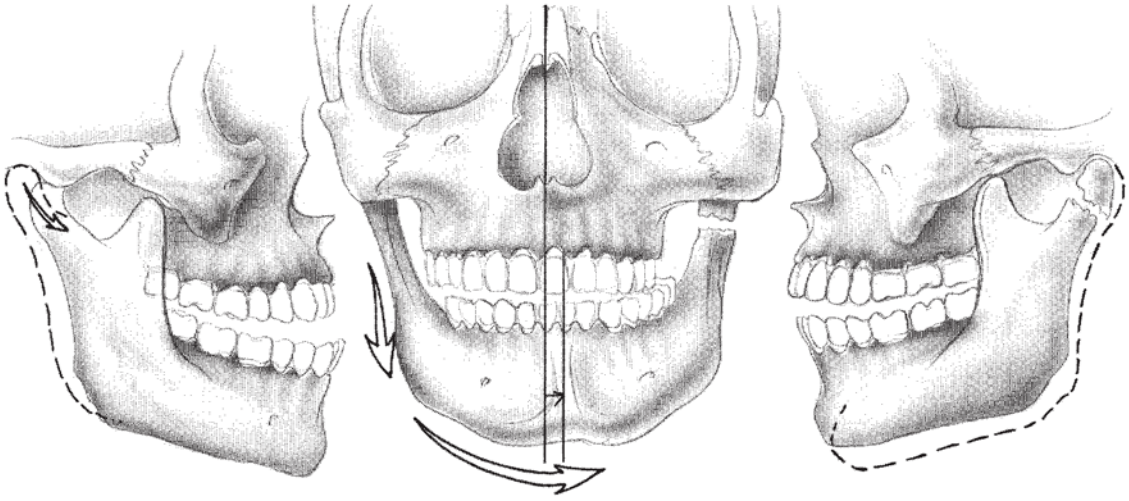

Figure 80.5 Fractured condyle does not translate down the articular eminence during jaw opening. The unopposed translational movement of the opposite condyle deviates the chin toward the side of the fractured condyle.

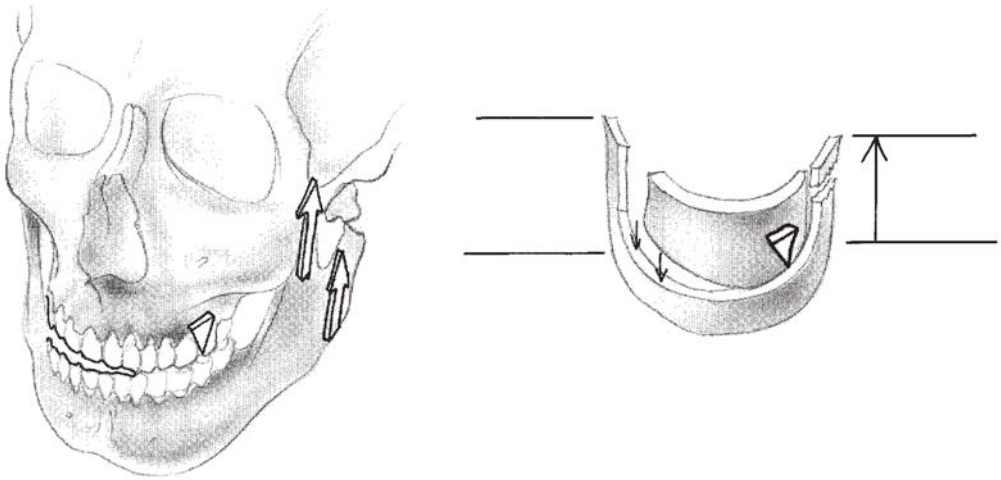

Figure 80.6 Fractured condyle distracted anteromedially by the lateral pterygoid muscle. This produces a shortened functional height of the ramus as the masseter, medial pterygoid, and temporalis muscles draw the ramus closer to the skull base. The ipsilateral molar teeth act as a fulcrum to produce a slight contralateral open bite.

Closed Reduction

Many favorable fractures in adult patients can be managed by means of closed reduction with arch bars, bone screws, or other means of intermaxillary fixation (IMF). Four to six weeks of IMF is generally considered appropriate for the symphysis, angle, and body. Considerable variation among experts exists regarding the duration of IMF for condylar fractures to optimize condylar mobility while achieving osseous union. Longer periods of IMF (4 to 6 weeks) have been associated with poor range of motion, ankylosis at the TMJ, muscle atrophy, and loss of interincisal opening (6). Nevertheless, many condylar fractures are successfully managed with closed techniques (7). Closed reduction techniques are still commonly used for fractures in children involving the developing dentition and in nonmobile, nondisplaced fractures. The indications for closed reduction vary widely; however, closed techniques should be utilized for cases in which an open reduction is either unnecessary or contraindicated.

Open Reduction

Table 80.2 summarizes treatment options for open reduction with internal fixation (ORIF) for mandibular fractures in adult patients according to fracture location. Internal fixation can be classified as being rigid (reconstruction plates, lag screws), semirigid (miniplates), or nonrigid (interosseous wires). Most rigid and semirigid techniques obviate the use of postoperative IMF, and the occlusion may be guided with postoperative dental elastics when

TABLE 80.2 OPEN REDUCTION INTERNAL FIXATION OPTIONS FOR ADULT DENTATE PATIENTS

Fracture Location	ORIF
Symphysis and parasymphysis	Inferior plate and arch bars Inferior locking or nonlocking reconstruction plate Inferior locking or nonlocking 2.0-mm mandible plate and superior border monocortical tension band Two 2.0-mm miniplates (8) Two lag screws (9)
Body	Inferior plate and arch bars Inferior locking or nonlocking reconstruction plate Inferior locking or nonlocking 2.0-mm mandible plate and superior border monocortical tension band Two 2.0-mm miniplates (8) Multilag screw technique, if oblique
Angle	Single malleable superior border miniplate (11) Two biplanar or monoplanar miniplates (12) Inferior locking or nonlocking reconstruction plate with superior tension band
Ramus and condyle	One 2.0-mm miniplate Two 1.5/2.0-mm miniplates

required. This is an especially important consideration among patients with epilepsy, diabetes, alcoholism, psychiatric disorders, or severe disability, who may not tolerate IMF. The classic indication for open reduction and rigid internal fixation is inability to reduce or stabilize the fracture with a closed technique. Other indications include associated midface fractures, associated condylar fractures, IMF is either contraindicated or not possible, to preclude the need for IMF for patient comfort, and to facilitate the patient's return to work or other activities. The fundamental principles of rigid internal fixation include accurate anatomic reduction, stable internal fixation, early mobilization, and careful tissue handling with preservation of the neurovascular supply. The application of appropriately stable fixation varies depending on the location and severity of the fracture. Internal fixation is the application of sufficient hardware to prevent movement across the fracture site during function; however, this is not necessarily rigid internal fixation in many situations. Thus the concept of *load-bearing* versus *load-sharing* fixation merits review. *Load-bearing* fixation is the application of hardware of sufficient rigidity to resist all functional forces until osseous union is achieved. When treating comminuted mandibular fractures, atrophic mandibular fractures, and those with segmental defects, load-bearing fixation is generally required. In contrast,

load-sharing fixation refers to the application of hardware that allows the functional load to be shared between the hardware and the apposed mandibular cortices after fracture reduction is achieved along the fracture site. The majority of mandibular fractures are adequately treated with load-sharing fixation.

Comminuted fractures are defined as a fracture pattern in which a single anatomic region is broken into pieces. Comminuted fractures of the mandible have been treated in a variety of fashions, including closed reduction, external pin fixation, internal wire fixation, and ORIF with titanium plating systems (8–10). Most nonunions in these fractures result from inadequate immobilization of comminuted fragments. Investigations have revealed that periosteal stripping during ORIF does not lead to increased infections as long as fragments are properly stabilized (9,10). Comminuted mandibular fractures treated with formal ORIF using reconstruction plates exhibit lower complication rates and decreased recovery time when compared to external pin fixation and closed reduction techniques (Fig. 80.8) (9,10).

In terms of soft tissue approaches, similar complication rates have been observed when comparing transoral versus extraoral reduction of mandible fractures (11). The majority of mandibular fractures may be treated via the transoral approach, which allows direct occlusal visualization during reduction and internal fixation, eliminates facial scarring, and limits the risk of facial nerve injury. In many instances, posterior body, angle, ramus, and condyle fractures can be addressed through combined intraoral and extraoral approaches utilizing trocars to reduce external scars. The main advantage of the extraoral approach is enhanced visualization and access for complex or comminuted fractures. Extensive comminution or fractures in the severely atrophic mandible often require an external approach to appropriately address the fracture.

Selection of Hardware

In comminuted, segmental, and infected fractures, when load-bearing fixation is required, large reconstruction plates using 2.4 or 2.7-mm screws are advised (Fig. 80.8). In general, these reconstruction plates require placement of at least three to four screws on either side of the fracture within stable portions of the mandible. Locking reconstruction plates retain their yield load, yield displacement, and stiffness even when imprecise contouring to the bone has occurred, whereas nonlocking reconstruction plates demonstrate significant differences in these factors even with as little as 1 mm of displacement from the bone (12). For this reason, many now prefer the use of locking reconstruction plates in these situations. The benefit of locking technology may be less apparent in load-sharing fixation schemes and nonlocking plates are often sufficient (13).

Miniplates (1.5 to 2.0 mm) are commonly used for mandibular fracture repair (13–15). Generally, a six-hole plate is positioned at the inferior border and bicortical screws are placed; a four-hole plate is placed at the upper border with either bicortical or monocortical screws to provide a tension band. Careful attention to the location of the mental nerve and tooth roots is required. Sagittal and oblique fractures may be amenable to repair with lag screw techniques. To achieve optimal compression without displacement, the lag screw hole must be drilled perpendicular to the fracture (Fig. 80.9). The most common indication for the lag screw technique is the symphyseal fracture. It should be noted that dynamic compression plates, which produce interfragmentary compression of bone, were historically thought to offer an advantage over standard reconstruction plates. Investigations have revealed that dynamic compression may introduce unwanted forces resulting in difficulty with hardware application, oblique fracture displacement,

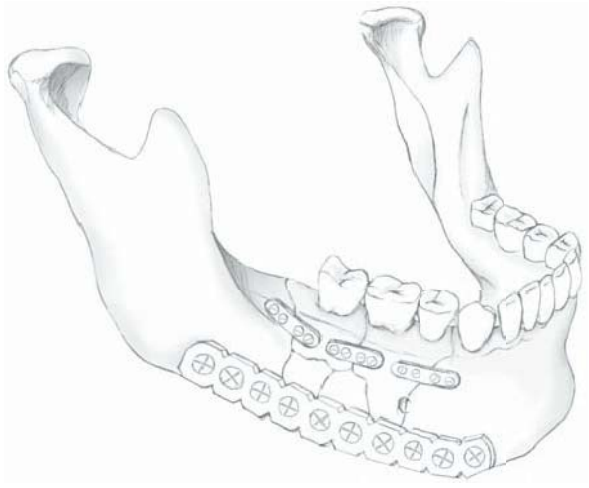

Figure 80.8 Reconstruction plates (2.4 or 2.7-mm) are used in comminuted, gap, and infected fractures. Small fragments may be reduced and stabilized with smaller (2.0-mm) plates prior to application of the reconstruction plate.

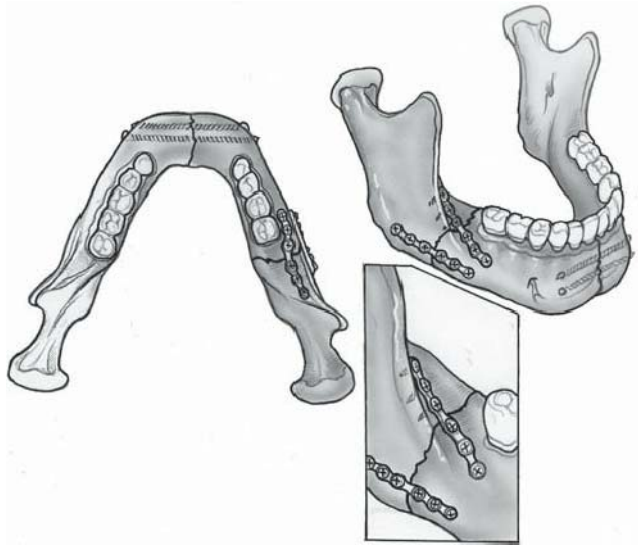

Figure 80.9 Reduction and fixation of a symphyseal fracture and angle fracture with lag screw technique in the symphyseal region and superior border plate (2.0-mm) for the angle fracture.

and malocclusion (16). In addition, dynamic compression does not follow physiologic principles as bone tends to resorb under compression and therefore this technology is rarely indicated.

Symphysis–Parasymphysis

Symphysis and parasymphyseal fractures are those fractures located between the canines (see Fig. 80.1). Vertically unfavorable symphyseal fractures tend to collapse the mandibular arch in response to the medial pterygoid and mylohyoid musculature. A rigid technique necessitates application of arch bars and temporary intraoperative interdental wiring to establish the proper occlusion. Open reduction with rigid internal fixation of symphyseal fractures may be accomplished with a variety of hardware configurations. These include an inferior border contoured mandibular fracture plate with mandibular arch bar, an inferior locking or nonlocking reconstruction plate, an inferior locking or nonlocking 2.0-mm mandible plate and a superior border monocortical tension band, two lag screws, or two properly placed 2.0-mm miniplates (Fig. 80.10) (15,17–20). Inferior border plates placed in these regions should be slightly overbent to prevent lingual splay of the fracture resulting in widening at the mandibular angles and transverse occlusal discrepancies. Recent biomechanical investigations indicate that the lag screw technique addresses the issue of lingual cortex reduction and likely provides the most stable construct for symphyseal fractures (17,18). Nevertheless, knowledge of multiple techniques is required to address the variety of fracture patterns of the mandibular symphysis for predictable outcomes.

Body

Fractures of the body are located between the canine and the last molar (Fig. 80.1). Fixation of body fractures is accomplished by the same means as fractures of the symphysis; however, special attention must be directed to the inferior alveolar/mental nerve and dentition. In addition, the marginal mandibular branch of the facial nerve is at risk when an external approach is utilized. Rigid fixation can be easily applied to body fractures using a retromandibular or submandibular approach, or via an intraoral approach with or without transbuccal trocars.

Hardware configurations for mandibular body fractures are similar to those for the fixation of symphyseal fractures with the exception of lag screws, which are less commonly indicated. Anterior body fractures coursing through the mental foramen can be managed by placing an inferior bicortical mandibular plate (2.0 to 2.4 mm) and a superior border monocortical tension-band plate. If the fracture occurs in an edentulous area of the body, or an atrophic situation exists, consideration of load-bearing fixation is recommended due to the increased leverage produced by any remaining anterior dentition on the hardware construct.

Angle

Fractures of the mandibular angle occur posterior to the second molar within the retromolar triangle (Fig. 80.1). Fractures of the angle are associated with a high incidence of infection and often require ORIF due to the relatively small cross-section of bone in this region, and the

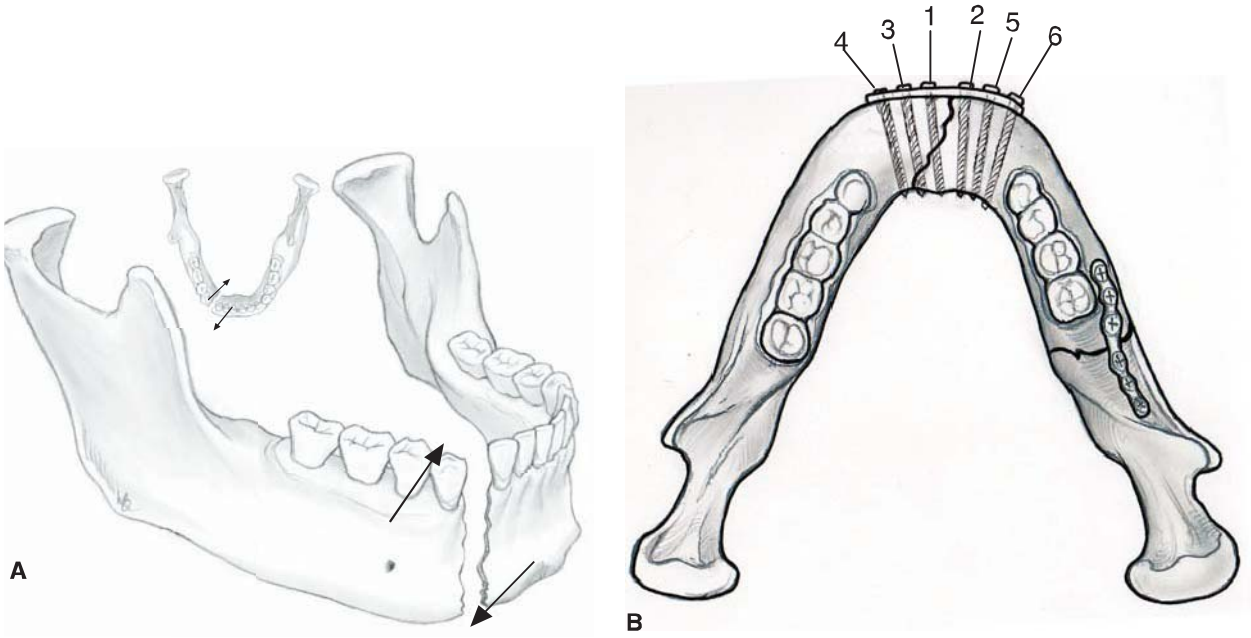

Figure 80.10 **A:** An oblique symphyseal fracture. **B:** Initial compression and reduction at the superior mandibular border provided by the arch bar. The 2.0- or 2.4-mm mandibular reconstruction plate is slightly overbent and is applied with bicortical screws. The screws are numbered in the order that they should be placed.

oblique and irregular fracture configuration. Additionally, impacted wisdom teeth in this area increase the risk of fracture, complicate treatment, and may require removal in the event reduction is not possible or the tooth is loose (21,22). Transoral placement of a single malleable miniplate (noncompression with 2.0-mm monocortical screws) along the superior border of the angle has been commonly used with excellent results (Fig. 80.11A and B) (21,23,24). Two-miniplate rigid fixation of the angle also produces acceptable results and can be accomplished thorough an intraoral approach. These two miniplates can be placed in either a biplanar or monoplanar manner, although studies confirm that the biplanar method is more stable (Fig. 80.11A and C) (25).

The external approach can also be used to apply a variety of hardware configurations: an inferior border locking or nonlocking reconstruction plate with or without a monocortical superior tension plate, an inferior bicortical dynamic compression plate with neutral screw placement and a superior monocortical tension plate, or two monoplanar miniplates. These systems can be applied using an intraoral approach with the aid of transbuccal trocars as well. Although many technical variations for ORIF of mandibular angle fractures are effective, selection should be based on the availability of equipment and the experience of the surgeon.

Condyle

The condyle is classified as the area superior to the line extending from the sigmoid notch to the posterior border of the mandible (Fig. 80.1). The goals of treating condylar fractures include normal range of motion without pain, preinjury occlusion, and symmetry of the mandible. The treatment of fractures of the mandibular condyle include open and closed techniques; however, considerable controversy exists regarding optimal management (7,26–28). Generally, nondisplaced condyle fractures are treated conservatively with arch bars and guiding elastics. Brief periods of IMF have been advocated; however, no consensus exists regarding the optimal duration (7,29). As noted previously, long periods of IMF can result in TMJ ankylosis and limited opening and are therefore not recommended. Early mobilization with guiding elastics to support the occlusion allows for return to preinjury range of motion and increased patient comfort (6,7). The indications for open reduction of condylar fractures remain debatable; however, the classic indications summarized in Table 80.3 provide a framework for treatment consideration. Nevertheless, there are many advocates for ORIF of mandibular condylar fractures, as several investigations have demonstrated faster recovery with improved occlusion, excellent function, and improved facial symmetry (30,31). Condylar, subcondylar, and ramus fractures can each be stabilized with a single 2.0-mm mandibular miniplate with at least two screws on each side of the fracture line. Complications that can occur with open treatment of condyle fractures include hematoma, facial nerve damage, infection, auriculotemporal nerve dysfunction, Frey syndrome, and scarring. Recent transoral endoscopic treatment of condylar fractures offers an excellent approach and avoids facial nerve injury (28,32,33). The technique requires specialized equipment and can be technically challenging until significant surgical experience is achieved (23,25–27). It should also be noted that the transoral technique is not without complications (34).

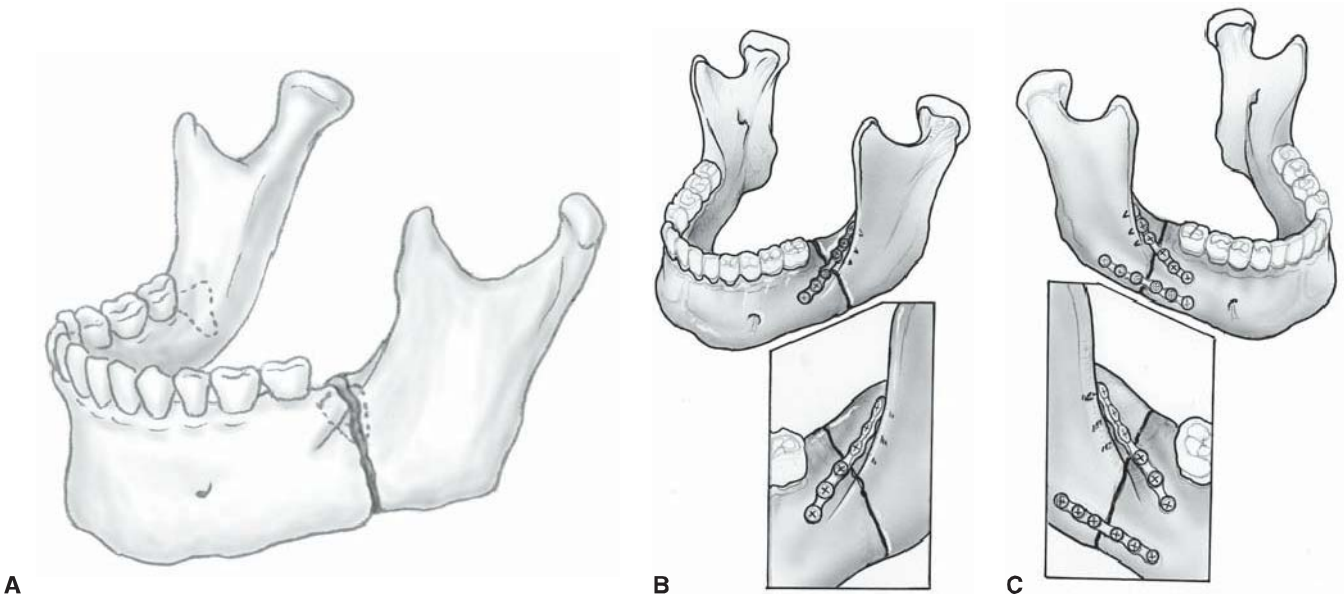

Figure 80.11 **A:** Transverse angle fracture with minimal displacement. **B:** Transoral placement of a single malleable 2.0-mm miniplate with monocortical screws near the superior border of the angle. **C:** Two 2.0-mm miniplate rigid fixation of the angle fracture placed in a biplanar manner.

TABLE 80.3 INDICATIONS FOR OPEN REDUCTION OF MANDIBULAR CONDYLE FRACTURES

Absolute Indications
- Displacement into the middle cranial fossa
- Foreign body in the joint capsule (e.g., gunshot wound)
- Lateral extracapsular deviation of the condyle
- Inability to open mouth or achieve occlusion after 1 week
- Open fracture with the potential for fibrosis

Relative Indications
- Unilateral or bilateral condylar fractures associated with comminuted midfacial fractures
- Comminuted symphysis and condyle fracture with loss of teeth
- Displaced fracture resulting in an open bite or retrusion in medically compromised, mentally unstable or retarded adults
- Displaced condyle with edentulous, or partially edentulous, mandible with posterior bite collapse

Adapted from Zide MF. Open reduction of mandibular condyle fractures. Indications and technique. *Clin Plast Surg* 1989;16(1):69–76, with permission.

Although intracapsular condylar fractures have been traditionally managed with closed techniques due to the risks of necrosis and TMJ arthrosis, open techniques have been applied to these situations with reasonable results, and the optimal management remains elusive (26,27,35).

Ramus

The ramus is the area superior to the angle and inferior to an angle formed by two lines with the apex at the sigmoid notch (Fig. 80.1). In many situations, ramus fractures may be treated closed when they occur in isolation as they are seldom displaced and splinted by the pterygomasseteric sling. Traditional techniques of internal fixation may be used in situations of displacement or comminution of the mandibular ramus.

SPECIAL CONSIDERATIONS

External Fixation

Historically, stabilizing mandibular defects and fractures by external fixation was frequently used in contaminated gunshot wounds or infections resulting in the loss of mandibular continuity (Fig. 80.12A). Although current locking reconstruction technology addresses many of these situations (Fig. 80.12B), external fixation provides the advantage of fragment stability and allows wound debridement and stabilization prior to rigid internal fixation and is appropriate in some situations. Following the resolution of infection and the healing of the soft tissue envelope, reconstruction can be accomplished using a traditional reconstruction plate with bone grafting or free tissue transfer.

Management of Teeth in the Line of Fracture

It is generally agreed that previously healthy teeth can be left in the line of fracture if the tooth is stable and the periodontal ligament associated with the tooth is reasonably intact. Conversely, teeth that have suffered structural damage, periodontal ligament damage compromizing the blood supply, or which prohibit proper fracture reduction should be removed. Removal of previously healthy third molars in the line of angle fractures can contribute to fracture instability and distraction and, therefore, are retained but monitored for infection in the postoperative period (22).

Edentulous Fractures

Edentulous fractures are more common in older patients (Fig. 80.13). Historically, the management of an edentulous mandibular fracture was often closed reduction in which arch bars are applied to the dentures or Gunning splints to allow IMF. This technique has several disadvantages including poor mandibular segment control and poor reduction of the fracture. Current treatment of edentulous mandible fractures is performed with open reduction internal fixation using a reconstruction plate in the majority of cases. Locking reconstruction plates are generally recommended; however, multiple options have been used with success provided load-bearing fixation is achieved (36–38). Severely atrophic mandible fractures (less than 10 mm vertical height) have the greatest risk of complications, and consideration to primary bone grafting should be entertained provided there is no evidence of active infection (39). A variety of bone grafting techniques have been used in the treatment of atrophic mandibular fractures, including corticocancellous iliac crest and free tissue transfer (39–42).

Pediatric Fractures

Pediatric mandibular fractures represent a somewhat unique situation due to the presence of the unerupted dentition and the growth potential in this population. In addition to providing areas of weakness prone to fracture, unerupted tooth buds also present challenges for fixation and screw placement. When compared to the adult situation, a significantly larger proportion of pediatric mandibular fractures can be managed by means of closed reduction. Some scenarios such as nondisplaced, stable fractures may be managed with soft diet and observation. Placement of standard archbars during the mixed dentition stage can be problematic, and involvement of the dentist/orthodontist to provide anchorage devices to facilitate closed management is recommended. Functional appliance therapy with guiding elastics, begun immediately after the injury, is useful in maintaining proper occlusion and restoring mandibular position. Rigid and open techniques are considered

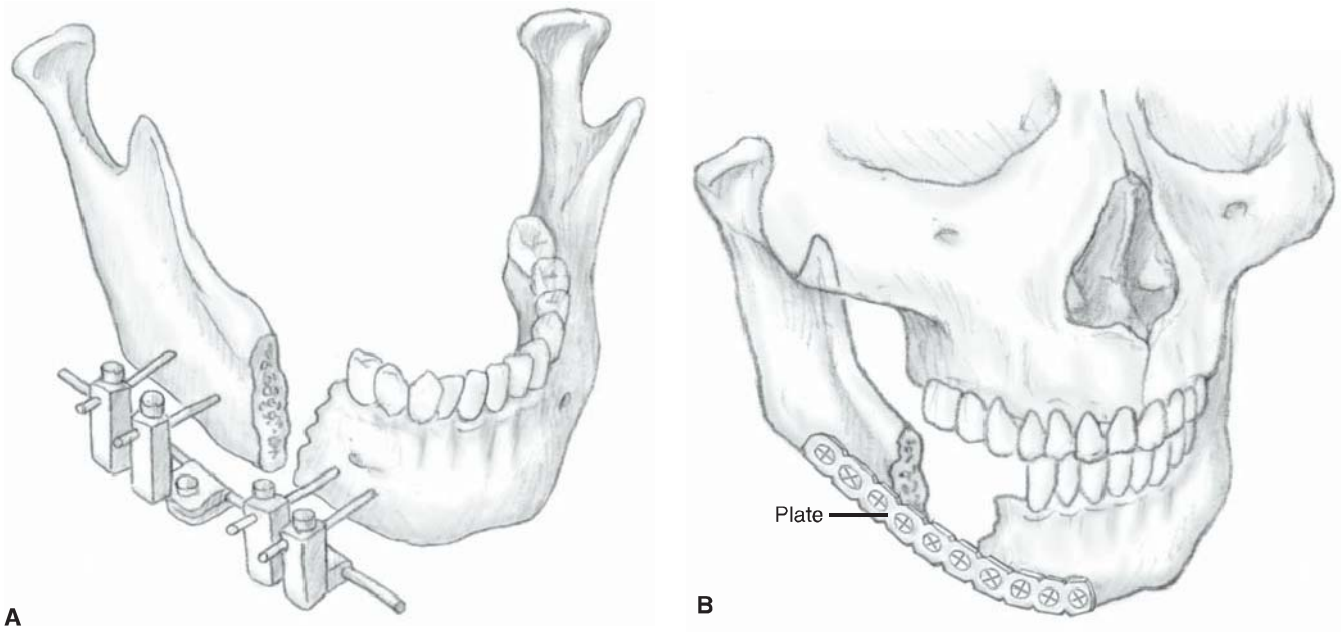

Figure 80.12 **A:** Application of an external fixation system allows alignment of the fracture or defect, appropriate for some situations in which rigid internal fixation is contraindicated. **B:** 2.4- to 2.7-mm reconstruction plate (generally locking) used to bridge a mandibular defect.

in situations of severe displacement, occlusal instability, and comminuted fractures. The selection of hardware is similar to the adult situation; however, consideration for monocortical techniques to avoid the developing dentition, inferior border placement of hardware, and resorbable technology is warranted to avoid complications. The most dreaded complication of pediatric condyle fractures is the development of ankylosis of the TMJ, which can result in growth disturbances producing facial asymmetry/deformity. Consideration for open reduction of severely displaced, bilateral subcondylar fractures is warranted to prevent loss of facial height, mobility, and anterior open bite if closed techniques fail. Regardless of whether closed or open techniques are utilized, early mobilization reduces the risk of limited mobility due to fibrosis/ankylosis, and should be a tenet of treatment.

Removal of Hardware

The need for hardware removal has been somewhat controversial historically; however, current titanium fixation systems are extremely biocompatible and form an intimate association with bone that makes plate removal technically difficult and probably unnecessary in the majority

Figure 80.13 The atrophic, edentulous mandible often fractures at the midbody, in the area of minimal bone height.

of situations. Mandibular fractures require hardware removal more commonly when compared to midface fractures. Infection and mobility of the hardware are the most common indications for hardware removal after ORIF of mandibular fractures (43). In the pediatric situation, controversy continues regarding titanium plate removal with concerns of long-term growth disturbances, systemic titanium absorption, and "false migration" of hardware during growth (44,45). Nevertheless, while hardware removal is often recommended, the literature indicates that long-term retention of titanium hardware has minimal effects on mandibular growth with the possible exception of the condylar growth center (46,47).

COMPLICATIONS

Table 80.4 lists complications of mandibular fractures. Total complication rates have been reported at approximate rates of 15% to 40% (16,25,34,48–50). The most common factors contributing to poor outcomes in fracture repair are the absence of teeth, medical comorbidities, poor patient compliance, delay in presentation, and trauma severity. The infection rate after ORIF of mandibular fractures is about 6% to 10% provided appropriate preoperative antibiotics are administered. As noted previously, postoperative antibiotics are likely unnecessary in the majority of cases (5). Marked malocclusion immediately after rigid fixation is usually caused by an error in fragment alignment and is permanent unless corrected by prompt revision surgery. Standard orthognathic surgical techniques can be used to correct malocclusion caused by late malunion of jaw fractures. Although posttraumatic TMJ ankylosis is rare with mobilization, the true incidence of TMJ dysfunction after mandibular fracture is difficult to establish. There are, however, fracture patterns related to the condyle, which likely result in significant joint disturbance (51). Sensory disturbances of the inferior alveolar nerve are relatively common after mandibular fracture, but traumatic neuroma formation is rare.

EMERGENCIES

Emergencies related to mandibular fractures are relatively rare and are listed in Table 80.5. Bilateral fractures of the mandibular body can cause posterior displacement of the anterior mandibular arch owing to the presence of the suprahyoid musculature. This can precipitate airway compromise, especially when the patient is in the supine position. Immediate intervention is required to establish a stable airway and includes patient repositioning, wire stabilization, intubation, or tracheotomy. Cerebrospinal otorrhea can herald displacement of a condylar head into the middle cranial fossa. Such an injury can be associated with a dural tear; neurosurgical consultation and prompt ORIF is recommended. Concomitant injury to the adjacent internal carotid artery occasionally occurs in conjunction with fractures of the condylar neck. A severely displaced fracture can prompt further radiologic investigation of the adjacent carotid artery. Gross hemorrhage rarely accompanies mandibular fracture, but troublesome bleeding occasionally arises from the inferior alveolar artery within the mandibular canal. Ligation of this vessel is difficult, and temporary reduction of the fracture effectively tamponades the bleeding site.

FUTURE CONSIDERATIONS

Further improvements in endoscopic and hardware technology will drive improvements in the treatment of facial fractures (28,32,34,52). Resorbable fixation systems for internal fixation are an attractive option in the treatment of adult and pediatric mandibular fractures and is currently under investigation (53,54). Improved imaging modalities, stereotactic image guidance, and medical modeling will likely improve the treatment of acute fractures and the correction of late deformities. Improved biotechnology, such as bone morphogenetic protein, will likely contribute to improved bone healing in these situations (55–58).

TABLE 80.4 COMPLICATIONS MANDIBULAR FRACTURES

Infection

Adjacent injury to internal carotid artery
Hemorrhage
Severed facial nerve
Anesthesia or paresthesia of lower lip and chin

HIGHLIGHTS

- Fractures of the condylar neck are associated with anteromedial displacement of the condyle owing to the action of the lateral pterygoid muscle.
- Unilateral condyle fractures produce a characteristic open bite on the side opposite the fracture.
- During opening, the chin deviates toward the side of a fractured condyle.
- Bilaterally displaced fractures of the condyles are associated with a symmetric anterior open bite.
- Almost all fractures of the mandibular angle are unfavorable and necessitate open reduction.
- Vertically unfavorable angle fractures result in medial displacement of the proximal fracture segment.
- Normal maximal interincisal opening is approximately 40 to 50 mm.
- The majority of stable teeth in the line of a mandibular fracture are preserved.
- Posttraumatic ankylosis of pediatric condylar fractures produces severe functional disturbances and developmental facial asymmetry.
- Bilateral fractures of the mandibular body, especially in edentulous patients, can allow the anterior arch of the mandible to fall posteriorly and may obstruct the airway.
- When malocclusion is detected immediately after open reduction with rigid fixation, revision surgery is indicated to correct errors in fracture alignment.

Midface Fractures

81

Brendan C. Stack Jr *Francis P. Ruggiero*

ANATOMY

Buttresses

The structure of the midfacial skeleton is related to its mechanical adaptation to forces generated by mastication. Forces of up to 200 pounds per square inch are developed during chewing. Additionally facial contours result from paranasal sinus pneumatization. These sinuses are involved in voice resonance, act as shock absorbers, and account for an approximate lightening of the head of 1 kg if they have otherwise been solid bone. The concept of *buttresses* describes the relatively stronger areas of the midfacial skeleton that bear the bulk of the vertically oriented forces produced during mastication. These forces are absorbed and transmitted to the base of skull (Fig. 81.1) (1).

The vertical buttress system has seven components, including three paired pillars and one unpaired structure: (a) The *nasomaxillary* (NM) (aka medial, nasofrontal) buttresses extend from the anterior maxillary alveolus along the pyriform aperture and medial orbit, through the nasal and lacrimal bones to the frontal bone. (b) The *zygomaticomaxillary* (ZM) (aka lateral) buttresses extend from the lateral maxillary alveolus along the lateral maxilla to the malar eminence of the zygoma, then superiorly along the lateral orbital rim to the frontal bone. (c) The *pterygomaxillary* buttresses extend posteriorly from the maxilla to the pterygoid plates of the sphenoid bone. (d) A midline buttress, consisting of the vomer and perpendicular plate of the ethmoid bone, connects the palatine process of the maxilla to the frontal bone (2).

The mostly curved, vertical buttresses are reinforced by a number of horizontal buttresses. These include the frontal bar (superior orbital rims plus the frontal bone), the inferior orbital rims, and the maxillary alveolus, among others (3).

Maxilla

The maxilla consists of paired bones also called maxillae. Each has a hollow body that is the maxillary antrum. Projections from the maxillary body extend superiorly and medially to the frontal and nasal bones, and laterally to the zygoma. The inferior and medial palatine process of the maxilla forms the bulk of the primary hard palate. The alveolar process of the maxilla extends inferiorly and holds the roots of the upper teeth (4).

The bone of the maxilla is for the most part quite thin. The lateral wall of the maxillary antrum however includes a wedge of thicker, compact bone. It is in this area that the ZM buttress arises. It appears that the greatest occlusal load is borne by this buttress.

Zygoma

The zygoma is a relatively sturdy bone that is important structurally, as an integral component of the buttress system, and also forms the aesthetically vital malar prominence. It is related to the surrounding facial bones via articulations with four bones—the frontal, maxillary, temporal, and sphenoid bones.

The superficial projections of the zygoma define two critical external arcs of facial contour (Fig. 81.2). The vertical arc follows the course of the ZM buttress (concave), running from the zygomatic process of the frontal bone, over the zygoma itself to the lateral antral wall of the maxilla (convex). The horizontal convex arc runs from the maxilla in the area of the lacrimal fossa, across the zygoma, to the zygomatic process of the temporal bone. The point of intersection of the vertical and horizontal arcs defines the location of the malar prominence.

The deep projections of the zygoma are the sphenoid projection, which articulates along the lateral orbital wall with the orbital plate of the sphenoid bone, and the orbital floor projection, that articulates with the orbital surface

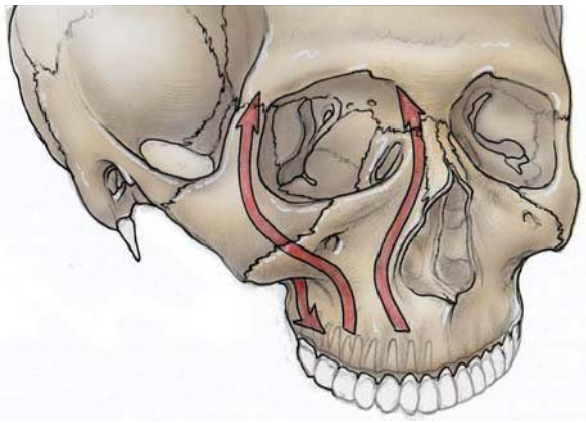

Figure 81.1 Vertical buttresses of the facial skeleton: The NM (medial), ZM (lateral), and pterygomaxillary buttresses of the facial skeleton are illustrated.

of the maxilla along the lateral aspect of the orbital floor. The zygoma therefore constitutes the majority of the lateral orbital rim and wall, and a portion of the inferior rim and the orbital floor.

PATHOPHYSIOLOGY/MECHANISM OF TRAUMA

With the midfacial skeleton adapted to the vertical forces of mastication, it is the force delivered at other vectors that cause the bulk of midface fractures. Common etiologies of midfacial fractures include motor vehicle accidents, assaults, and sporting events (5).

Maxilla

Le Fort Fractures

Rene Le Fort introduced a classification of midfacial fractures on the basis of cadaver experiments he performed in the early part of the 20th century (6). He noted that fractures tend to occur at characteristic locations, which correspond with relatively weak areas of the facial skeleton.

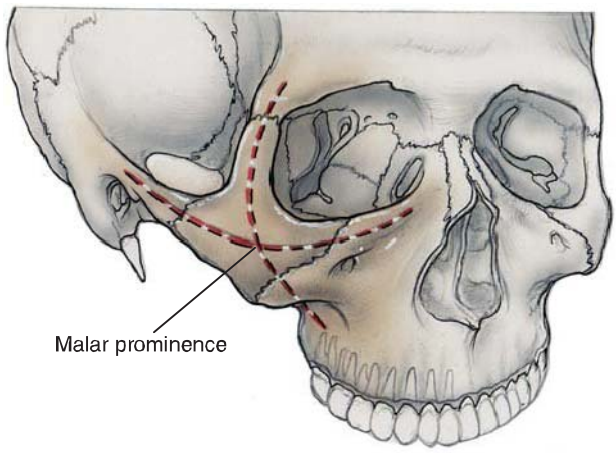

Figure 81.2 Vertical and horizontal projections of the zygoma. Their intersection defines the location of the malar prominence.

Le Fort Level I fractures are transverse fractures separating the maxillary alveolus from the rest of the midfacial skeleton (Fig. 81.3).

These injuries generally result from anterior force directed at the lower midface. The *NM* and *ZM buttresses* are disrupted (7). The fracture line then extends transversely through the maxillary sinus and nasal septum and posteriorly across the pyramidal process of the palatine bone and pterygoid processes of the sphenoid bone (2).

Le Fort Level II fractures create a pyramidal NM fragment separate from the upper craniofacial skeleton. They result from either direct anterior force against the midface or inferior impact at the mandibular symphysis transmitted to the midface via the dentoalveolar segments of the mandible. Once again the NM and ZM buttresses are disrupted, this time more superiorly than the Le Forte I level. The fracture line extends from the nasal root via the lacrimal bone and medial orbital wall, then anteriorly along the orbital floor to the infraorbital canal. From this point, the fracture line follows the ZM suture to anterolateral maxillary wall. Posteriorly, the fracture line passes across the infratemporal surface of the maxilla through the lower pterygoid plates (7,8).

Le Fort Level III fractures, which result in complete separation of facial skeleton from the skull base, are less common. They usually result from anterior force directed obliquely to the plane of the vertical buttresses (1). The vertical buttresses are disrupted at their superiormost extent. The fracture line extends through the root of the nose, across the lacrimal bone and medial orbital wall, across the orbital floor to the inferior orbital fissure. From this point, one fracture line traverses the lateral orbital wall as it approaches the frontozygomatic suture; a second line passes over the back of the maxilla to the lower pterygoid plates. An additional fracture line through the zygomatic arch completes the craniofacial dysjunction (8,7).

In clinical practice, the patterns of maxillary fractures encountered are rarely as orderly as the above suggests. Le Fort's original work demonstrates that he was certainly not unaware of this. The level I to III classification scheme is a distillation of some of his most significant experimental observations. In his experiments, and most definitely in real-life trauma, force is delivered unevenly to each side of the face, at varying angles, and at variable locations. The resulting fractures may be asymmetric from one side of the face to the other (i.e., Le Fort II on the left, Le Fort III on the right), may combine with other fractures to create a more complex pattern (e.g., a Le Fort II fracture and a zygomaticomaxillary complex (ZMC) fracture on the same side of the face constituting a "complex" Le Fort III fracture), or may be maxillary fractures not described by the classification at all.

Other Maxillary Fractures

Anterior forces localized between the nose and malar prominence may produce anterior maxillary wall fractures. Significant force delivered to the lower anterior midface, in addition to generating the classic fracture patterns described by Le Fort, may less commonly cause fractures

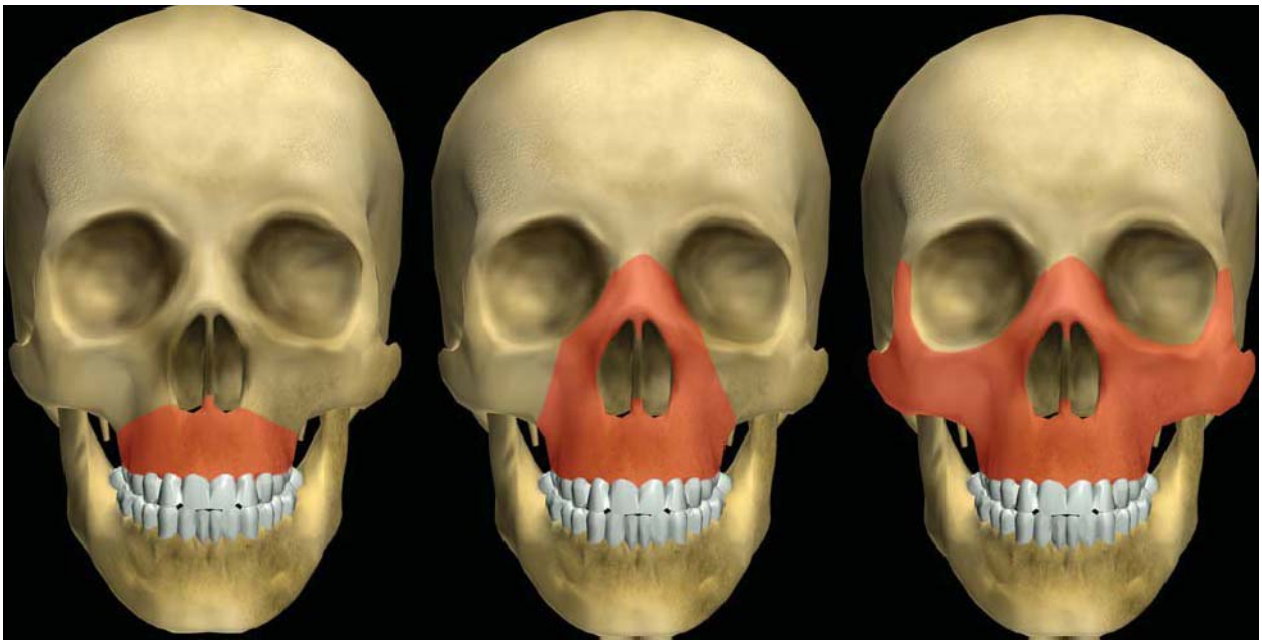

Figure 81.3 Anterior view of facial skeletons. Shaded areas correspond to Le Fort levels I, II, and III fractures. LifeART image copyright (c) (2012) Lippincott Williams & Wilkins. All rights reserved.

of the palate. While they may occur in isolation, *palatal fractures* tend to accompany extensive facial injuries (9). Most often, the palate is fractured in a sagittal fashion, in a paramedian plane (see Fig. 81.11). Fractures in a number of other orientations and locations are also possible (10). Clinical indicators of palatal fractures include palatal lacerations, lip lacerations that extend into the gingivolabial sulcus, maxillary tooth loss, and malocclusion.

Palatal fractures, and in particular those oriented sagittally, alter the width of the maxilla and permit the rotation of the maxillary dentoalveolar segments. One of the fundamentals in management of severe facial fractures is the intraoperative restoration of normal maxillomandibular occlusion, with anatomic reduction of fractures following from this basis. Palatal fractures, by complicating the restoration of occlusion, can confound this strategy if not appropriately addressed first (10,11).

Zygoma

Zygomaticomaxillary Complex Fractures

Various terms are used to describe fractures involving the zygoma and its articulating bones. These include malar fractures (12), zygoma or zygomatic fractures (13), ZMC fractures (14), tripod fractures (15), tetrapod fractures, trimalar fractures, zygomatico-orbital fractures (16), and orbitozygomatic fractures (17). All of these terms emphasize certain salient features of this type of injury. For example, the term "tripod" underscores the observation that blunt force to the zygoma tends to disrupt not the zygoma itself, but rather, its three superficial articulations, to the frontal, maxillary, and temporal bones; the intact body of the zygoma has a tripod-like appearance (Fig. 81.4). The terms "zygomatico-orbital fracture" and "orbitozygomatic fracture" stress that because it forms portions of the lateral and inferior orbit, fractures that involve the zygoma are necessarily also orbital fractures. The most important point for the surgeon-in-training to understand is that all of the terms refer to the same injury. Henceforth within this chapter, the term *ZMC fracture* is used for uniformity.

ZMC fractures generally result from blunt trauma to the malar eminence, the most prominent feature of the lateral midface. They are the second most common facial fracture, after nasal fractures (18). Routinely, they involve disruption of the projections of the zygoma. The severity of ZMC fractures seems most related to the force and velocity of impact (14). In the most severe injuries, the sturdy zygoma itself may be fractured.

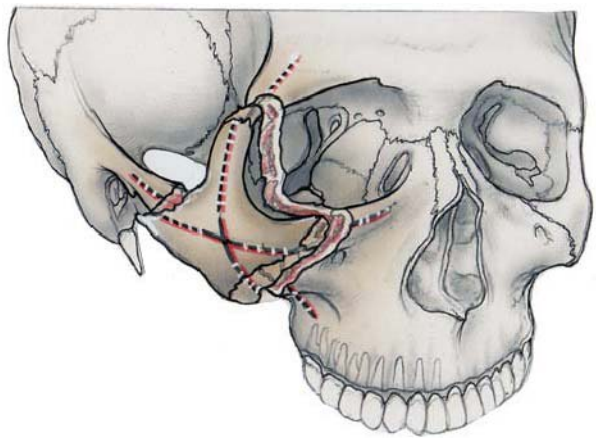

Figure 81.4 ZMC fracture—ZMC fracture, illustrating the tripod-like appearance of the displaced zygoma, as well as the orbital involvement in the injury.

A distinctive clinical feature of ZMC fractures is orbital injuries that differ somewhat from those found in isolated orbital trauma. In a typical orbital floor blowout fracture, orbital volume expands; the extent of expansion predicts the likelihood of enophthalmos and diplopia, and the need for surgical repair. In ZMC fractures, the typical inward and medial displacement of the zygoma often results in a *decrease* in orbital volume (19). Therefore, acute enophthalmos is rarely seen at the time of presentation of a ZMC fracture. The need for floor exploration/repair in ZMC fractures must also take into account the effect that reduction will have on orbital volume.

Another common clinical feature of ZMC fractures is facial numbness and paresthesia. This is caused by damage to the infraorbital nerve (V_2) at its exit from the midportion of the inferior orbital rim, which lies directly within one of the fracture lines. These symptoms are present in as many as 90% of ZMC fracture patients at presentation (20). The symptoms resolve spontaneously in many, but not all, patients after disimpaction of the fragments.

Zygomatic Arch Fractures

The zygomatic arch is most frequently disrupted as a component of a ZMC fracture (21). Less common, and distinct from this type of injury, is the isolated zygomatic arch fracture. Isolated arch fractures result from a direct lateral force to the arch, most frequently the result of a motor vehicle accident or fisticuffs (21).

Several fracture patterns may be seen in isolated arch injuries. The most common pattern is two mobile fragments of arch resulting from a total of three fractures. In this pattern, the fragments are displaced medially, in a v configuration (Fig. 81.5).

Figure 81.5 Axial bone-window CT demonstrates the most common pattern of isolated fractures of the zygomatic arch: a total of three fractures create two fragments, displaced medially in a V-like configuration.

Figure 81.6 Patient who suffered an isolated fracture of the left zygomatic arch after direct blow from a batted softball. Depression of the lateral midface is quite visible in this case.

Patients with isolated arch injuries, particularly those with the characteristic v pattern, will have a palpable, and frequently visible, deformity of the lateral midface (Fig. 81.6). This finding is often accompanied by a degree of trismus, resulting from the impingement of the fracture segments on the underlying coronoid process of the mandible or the temporalis muscle.

PATIENT EVALUATION

Evaluation of the patient is the critical first step to assure complete and accurate fracture repair and optimal aesthetic results. There may be a temptation to truncate the physical exam, in deference to the almost universal use of admission pan computerized tomography (CT) for trauma patients. Although high-resolution CT has been a great advance in the diagnosis, treatment, and postoperative critical evaluation of facial trauma, imaging is not a substitute to the laying on of hands in a focused head and neck trauma evaluation. Poor aesthetic results should not be accepted in facial fracture repair, as the primary motivation for their repair in many cases is cosmesis.

Physical Exam

Regardless of the existence of scans, or the putative diagnosis offered by the consulting physician, each new facial trauma patient should be evaluated in a systematic fashion, beginning with the history and physical exam.

All facial trauma patients are trauma patients, and are best served by the standardized *Advanced Trauma Life Support (ATLS)* approach taught by the *American College of Surgeons*. This evaluation process ensures the orderly evaluation and *prioritization of treatment of the most lethal injuries first*. All residents and those practicing surgeons who manage facial trauma must be familiar with the trauma

evaluation process, and should consider certification in ATLS. We shall highlight portions of the trauma evaluation process that are particularly germane to the care of the maxillofacial trauma patient.

Airway issues can potentially be seen with any head and neck trauma sufficient to result in midface fractures. While isolated midfacial trauma is unlikely to compromise the airway, accompanying mandible fractures are particularly significant in this regard. A loss of continuity of the mandible arch results in retrusion of the tongue and larynx, which may create an obstructed upper airway. When evaluating such a patient, consideration should be given both to immediate need for airway management and its implications for fracture repair. If elective intubation (as opposed to an emergent airway) is possible, alternatives to oral intubation should be entertained if maxillomandibular fixation (MMF) will be required for fracture repair.

Concomitant *C-spine injuries* are also common in patients with facial fractures, with an incidence approaching 10% (22). All facial trauma patients should thus be managed with C-spine precautions as proscribed by ATLS, even though this can significantly complicate the evaluation and management of the facial injuries.

Neurologic deficits should be sought and well documented if they exist. Of particular pertinence in the facial trauma patient are cranial neuropathies. A regimented exam of cranial nerves II–XII should be performed. Findings of significance that may impact the timing and approach to repair include neuropathies affecting the eye (cranial nerves II, III, IV, and VI), the trigeminal nerve, and the facial nerve.

Eye-related cranial neuropathies might make surgery an emergency, especially if associated with an open globe. Conversely, the presence of a compromised optic nerve *(optic neuropathy)* may delay facial fracture management. More details of the ophthalmologic evaluation of facial trauma patients are presented below.

Trigeminal nerve injury is not an emergency *per se* but must be documented preoperatively. If not, the assumption is made that it was a surgical complication and this has been a point of litigation specifically related to facial fracture repair. Facial nerve dysfunction is usually related to a temporal bone fracture or extensive facial soft tissue injury. It is important to know if the nerve was functioning upon presentation or not. This will help with the decision to explore and perhaps repair the nerve immediately or to treat expectantly.

The Facial Assessment

There are key elements of the exam that must be appreciated and documented preoperatively. These elements will help the surgeon appreciate the full extent of the facial trauma as well as avoid problems with litigation that is a potential element in trauma cases.

The appearance of the face is examined. Is it wide or long? Is it asymmetrical? It is helpful but often difficult to obtain current pretrauma photos to assist with this assessment. Appreciation of any lacerations is important for planning surgical access as well as to focus exam for cranial nerve deficits. A full facial movement and sensory examination is also advised regardless of hard or soft tissue injury.

Overlying edema and patient discomfort may limit the utility of palpation. Still, palpation of the facial skeleton is mandatory, and can provide a more thorough understanding of the location of fractures and the extent of their displacement and mobility. A bimanual exam of the face should be performed. Placing gloved fingers in the mouth while stabilizing the head and face at various levels is used to examine for dentoalveolar and palatal stability, as well for the Le Fort fractures. Both visual and subjective (patient's report) occlusal changes are vital to obtaining a successful reduction of facial fractures. Finally, are there exposed fracture elements and what is the status of the soft tissue? Will there be adequate soft tissue for reduction and closure of the fracture?

The Ophthalmologic Evaluation

The ophthalmologic exam of facial trauma patients deserves special emphasis and should never be deleted. Ocular injury is common in the facial trauma patient, at the time of initial injury, during the course of surgical repair, and even postoperatively. These injuries may be particularly devastating for patient and surgeon alike.

Early and complete ophthalmologic evaluation of every patient who has sustained a ZMC fracture (or any fracture involving the orbit) is an ideal yet often unrealized goal. The incidence of major (potentially blinding) ocular injury in ZMC fractures that require repair has been reported as 10% (23). Reconstructive surgeons must be sensitive to the possibility of direct ocular trauma and obtain consultation as indicated. A minimal preoperative examination includes testing of visual acuity (subjective and objective in both eyes), pupillary function, and ocular motility; inspection of the anterior chamber for hyphema; and visualization of the fundus for gross disruption. The presence of an *afferent pupillary defect* should be specifically sought, as this is a sensitive indicator of the presence of *optic neuropathy*. A decrease in visual acuity, alteration in color perception, or any abnormality observed on the other portions of this screening examination warrants detailed examination by an ophthalmologist before reconstruction of the bony injuries is undertaken.

COMPUTED TOMOGRAPHY

Evaluation of a patient with midface trauma has been greatly improved by the use of high-resolution CT. One millimeter slice thickness has become standard in many institutions, allowing for excellent coronal and sagittal

TABLE 81.1 DIAGNOSIS/EVALUATION

- CT scan is the "workhorse" imaging study for the evaluation of midfacial trauma.
- Review of facial CT scan should include the status of the buttress system, zygomatic arches, orbital volume, and herniation of orbital contents.
- Direct coronal imaging for orbital floor and skull base imaging.
- Newer reformatting software of thin axial slice images offers high-quality image and avoids cervical extension.
- Sagittal imaging can facilitate orbital trauma evaluation.
- Postoperative CT imaging can document anatomic reduction.
- Basic evaluation of visual function (and documentation thereof) should precede operative management.

CT, computed tomography.

TABLE 81.2 TREATMENT

- Early repair of midface fractures prevents soft tissue contracture that can be difficult to normalize in a delayed approach.
- Meticulous attention to soft tissue closure and facial soft tissue redraping is essential to achieving a pretraumatic facial appearance.
- Anatomic reduction prior to plate fixation is key. Rigidly fixated, malreduced structures will result in a persistent facial deformity requiring revision surgery.

reconstructions. This modality is the "work horse" for evaluation of midface trauma. Axial and coronal scans identify fracture lines throughout the entire facial skeleton (Table 81.1). The expense of CT evaluation of patients with facial fractures other than simple nasal and mandibular fractures appears justified and can be done in virtually all emergency rooms (24).

Using the CT images, the buttress system, particularly the vertical struts, must be systematically inspected preoperatively to document the degree of malalignment because of fracture fragment displacement. Fracture lines themselves through the buttresses do not mandate open reduction, but comminution, gross malalignment, and instability on physical exam all strongly suggest the need for reduction of the fractures in order to restore facial length and projection. Computed tomographic scans can show fractures of the condylar head, condylar neck, and vertical ramus of the mandible. The status of these structures must be known before fracture dislocations of the maxilla are placed into occlusion with the mandible.

The arcs of contour of the zygoma (see Fig. 81.2) are evaluated for decisions about the need for surgery and the appropriate operative approach. The CT finding of comminution and dislocation of both ends of the horizontal arc of contour indicates that exact reconstruction of the orbitozygomatic complex will be a challenge, and consideration should be given to additional access incisions, including an open approach to the zygomatic arch via a coronal incision.

FRACTURE MANAGEMENT: PRINCIPLES

Immediate Reconstruction

The goal of modern fracture management is acute near-total or total initial reconstruction of the bony architecture of the injured facial skeleton (Table 81.2). Early reconstruction usually is less difficult and more successful than delayed reconstruction, mainly because the latter can be complicated by cicatricial contraction of the facial soft tissues if the underlying skeletal support collapses or is lost. During the acute phase of injury, the soft tissues are pliable enough to allow restoration of the underlying bony configurations with local bone fragments or autogenous bone grafts. If the soft tissues are allowed to contract into a bone defect, restoration of the soft tissue to a normal position by delayed restoration of the supporting bone invariably produces a less desirable result. If revision surgery for minor residual bone defects or lacerations is required, it is greatly facilitated if the overall soft tissue envelope has been maintained in a normal position by a previous anatomic reduction of the facial skeleton.

Maxillomandibular Fixation

MMF maintains an important role in the management of midfacial trauma. In palatal and Le Fort fractures, as well as more complex pan-facial injuries, the relationship between the maxilla and the upper craniofacial structures is frequently altered and always destabilized. Placing the patient into occlusion (MMF) restores the position of the maxilla in the horizontal plane if the mandible is intact and correctly related to the skull base—that is, properly seated in the glenoid fossa. However, it does not automatically reestablish midfacial height if the vertical buttresses have been disrupted by fracture dislocations.

In most midface cases, MMF is used intraoperatively, as a guide to maxillary positioning, and then released at the end of the case. While closed reduction and MMF for 4 to 6 weeks are adequate management of less complex, minimally displaced maxillary fractures, patient discomfort and inconvenience rarely support this approach. Additionally, long-term immobilization of the temporomandibular joint (TMJ) (greater than 4 weeks) places the joint at jeopardy for developing an arthropathy. Early TMJ movement and physiotherapy are ideal. The vast majority of maxillary fractures are best managed by means of open approaches, with direct visualization and anatomic reconstruction of the buttress system with plating. Sometimes in pan-facial injuries, a period of *postoperative MMF* is appropriate as a stabilizing adjunct.

MMF can be accomplished with directly bonded orthodontic brackets applied before open reduction and fracture-line plating. This method reduces the risk of arch bar wiring and can reduce operative time. Other innovations in MMF, which reduce surgeon risk and decrease operative time include four-point screw fixation when tooth-bearing structures are intact and/or rapid plastic zip tie fixation with laced dental chain elastics (25–28).

Approaches

Extended access approaches expose the facial skeleton widely without compromising the facial soft tissue with visible scars. These approaches (coronal, transconjunctival, buccogingival, midfacial degloving, etc.) allow direct visualization and accurate reduction of fracture displacements. The zygoma and all of its projections, including the zygomatic arch, and all walls of the orbit can be safely and almost totally exposed through a combination of incisions, which if properly executed, should be either hidden completely or barely perceptible. The lower ends of the vertical buttresses can be exposed through extended sublabial incisions that essentially deglove the maxilla. Although this frequently removes all residual external periosteal attachments to displaced maxillary fracture fragments, bony union should proceed in a timely manner if the fragments are adequately stabilized and the periosteum is redraped over them. When extended access approaches are used, care should be taken to close them meticulously with attention to periosteal closure, soft tissue resuspension, hemostasis, and wound drainage.

The choice of approaches for a particular patient and a particular injury relies not only on the technical expertise to execute a variety of incisions well, but also wisdom, experience, and judgment. On the one hand, a surgeon may be hesitant to perform extended access approaches in favor of more limited approaches in the hope that any facial asymmetry resulting from incomplete fracture reduction will be imperceptible. However, the range of imperceptible asymmetry is small, and the surgeon cannot rely on it to hide suboptimal results from nonanatomic reductions that might have been improved with more extensive exposure and reconstruction. The classic clinical example is an incompletely reduced zygoma with unilateral facial widening. On the other hand, because these wide access approaches exist it does not mean that they are always indicated. The fact that incisions are hidden does not mean they are completely free of sequelae and the risk of complications. Experienced surgeons obtain excellent results with the judicious use of more "minimalist" approaches to some injuries, such as closed reduction or single incision access to ZMC fractures (29). The increasing use of endoscopes, surgical navigation systems, and intraoperative imaging is likely to facilitate selective use of limited access approaches to facial trauma without compromising accurate reduction.

Stable Internal Fixation

Although the term *rigid* is used to describe the fixation achieved with plating systems, it is somewhat overstated when applied to midface fractures. Rigidity sufficient to allow removal of MMF can be obtained, but it is not always sufficient to allow the patient to return immediately to a normal diet. Fixation devices do maintain the position of the maxillary dentoalveolar complex under the stresses of forces generated by mastication of soft foods, speech, and deglutition. They will preserve the anatomic reduction achieved and allow for bone healing.

FRACTURE MANAGEMENT: SURGICAL TECHNIQUES

Zygomaticomaxillary Complex Fractures

The goals of ZMC fracture repair are (a) restoration of the normal facial width and projection at the malar prominence, (b) restoration of normal orbital volume, and (c) achievement of the first two goals while eliminating, or at least limiting, the sequelae and complications associated with the operative repair itself. These are the considerations the surgeon managing a ZMC fracture must have in mind as he or she considers the options—in terms of incisions used, methods of reduction, and the number, type, and configuration of plates.

The incisions typically employed for ZMC repair are shown in Table 81.3. Each incision offers access to one or more of the articulations of the zygoma, at a variable cost in terms of the residual scar and the other attendant soft tissue changes. Access to articulations serves two purposes: (a) a means to confirm the alignment of reduced fragments visually and (b) the ability to plate the area to stabilize the reduction. Choice of incisions varies significantly based on the severity of displacement and comminution, surgeon preference, and other factors. On some principles, there is considerable agreement—for instance, the subciliary incision has fallen into general disfavor because of the relatively high risk of ectropion and lid shortening with it, in comparison to the other incisions (subtarsal, transconjunctival) that expose the same anatomy (17).

A related issue is the decision regarding how many articulations, and which ones, to expose. Each articulation site has differing value for (a) confirming the alignment of reduction and (b) bearing the hardware required to stabilize reduction. For example, the sphenozygomatic (SZ) articulation within the lateral orbit is generally regarded as best single place to assess the accuracy of reduction (17,30–32). Conversely, the ZM and zygomaticofrontal (ZF) sutures, with their relatively thick bone stock along the load-bearing ZM buttress, are the most favorable sites for plate fixation (33). Table 81.4 describes the relative values for each purpose for each articulation, along with an estimate of the accessibility of the suture, in light of soft tissue cost of approaching it.

TABLE 81.3 INCISIONS USED IN MANAGING ZMC FRACTURES

Incision	Pros	Cons	Exposed for Alignment	Exposed for Plating/Repair
Gingivobuccal sulcus	No visible scar	Oral flora contamination	ZM buttress infraorbital rim	ZM buttress
Lower eyelid subciliary subtarsal transconjunctival	Only access for floor exploration/ repair	Risk of ectropion, scleral show, etc.	Infraorbital rim ZF suture ZS suture	Infraorbital rim ZF suture orbital floor
Upper eyelid lateral brow upper blepharoplasty	No cantholysis needed to access ZF suture	Visible scar	ZF suture ZS suture	ZF suture
Coronal	Excellent exposure of lateral orbit; only practical exposure of arch	Risks of widened scar, facial nerve branch weakness, and temporal hollowing	Arch ZF suture ZS suture	Arch ZF suture

In light of the potential sequelae and complications of surgery, some consideration must be given to *not* repairing non- or minimally displaced ZMC fractures (30). When this plan is chosen, patients should be followed for at least a few weeks to confirm that further displacement doesn't develop as a result of masseter muscle action, and that no unsuspected deformity becomes apparent as edema resolves.

Displaced fractures are generally repaired. Some groups have advocated the use of closed reduction techniques without any plating (34,35) in their efforts to eliminate the soft tissue consequences of repair. However, it has been demonstrated in at least one small study (36) that this approach is significantly inferior to open reduction internal fixation (ORIF) in terms of the accuracy of reduction; use of this should be limited to carefully selected cases.

The use of a single incision and a single point of fixation, either an upper eyelid incision and plating of the ZF suture (37,15) or an upper gingivobuccal sulcus (GBS) incision and plating of the ZM buttress (38), have yielded favorable results for some. More typically, three or more articulations are exposed, and at least two are plated.

One reasonable approach to the displaced ZMC fracture, and that favored by the authors, begins with a GBS incision. Through this, the ZM suture and infraorbital rim suture are both exposed. An initial attempt at reduction is then carried out through the same incision, by inserting an elevator under the body of the zygoma and elevating and rotating it toward a reduced position. In some cases, generally those with no comminution, this results in perfect reduction, and the reduction can then be stabilized with a single, appropriately contoured L-shaped plate along the ZM suture.

More commonly, reduction is incomplete or uncertain at this point, and a second incision is made. The second incision may be a lower lid incision, such as the transconjunctival or subtarsal incision, which allows access to the infraorbital rim, the SZ suture, and with a lateral crease extension and lateral canthotomy/cantholysis, the ZF suture as well. The lower lid incision is facilitated by the partial reduction of the zygoma carried out through the GBS incision; placing the transconjunctival incision properly over a displaced orbital rim is difficult. Another option for the second incision is the lateral portion of an upper blepharoplasty incision, through which the ZF suture and SZ suture (but not the infraorbital rim) may be exposed for inspection and plating.

Through this additional access, the reduction is further fine-tuned and confirmed. Plating on the ZM suture, the infraorbital rim, and/or the ZF suture are then carried out, while the reduction is maintained with the elevator.

TABLE 81.4 ARTICULATIONS WHICH MAY BE EXPOSED FOR MANAGING ZMC FRACTURES

Articulation	Stability	Alignment	Accessibility
Zygomaticofrontal	++	+	++
Arch	++	+	+
Infraorbital rim	+	+	++
Zygomaticosphenoid	*a*	+++	+
ZM	+++	++	+++

[a]Although it has been described as a particularly stable plating position by some authors (Rohner 2002; others), many authorities consider the ZS suture quite difficult to access for plating (AO).

Orbital floor exploration is carried out at this point if indicated (see discussion below). The repair is completed by soft tissue resuspension over the degloved maxilla. The undersurface of the malar soft tissue is sutured with one or more absorbable stitches to a stable superior structure, such as a plate or intact periosteum. If a cantholysis has been performed, canthotomy is performed at this point. Finally, the mucosal and skin incisions are closed.

Other Issues in ZMC Fracture Repair

Methods of Reduction

There are a number of options for the method of reduction of the displaced zygoma. The authors find that in most cases, the introduction of an elevator under the body of the zygoma through the GBS incision provides adequate control of the zygoma to achieve reduction. Other methods, including use of percutaneous hook (34,37), introduction of the elevator through a separate incision such as the Gillies incision (36), and the use of a Carol-Girard screw (33) are usually unnecessary, but should be kept in mind for particularly difficult reductions, or if the GBS incision is not being used.

Hardware

In the past, midface plating systems consisted of progressively thicker plates paired with progressively larger diameter screws, with the screw diameter used as the identifying measurement and a proxy for the thickness and rigidity of the plate. That is, a "2.0" system would comprise a relatively thick and rigid plate and a 2-mm diameter screw, a "1.0" system would consist of a 1-mm diameter screw paired with a thin and more malleable miniplate, and "1.3" and "1.5" systems would occupy intermediate positions. This taxonomy is obsolete now, as most of the hardware manufacturers offer systems in which a single diameter screw is used with all thicknesses of plate, or several plate thicknesses are available for a given screw size. Nevertheless, all manufacturers continue to offer an array of systems with different thicknesses and rigidity within their midface sets. Hardware is chosen for a particular site based primarily on: (a) the load to be borne by that site and (b) the amount of soft tissue coverage available to camouflage the plate. For example, the ZM buttress, which bears a significant load during mastication and is covered by a generous soft tissue envelope, is generally plated with a larger (i.e., the plates formerly known as 1.5 and 2.0), L-shaped, midface plate. Figure 81.7 offers a schematic representation of typical hardware deployment in ZMC fracture repair.

Orbital Floor Management in ZMC Fractures

Prior to the widespread application of CT scans in ZMC fractures, the orbital floor was frequently explored via the same lower lid incision used to repair the ZMC (39). With the routine use of preoperative CT scans in these injuries have come fairly standardized clinical and radiographic

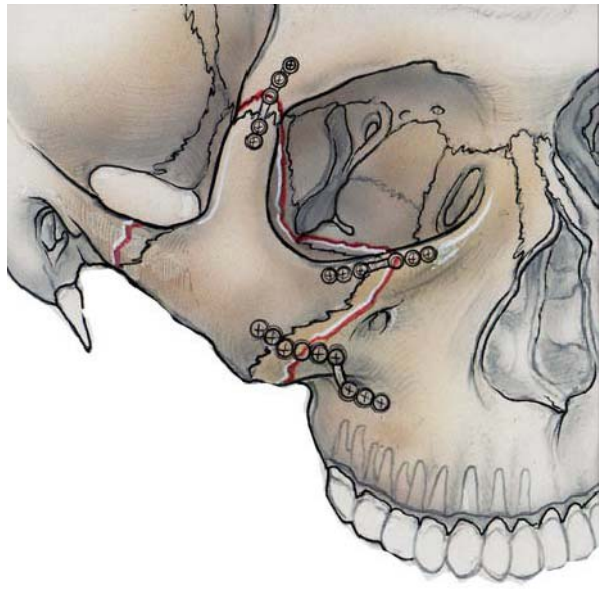

Figure 81.7 The location, shape, and size of some of the plates commonly used in the ORIF of ZMC fractures. (a) ZF suture: a thin (1.3 equivalent), linear midface plate. Alternatively, a box-shaped plate may be used for enhanced stability. (b) Infraorbital rim: a very thin (1.0 equivalent), gently curved, midface plate. (c) ZM suture: an intermediate to thick (1.5–2.0 equivalent), L-shaped plate.

criteria for orbital floor exploration. These include entrapment of orbital soft tissue, herniation of soft tissue into the maxillary sinus, and 2 cm^2 or greater of orbital floor disruption. This has reduced the need for "diagnostic" floor exploration in many ZMC patients, reducing the rate of floor exploration to 30% to 40% (39,40).

The orbital floor injury associated with ZMC fractures is distinct from that seen in isolated orbital injuries, such as "blowout" fractures. In blowout fractures, the orbit volume is almost uniformly increased. In ZMC fractures, the posterior–medial displacement of the zygoma often causes a *decrease in orbital volume*. This has promulgated the theoretic concern that reduction of the zygoma anterolaterally could increase orbital volume, perhaps above the threshold where postoperative enophthalmos might ensue. This issue has been addressed is several excellent recent studies (19,39,40). In each study, the suspicion that reduction of the zygoma might lead to orbital volume expansion beyond that seen of the preoperative imaging was confirmed; however, it was also shown consistently that in nearly every patient, the expansion was not clinically significant—that is, unlikely to expose patients to an increased risk of enophthalmos.

With this in mind, it is clear that the orbital floor in ZMC fractures may be managed selectively, using criteria for exploration similar to those in use for other orbital floor fractures. Many surgeons have taken advantage of this fact by avoiding lower lid incisions entirely in some of their ZMC patients in favor of say, a combined GBS and upper blepharoplasty incision. This spares the patient from the risk of scleral show and ectropion.

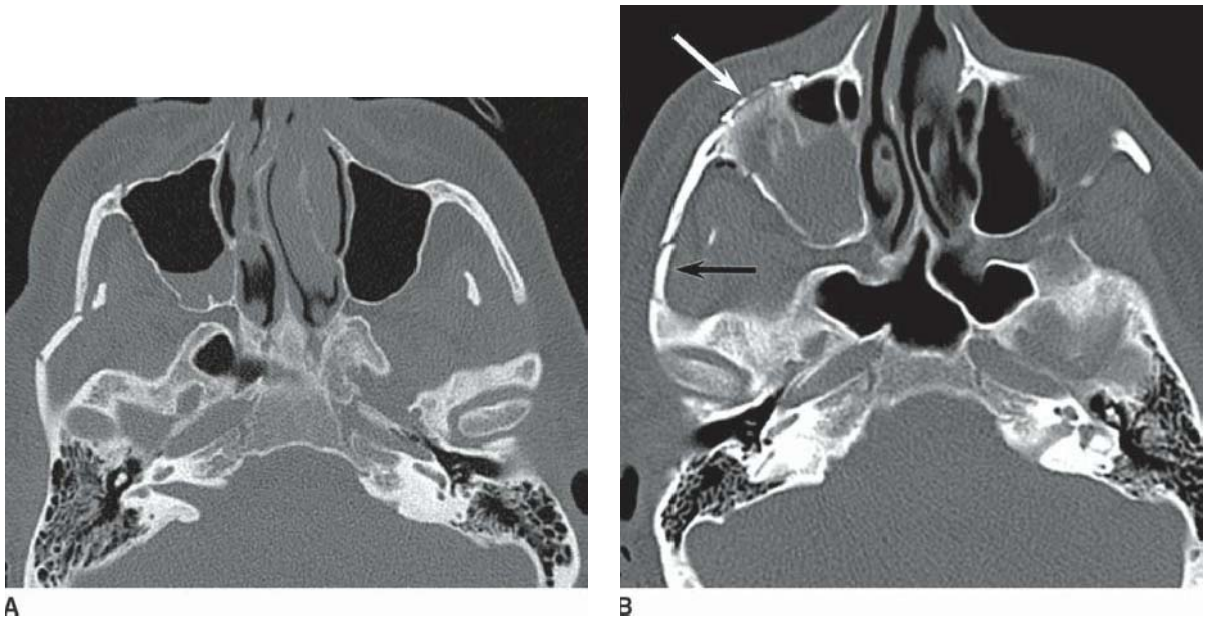

Figure 81.8 **A:** Preoperative axial bone-window CT demonstrates a right ZMC fracture with mild external rotation and medial displacement of the arch. The patient had moderate trismus. **B:** Post-reduction CT of the same patient. Fracture repair was performed through a GBS incision and a trans-conjunctival incision, with plating of the ZM buttress (not shown) and infraorbital rim (*white arrow*). The zygomatic arch alignment has been restored (*black arrow*) without being directly visualized or addressed, simply by reducing the zygoma through the GBS incision.

The technical details of orbital floor repair are similar to those in blowout fractures, which are covered extensively in Chapter 82 of this text. Needless to say, in patients where floor repair is indicated, this is carried out *after* the ZMC reduction and plating.

The above discussion is most applicable to the typical, isolated ZMC fracture that results from low to midenergy trauma. High-energy injuries, those with greater displacement and/or comminution, and those found in the setting of pan-facial injuries require a more aggressive approach. Consideration should be given to the exposure of additional fracture sites, including the zygomatic arch. This allows additional points of reference to confirm anatomic reduction and the placement of other plates to enhance stability. Another factor that favors additional exposure is less experience on the part of the surgeon (33).

In summary, repair of ZMC fractures offers the surgeon many options. An effective approach to management carefully balances the benefits of exposure, for alignment, plating, and orbital floor repair, with the cost in terms of soft tissue sequelae and potential complications incurred by each incision. As long as this balance is respected, excellent results can be achieved in a variety of ways.

Zygomatic Arch Fractures

In arch fractures that are a component of a ZMC fracture, reduction of the zygoma frequently results in satisfactory reduction of the arch (41) (Fig. 81.8).

In some cases, after reduction and plating of the zygoma, a closed reduction of the arch via a Gillies (described below) or intraoral (Keen) approach may be necessary to realign the arch. It is an uncommon event that the arch component of a ZMC fracture needs to be directly visualized and plated (13). These exceptional cases would typically be in the setting of high-energy injuries or pan-facial trauma.

Isolated arch fractures, especially those with the characteristic V configuration, are amenable to closed reduction by the method described by Gillies (42). In this technique, a small incision is made in a hair-bearing portion of the temporal scalp (Fig. 81.9). Dissection is carried down through the fascia of the temporalis muscle. A blunt instrument can be safely passed in this plane, deep to the frontal

Figure 81.9 Placement of the incision Gillies approach to isolated zygomatic arch fractures. The incision may also be oriented transversely or obliquely—the patient's hair provides excellent camouflage.

Figure 81.10 Incisional scar from Gillies approach to the zygomatic arch at 2 weeks. Even at this early stage, in a patient with short hair, the scar is barely perceptible.

branch of the facial nerve, and underneath the arch. While palpating the fracture with one hand, the instrument is elevated with other, effecting reduction. The reduced fragments, particularly those in a v-shaped arch fracture, are usually stable in the reduced position. In instances when they are not, several transcutaneous sutures may be used to suspend the fragments from a plate or finger splint affixed to the area. Other methods of temporarily supporting the reduction have also been described (43).

The advantages of the Gillies technique for zygomatic arch fracture repair include an imperceptible incisional scar (Fig. 81.10); minimal disruption of the sensitive soft tissue structures adjacent to the zygomatic arch, meaning very little risk of frontal branch injury or temporal hollowing; its simplicity; and the possibility of performing the procedure with local anesthetic, with or even without sedation.

Palate

The integrity of a fractured palate must be reestablished in order to establish a stable occlusion. Palatal fractures, most commonly parasagittal splits, can be reduced anteriorly at the inferior rim of the piriform aperture. Occasionally, the need for stability mandates plate placement posteriorly on the oral surface of the palate to allow a solid, structurally accurate dentoalveolar complex to be related to the mandibular teeth (see below). Open reduction and internal fixation of the anterior extent of a palatal fracture can be accomplished through the same extended gingivobuccal sulcus incision used to expose and repair the vertical buttresses of the face.

The bone above the anterior teeth is more than adequate for placement of a miniadaptation plate with multiple monocortical screws. In some instances, a small amount of bone can be removed immediately below the anterior nasal spine to facilitate placement of a plate with a flat contour under the upper lip and base of the columella. Care to prevent tooth root injuries should be exercised. This can be achieved both by placing the plate above the root tips, using monocortical screws, and ensuring screw holes are placed in the tooth root interspaces.

The posterior extent of a palatal fracture usually can be reduced in a closed manner if the overlying palatal mucoperiosteum is intact. Difficulty can result from an inability to align the lower end of the ZM buttress with an accurately reconstructed zygoma above. Also the need to overtighten the MMF wires to pull the lingual cusp tips of the maxillary molars and premolars into the central fossae of the mandibular teeth can be problematic. In these cases, an incision can be made over the posterior extent of the palatal fracture, and a transosseous wire or small plate can be placed across the fracture. This wire does not serve as a point of rigid fixation of the palatal fracture, but it reduces the fracture gap posteriorly after it is tightened. Stable fixation is obtained with superficial triangulation of the palate with plates and screws placed across the anterior extent of the palatal fracture and across both ZM buttress areas (Fig. 81.11).

Transoral palatal plates are often difficult to cover with mucosa. These plates can be placed transmucosally and removed once fractures have healed. Posterior distraction of a parasagittal palatal fracture can be overlooked easily if a parasymphyseal mandibular fracture is present that has been incompletely reduced at the lingual cortex. Both dental arches are widened posteriorly, and the maxillary and mandibular teeth can appear to interdigitate correctly. However, when facial edema resolves, the patient

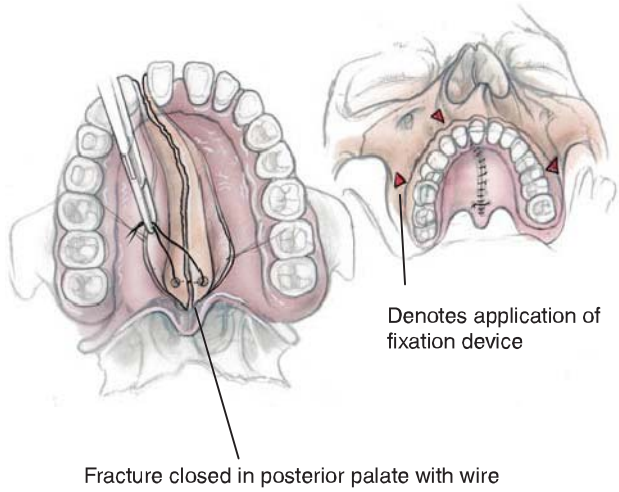

Figure 81.11 Reduction of the posterior gap in a displaced parasagittal fracture of the palate using a transosseous wire. *Arrows* indicate the location of plates that are points of triangular fixation that hold the fracture in reduction.

may notice widening of the intergonial distance and have a "cheeky" appearance.

Palatal fractures exposed by means of laceration of the mucoperiosteum usually are widely separated and impossible to reduce without a transosseous wire to pull the palatal shelves together posteriorly. If this method of reduction is not used, and tightening of the MMF wires only is used to pull the teeth into occlusion, the maxillary teeth probably will be lingually tipped or left in some degree of unilateral or bilateral posterior crossbite deformity. The exposure through the laceration may be adequate to allow placement of a plate across the split palate; however, this procedure can be technically difficult, and these plates frequently become exposed in the mouth and must be removed.

Acrylic palatal splints are essential adjuncts for stabilization of teeth in a segment of maxillary bone separated from the palate by an alveolar fracture. Even if a rigid fixation device cannot be used to attach the isolated alveolar segment to the surrounding maxillary bone, the combination of a sturdy buccal arch bar, a palatal splint, and circumdental wires to cinch the involved teeth between the bar and the splint usually provides enough stability to allow removal of the MMF at the end of the case.

Maxilla

Restoration of the pretrauma relationships of the tooth-bearing segments of the maxilla to the mandible and skull base necessitates reestablishment of the proper occlusal relation of the maxillary and mandibular teeth and stabilization of the midfacial buttress system (Fig. 81.12). If the mandible also is fractured, the lower dental arch must first be stabilized and accurately related to the skull base; proper alignment of the mandibular condyles in the glenoid fossae is an absolute requirement. The anteroposterior position of the maxilla can be established by means of occluding the teeth in stable MMF. The midfacial vertical dimension is established by means of reduction and fixation of all fracture lines between the palatoalveolar complex and the base of the skull. When subcondylar fractures or fractures of the condylar head cannot or should not be managed with open reduction, the midfacial buttress system can be reconstructed first to establish vertical and horizontal positioning of the occlusal plane. This alternative approach may not restore the relation of the maxilla to the base of the skull with the same accuracy that can be achieved if it is first related to an intact or totally reconstructed lower dental arch. This sequence, however, is the preferred sequence if mandibular vertical ramus height cannot be accurately restored because of the presence of posterior mandible fractures or comminution.

Although not a part of the maxilla, each zygoma must be accurately repositioned and stabilized before reattachment of the maxilla to the upper ends of vertical buttresses. Zygomatic fractures associated with Le Fort fractures of the middle third of the facial skeleton often necessitate open reduction and internal fixation of the zygomatic arch to position the

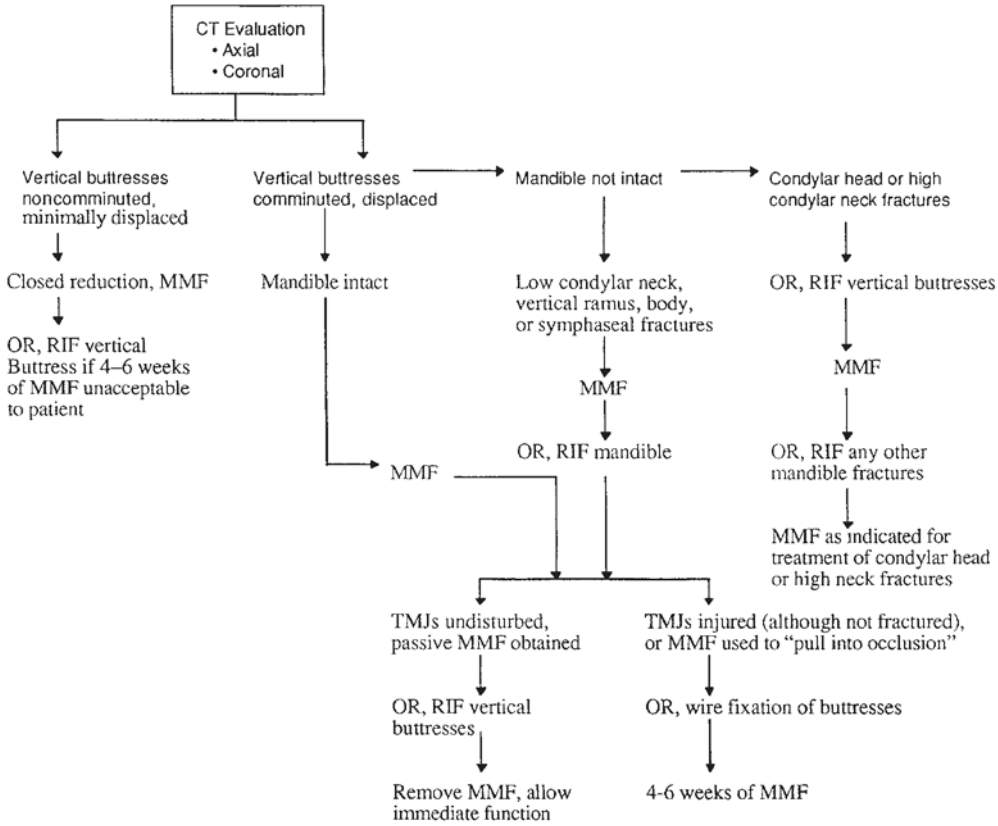

Figure 81.12 Algorithm for the management of fractures of the vertical buttresses.

zygoma correctly before reattachment of the maxilla. This is particularly critical if mandibular condylar fractures necessitate reconstruction of the upper jaw first. Failure to recognize and correct the amount and direction of displacement at the time of reduction leaves a flattened cheek and widened face and can produce a rotation and tilting of the maxilla when it is reattached to a malpositioned zygoma.

Only after the zygomatic and palatal fractures have been repaired can the maxillary complex be reattached superiorly. Reattachment begins with the ZM buttress that has the less severe injury. Unlike the anterior wall of the maxilla, which often is severely comminuted, the ZM buttress often is traversed by a single fracture line that can be easily reduced, or it has a single free-floating fragment that can be accurately related to the zygoma above and the lower maxilla below. At least one ZM buttress usually can be reduced in this way to set the correct vertical dimension of the middle third of the face. After stabilization of this buttress, reduction and fixation of the other ZM buttress and the NM buttresses can proceed. If both ZM buttresses are severely comminuted, reconstruction of the NM buttresses can facilitate reestablishment of the vertical dimension. In most cases of comminution of the ZM struts, however, the NM buttresses are even more fragmented and difficult to realign.

Stability of the reattached maxillary complex is gained mainly through reconstruction of the ZM buttresses. Reconstruction of the NM buttresses can provide some supplementary vertical stability to the overall reconstruction, but only if the upper confluence of these struts (nasoorbitoethmoidal complex) is intact. If plates and screws are used for fixation and the patient is allowed to function early, a delicate nasoorbitoethmoidal repair cannot be relied on to transmit occlusal forces to the base of the skull. Instead, ZM buttress reconstruction must be used to hold the repositioned maxilla in place during healing. Plates must be positioned to overlie the ZM buttresses as closely as possible, and three screws are used to anchor the plate to the zygoma above and the maxilla below. Placement of screws into the lower end of a plate or a bone graft can be difficult if the fracture line closely parallels the apices of the molar and premolar teeth. This problem usually can be overcome with L-shaped plates that allow placement of more screws close to (often in between) but not through the root tips.

Comminution of the lower ends of the vertical buttresses severe enough to mandate bone grafting for adequate stabilization is uncommon, although occasional cases occur in which gaps of 1 to 2 cm of severely comminuted or absent bone exist in one or both lateral antral walls. Onlay split cranial bone grafts are attached across these gaps. The grafts can be contoured and positioned to allow placement of lag screws that do not damage the root tips. Reconstruction of the vertical dimension cannot be done with the same precision for these patients as for those who undergo successful edge-to-edge approximation of *in situ* fracture fragments.

COMPLICATIONS AND SEQUELAE

Perhaps the most common complication of midface fractures is inadequate reduction resulting in facial deformity, and in some cases, functional deformity (see below). This complication represents a technical error at the time of surgery.

Eye/Eyelid/Orbital Complications

Eye-related complications are common in midface trauma (especially in ZMC fractures) and include lower eyelid injury, including ectropion, entropion, and most commonly, scleral show; enophthalmos, with or without diplopia; corneal abrasion; and visual loss (rare). One way that many surgeons are preventing lower lid sequelae of midface trauma is by simply choosing not to make lower lid incisions when possible; for instance, in patients with ZMC fractures who do not require floor exploration, an upper blepharoplasty incision access to the FZ suture is chosen over the lower lid approach to the infraorbital rim. This approach essentially eliminates the risk of scleral show and other lower lid issues, otherwise quite common even with a well-executed transconjunctival incision.

In other respects, the eye, eyelid, and orbital complications of midface trauma mirror those seen in isolated orbital fractures, and are covered in greater detail in Chapter 82.

Lip Distortion

A subtle but disturbing deformity can be caused by use of the sublabial approach to maxillary fractures. This deformity includes hollowing of the soft tissue contours over the canine fossa area and superior deviation of the corner of the mouth and lateral aspect of the upper lip. It is caused by collapse and contraction of the buccal soft tissues into large anterior and anterolateral antral wall defects. Although the exact size of the defect necessary to cause this is unknown, defects of greater than 1.0 cm^2 are considered for overlay bone grafting.

Implant-Related Complications

Miniplates and screws along the lateral orbital rim (ZF suture) and zygomatic arch usually are visually undetectable if low-profile (1.3 mm equivalent) titanium or cobalt–chromium alloy plates with are used. These fixation devices can be left in place permanently. Inferior rim plates are those that most likely produce an irregular contour visible through the thin skin of the lower eyelid. Prevention of this complication is critical because if such a plate is placed and is visible after healing is complete, a second surgical violation of this lower lid to remove the plate exposes the patient to a higher risk for lid complication. Options include the use of very low-profile (1.0 mm equivalent) hardware; wire, rather than plate, fixation of

the infraorbital rim; placement of the plate along the superior surface, rather than the anterior face, of the rim; and avoidance of rim fixation altogether by choosing the ZF suture as a second point of fixation.

Generous soft tissue coverage makes plate visibility along the ZM and NM buttresses extremely uncommon. *Intraoral* plate exposure does occur in these areas however, as well as on the palate; this can be managed expectantly in most cases, or with plate removal after bony union. Finally, plate and screw failure, such as is seen in mandibular fractures, is uncommon in midface trauma.

Malocclusion

While malreduction in ZMC fractures causes *cosmetic* issues such as facial widening and malar flattening, the same errors, when applied to Le Fort and palatal fractures, will have significant *functional* consequences. Rigid fixation is an unforgiving technique that produces serious occlusal disturbances if used inappropriately to manage fractures of tooth-bearing segments. If the plates are not correctly adapted to the bone, tightening of the screws can produce torque in the system, and the fragments can be distracted so that malocclusion is produced when the MMF is removed. This is less likely to occur now that thinner, more malleable titanium or cobalt–chromium alloy plates are being used rather than the stiffer, harder to bend stainless steel plates.

The surgeon must consider the risk of inaccurate condylar seating in the glenoid fossae in all cases involving tooth-bearing segments of bone. Patients with complex maxillary injuries can have a deranged occlusal relation that is difficult to correct and prevents the teeth from interdigitating in a passive manner before application of MMF. One or both mandibular condylar heads invariably are displaced from their normal centric occlusion position in the glenoid fossae if the MMF is used to "pull the patient into occlusion." Even if the plates are subsequently and accurately adapted to the repositioned maxillary fragments, malocclusion develops after MMF is removed and the patient's normal muscle balances return the mandible to its correct position. If gross malocclusion does not result and the patient learns to function in this altered position, chronic TMJ discomfort is likely to develop.

When postoperative occlusion is noted, the only successful form of remediation is revision surgery, *including revision of the reduction and fixation*. Simply reapplying MMF in the hope that the patient's muscles or orthodontic traction bands will pull the patient into occlusion is uniformly unsuccessful because of the rigidity of the fixation devices.

Sensory Disturbances

Numbness and paresthesias in the distribution of the infraorbital nerve (V2) are common in midface fractures, owing to the frequent involvement of the infraorbital canal and foramen within the fracture lines. In many patients, these symptoms resolve with or without treatment. In patients in whom they persist, they can be significant source of annoyance, particularly when eating (44). The impact that fracture management has on these symptoms is uncertain. Clearly, careful dissection around the nerve when exposing the maxilla through the GBS is advisable. Some studies suggest a salutary effect of operative repair on nerve recovery (45), while some authorities specifically advise against operative management to "decompress" the infraorbital nerve in the absence of other surgical indications (18).

Other Complications/Sequelae

Facial nerve injury, particularly to the frontal branch, may result if a coronal approach to the zygomatic arch is performed. Temporal hollowing due to atrophy of the temporal fat pad is a more common sequela of the coronal approach. Despite the transoral placement of implants, infectious complications of midface fractures are unusual (46).

TECHNICAL ADJUVANTS

Surgical Models and Computer-Aided Surgery

Although most information necessary to evaluate midface fractures can be seen on standard axial and coronal CT scans, three-dimensional reconstructions can help surgeons better conceptualize the overall injury. Precise calculation of displacement of superficial bony landmarks is possible with three-dimensional images (47,48). This is particularly valuable for patients who cannot be positioned for true coronal CT for optimal evaluation of the orbital walls. However, coronal reformations generated from fine-cut axial CT scans are less expensive and more readily obtained than three-dimensional reconstructions. Although they do not supply the same detail in equal clarity, the coronal reformations usually supply adequate information.

Additional technologic enhancements to aid the surgeon in repair of complex facial trauma include sagittal CT reconstruction for orbital floor fractures (49), computer-aided surgery navigation for facial fragment reduction (50,51), and preoperative computer-generated models for surgical planning, particularly helpful for reconstruction in the delayed setting and revision cases (52).

Intraoperative CT Scanning

Portable CT scanners allow immediate radiographic evaluation of fracture reduction in the operating room (53,54). The quality of these scans appears sufficient to allow evaluation of relocation of the malar prominence on axial scans and realignment of the orbital walls on

coronal reformations. This technology facilitates the use of closed reduction, single incision, endoscopic approaches, and other "minimalist" approaches to midface fracture repair by confirming the reduction of unexposed fractures. This spares the patient the soft tissue sequelae associated with multiple incisions and periosteal stripping. Furthermore, the expense of the scanner and technologist time can be offset by elimination of the need for extended access approaches to evaluate reduction of each fracture line, thus decreasing operating room time and expense.

HIGHLIGHTS

- Although reduction of the displaced zygoma in ZMC fractures may cause an *increase* in the orbital volume relative to that seen on the preoperative imaging, the amount of the increase is rarely clinically significant. Therefore, the orbital floor components of ZMC fractures can generally be managed according to the same principles applied to isolated orbital floor fractures.
- MMF serves as a very useful guide to the proper relationship between the maxillary dentition and the skull base *in the horizontal plane*. This relationship loses validity, and the patient is at risk of postoperative malocclusion, if the mandibular condyles are not seated properly in the glenoid fossa at the time the patient is placed into occlusion.
- Injuries to the eye and C-spine are common in midface fractures and patients must be carefully evaluated for these injuries. Preoperative visual evaluation is mandatory, and ophthalmologic consultation should be strongly considered, for all patients being brought to the operating room for repair of midface fractures involving the orbit.
- Intraoperative imaging and surgical navigation are two newer technologies that may in the future facilitate less invasive approaches to midface fractures without compromising accuracy of repair.
- Palatal fractures tend to occur in the setting of multiple other facial fractures. Palatal fractures must be addressed early in the sequence of repairing these injuries, in order to allow the use of the patient's occlusion as a guide to the accurate reduction of the other fractures.
- There is a wide array of successful strategies for managing ZMC fractures. Depending on the nature of the particular injury and the experience of the surgeon, options may include close reduction techniques, single incision approaches with plating, and multi-incision, wide access approaches with plating.

Orbital Fractures

82

Clinton D. Humphrey *J. David Kriet*

OVERVIEW

Orbital fractures occur both as isolated injuries and in conjunction with additional maxillofacial fractures or multisystem trauma. Patients with an orbital injury require initial evaluation by the emergency department (ED) physician and in some cases activation of the trauma team following current Advanced Trauma Life Support (ATLS) protocols (see Chapter 74). The identification of orbital fractures during the initial ED workup should lead to a request for facial trauma surgeon consultation. Computed tomography (CT) scanning is standard for confirming or identifying fractures. Fractures of the zygomaticomaxillary complex (ZMC), orbital rim, medial orbital wall, and orbital floor are most commonly encountered. Fractures of the superior orbit occur less frequently and are often associated with frontal sinus fractures and intracranial involvement. Naso-orbital-ethmoid (NOE) fractures tend to be associated with complex midfacial and maxillary trauma (see Chapter 81). The management of NOE fractures differ from the management of most orbital fractures and is discussed in detail elsewhere. The surgeon's prompt evaluation of orbital fractures is indicated once life-threatening injuries have been addressed and the patient is stabilized. Ophthalmology consultation is appropriate in selected cases (1). Certain indications and ideal timing for orbital fracture repair remain controversial. Surgical intervention should restore preinjury appearance and function.

ANATOMY

The orbital skeleton contains contributions from the frontal, sphenoid, lacrimal, ethmoid, maxillary, zygomatic, and palatine bones. The supraorbital rims are entirely comprised of the frontal bone. Laterally, the frontal bone articulates with the zygoma. More posteriorly, within the orbit, the zygoma also articulates with the greater wing of the sphenoid. Portions of both the zygoma and maxilla make up the infraorbital rim and, along with a small contribution from the palatine bone, the orbital floor. The medial orbit is a complex confluence of the ethmoid lamina papyracea, lacrimal bone, maxilla, and nasal process of the frontal bone. The bony orbit and locations of the optic foramen, ethmoid artery foramina, and orbital fissures are shown in Figure 82.1A. Moving posteriorly, the anterior ethmoid artery, posterior ethmoid artery, and optic nerve are located approximately 24, 36, and 42 mm, respectively from the anterior lacrimal crest Figure 82.2B. Upper and lower eyelid layers are detailed in Figure 82.2 (2).

The lateral canthal tendon consists of two limbs. A thin anterior limb blends with the orbicularis oculi muscle fibers and periosteum of the lateral orbital rim; a thicker posterior limb attaches to Whitnall tubercle of the zygoma. The medial canthal tendon attaches via two limbs as well. A thicker limb extends to the anterior lacrimal crest and a thinner limb containing Horner muscle to the posterior lacrimal crest. Intimately related to the medial canthal tendon is the lacrimal system. Upper and lower puncta begin 5 to 7 mm lateral to the canthus and continue as a common canaliculus into the lacrimal sac located between the anterior and posterior limbs of the medial canthal tendon within the lacrimal fossa. The sac empties into the inferior meatus via the nasolacrimal duct. Figure 82.3 demonstrates the complex relationship between the lacrimal drainage apparatus and the medial canthal tendon. The lacrimal gland is located along the superolateral orbit within the upper lid and divided into a larger orbital portion and a smaller palpebral portion by the lateral horn of the levator aponeurosis. Anteriorly, the gland's orbital portion is in contact with the orbital septum (3,4).

Extraocular muscles include the two oblique and four rectus muscles. The course of the superior oblique muscle brings it into nearly direct contact with the periorbita of the orbital roof and medial wall at the trochlea. The inferior

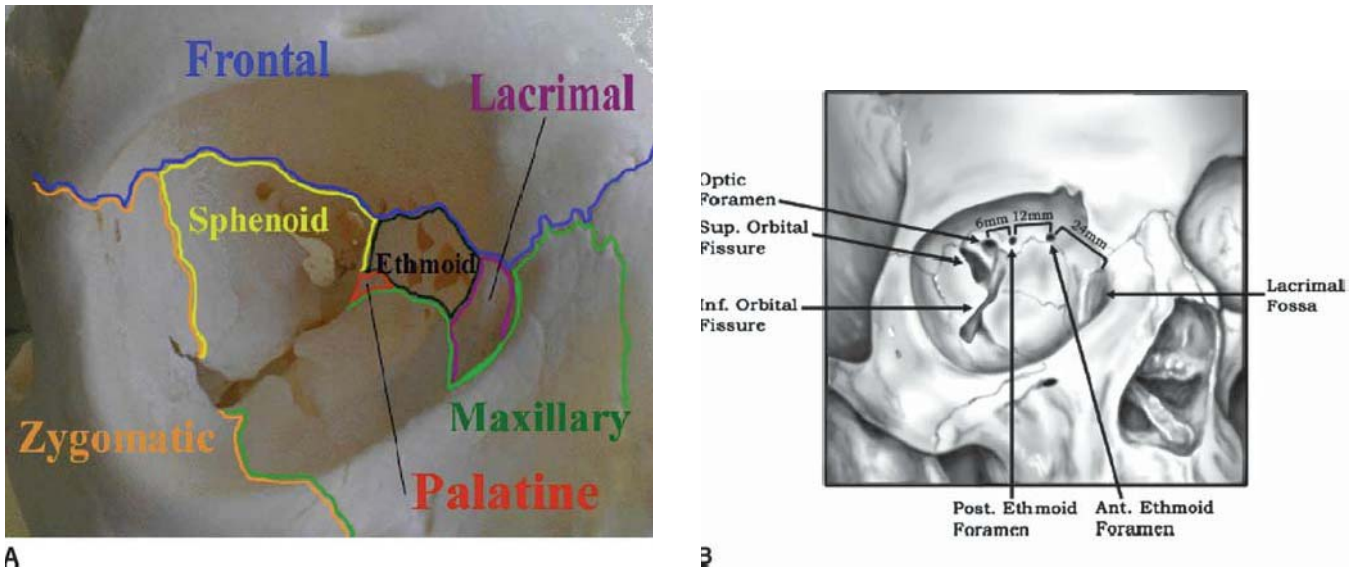

Figure 82.1 **A:** The frontal sphenoid, lacrimal, ethmoid, maxillary, zygomatic, and palatine contributions to the orbit are shown. **B:** As measured from the anterior lacrimal crest, the anterior ethmoid artery, posterior ethmoid artery, and optic foramina are located at 24, 36, and 42 mm, respectively. (**B** from Humphrey C, Kriet JD. Surgical approaches to the orbit. *Operat Tech Otolaryngol Head Neck Surg* 2008;19:132–139, with permission).

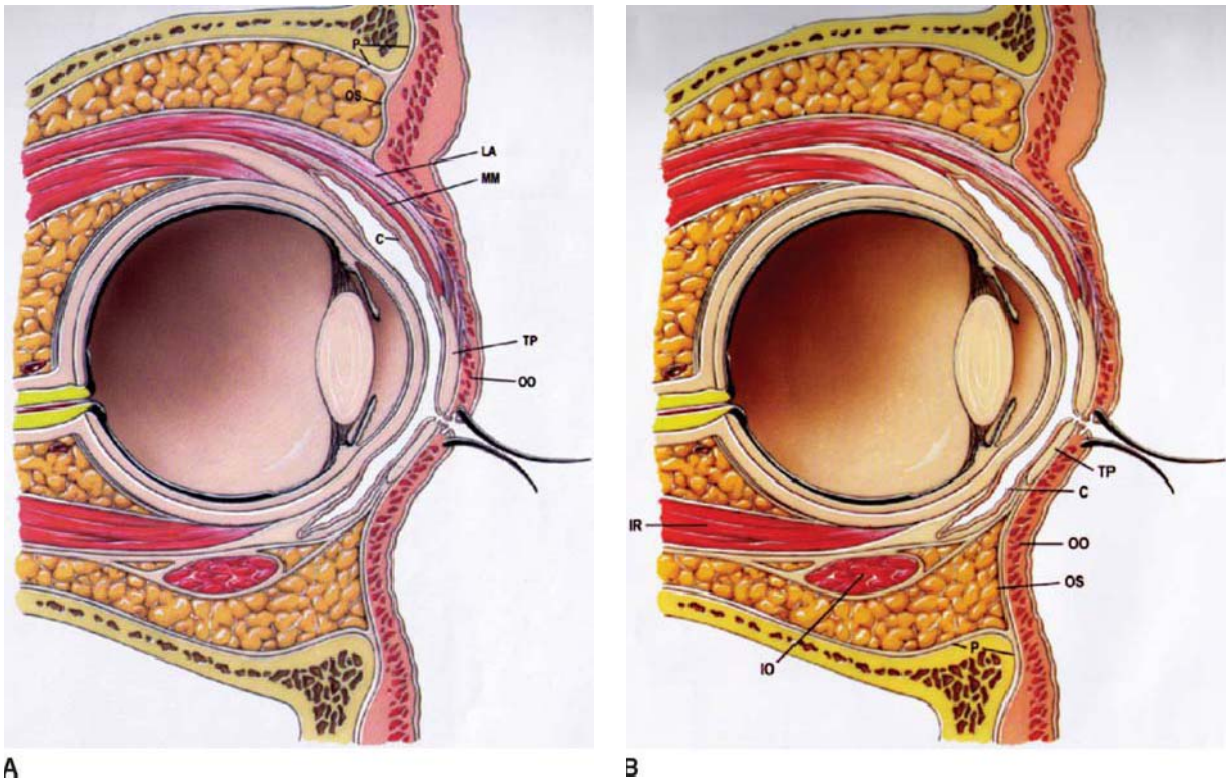

Figure 82.2 Lower eyelid layers include skin, orbicularis, oculi, tarsal plate, conjunctiva, and orbital septum **(A)**. Upper eyelid components include skin, orbicularis oculi, levator palpebrae superioris aponeurosis, Müller muscle, tarsal plate, conjunctiva, and orbital septum **(B)**. C, palpebral conjunctiva; IO, inferior oblique muscle; IR, inferior rectus muscle; LA, levator palpebrae superioris aponeurosis; MM, Müller muscle, OO, orbicularis muscle; OS, orbital septum; P, periosteum/periorbita; TP, tarsal plate. (From Ellis E, Zide MF. Surgical approaches to the facial skeleton 2nd ed., Philadelphia, PA: Lippincott Williams & Wilkins 2006, with permission).

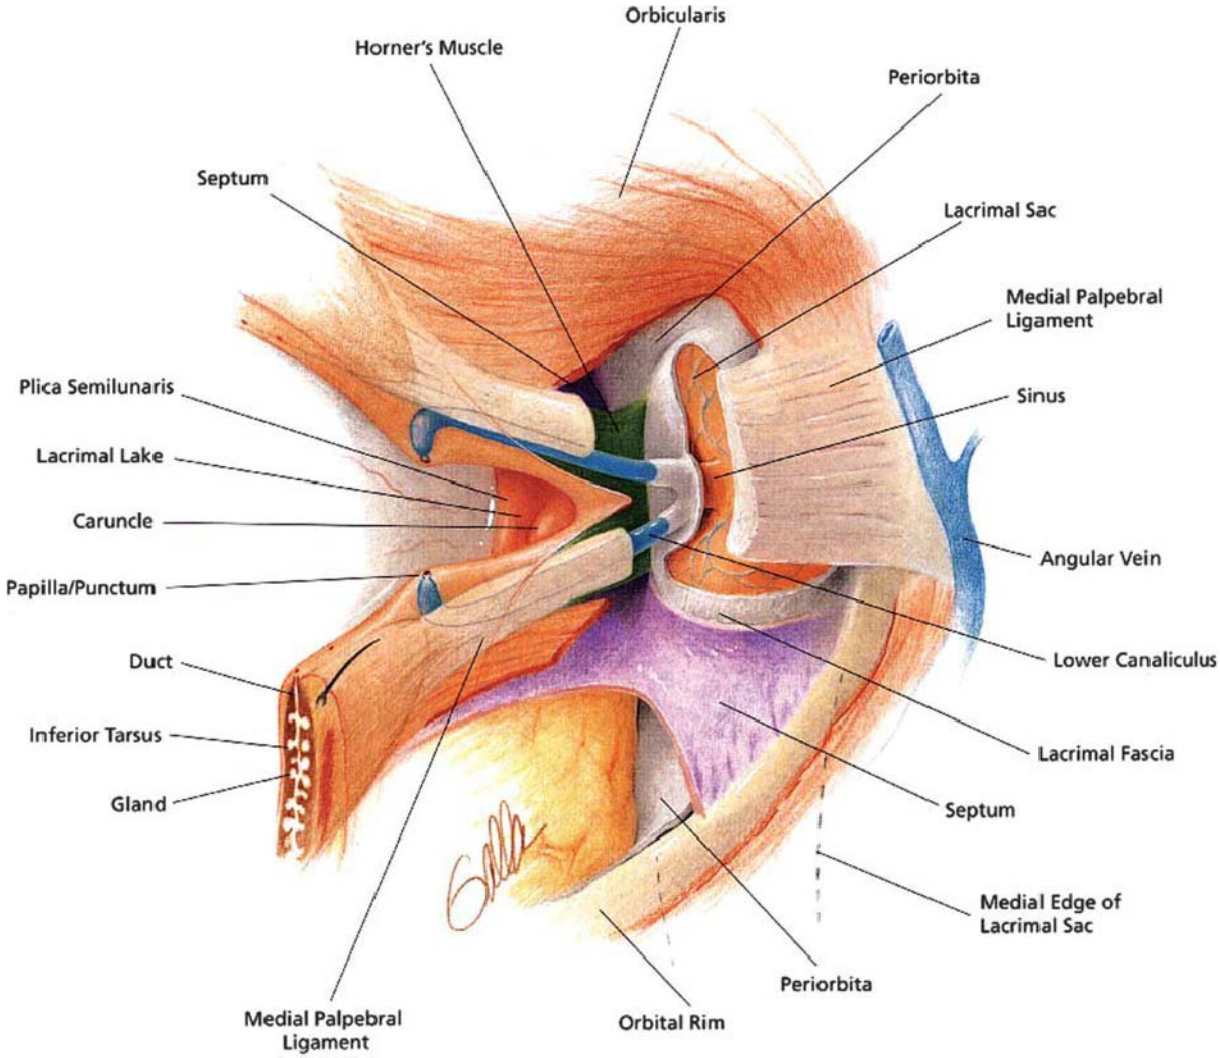

Figure 82.3 Upper and lower puncta begin 5 to 7 mm lateral to the canthus and converge to form the common canaliculus. The common canaliculus enters the lacrimal sac that is located between the anterior and posterior limbs of the medial canthal tendon. The posterior limb of the tendon contains Horner muscle. (From Janfaza P, Nadol JB, Galla, RJ, et al. Surgical anatomy of the head and neck, Philadelphia, PA: Lippincott Williams & Wilkins 2001, with permission).

oblique is in proximity to the orbit at its origin just posterior to the inferomedial orbital rim, lateral to the superior end of the nasolacrimal canal, and occasionally from the fascia over the lacrimal sac. The superior, inferior, lateral, and medial rectus muscles originate from the annulus of Zinn. All of the extraocular muscles insert directly onto the sclera.

DEMOGRAPHICS AND ETIOLOGY

Orbital fractures requiring treatment commonly occur secondary to blunt trauma incurred during violent assaults, accidental injury (falls, sports injuries, work-related), or motor vehicle accidents. While these fractures occur at any age, young males are most often affected. The most typical injury patterns among all patients are isolated blow-out fractures of the orbital floor and fractures of the ZMC. ZMC fractures by definition involve the orbital floor and lateral orbital wall (5). Isolated trapdoor type fractures of the floor are more common in the pediatric age group than in adults (6,7). Orbital roof fractures occur with high-energy injuries that often produce concomitant intracranial sequelae.

Orbital Blow-Out Fractures

The majority of orbital floor blow-out fractures occur medial to the infraorbital nerve and inferior orbital fissure with preservation of a medial strut extending posteriorly off of the nasomaxillary buttress and adjacent to the lacrimal bone (Fig. 82.4). Two wall fractures involving both the orbital floor and the medial wall are less common but must be identified preoperatively as reconstruction is exponentially more challenging, especially if the medial strut is disrupted. In both orbital floor and medial wall fractures, an intact posterior shelf of maxillary or palatine bone will be preserved that must be identified for stable and anatomic implant placement (Fig. 82.5). In medial wall

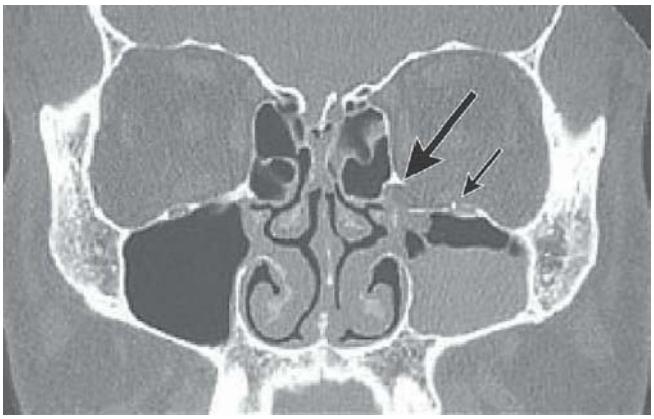

Figure 82.4 A medial strut extending posteriorly from the vertical nasomaxillary buttress is typically preserved following an orbital blow-out fracture. This strut is a useful landmark for orientation and provides a stable anteromedial shelf for implant placement when attempting repair. (From Farwell DG, Sires BS, Kriet JD, et al. Endoscopic repair of orbital fractures: use or misuse of a new approach. *Arch Facial Plast Surg* 2007;9(6):427–433, with permission).

fractures, there is usually a stable superior shelf of frontal bone above the level of the anterior and posterior ethmoid arteries. These arteries indicate to the surgeon the level of the cribriform plate and skull base.

Yano et al. presented a simple classification system for blow-out fractures, separating them into "linear," "punched-out," and "burst" fractures. Linear fractures were minimally dislocated. Punched-out and burst fractures referred to fractures involving respectively less than half or more than half of the wall (orbital floor or medial) (8). Unfortunately, this classification system and alternatives offered by others generally do not correlate well with the likelihood of developing enophthalmos or persistent diplopia (8,9). Further, any classification system based on radiologic findings alone is unlikely to reliably predict these sequelae and the need for surgical intervention.

Zygomaticomaxillary Complex Fractures

Classic "tripod," or tetrapod, fractures of the ZMC involve medial rotation of the zygoma at the arch due to blunt trauma at the lateral aspect of the malar eminence. Significant dislocation results in disruption of the horizontal buttresses at the infraorbital rim and zygomatic arch. The vertical zygomaticomaxillary and zygomaticofrontal buttresses are disrupted as well. Rotation of the body of the zygoma causes displacement along the lateral orbital wall at the zygomaticofrontal and zygomaticosphenoid suture lines (Fig. 82.6). The orbital floor is disrupted by an extension of the orbital rim fracture that runs posteriorly along the zygomaticomaxillary suture line and adjacent to the infraorbital nerve. Infraorbital anesthesia or dysesthesia is present in almost 25% of cases (10).

Zingg proposed a classification system that would stratify ZMC fractures based on concise description of the anatomic sites involved. Type A fractures are isolated to the zygomatic arch, lateral orbital rim, or infraorbital rim alone. Type B fractures are classic monofragment tetrapod fractures as previously described that involve disruption of all four zygomatic articulations. Type C fractures are more complicated tetrapod fractures in which there is comminution of the zygoma. This system does guide treatment somewhat as closed reduction was appropriate for select type A and B ZMC fractures, and open reduction was always indicated for type C fractures in a series of over 1,000 cases (10).

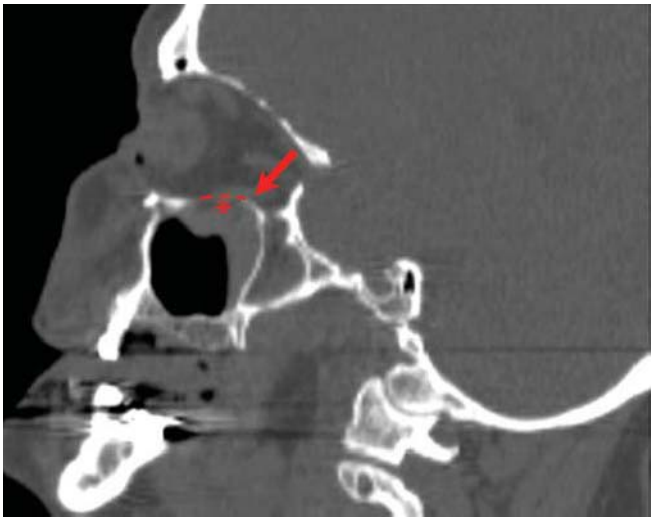

Figure 82.5 A posterior shelf of maxillary and/or palatine bone will be preserved following an orbital blow-out fracture (*large arrow*). During repair, this shelf must be identified and used for stable and anatomic implant placement. Note the convex contour of the posterior orbital floor (*asterisk*). An implant must also replicate this convex contour in order to correctly restore orbital volume. (Figure courtesy of Dr. Barton Branstetter).

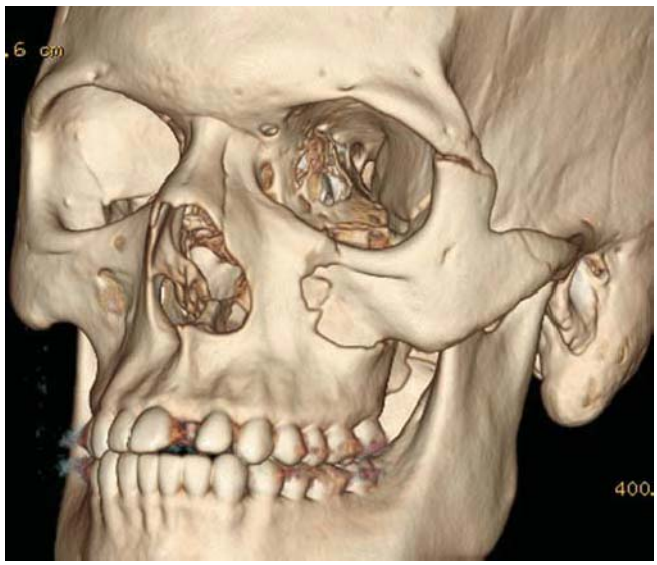

Figure 82.6 This three-dimensional CT reconstruction demonstrates a classic tetrapod fracture of the ZMC resulting from impact at the lateral aspect of the malar eminence. The impact results in counterclockwise rotation and posterior displacement of the zygoma. (Figure courtesy of Dr. Barton Branstetter).

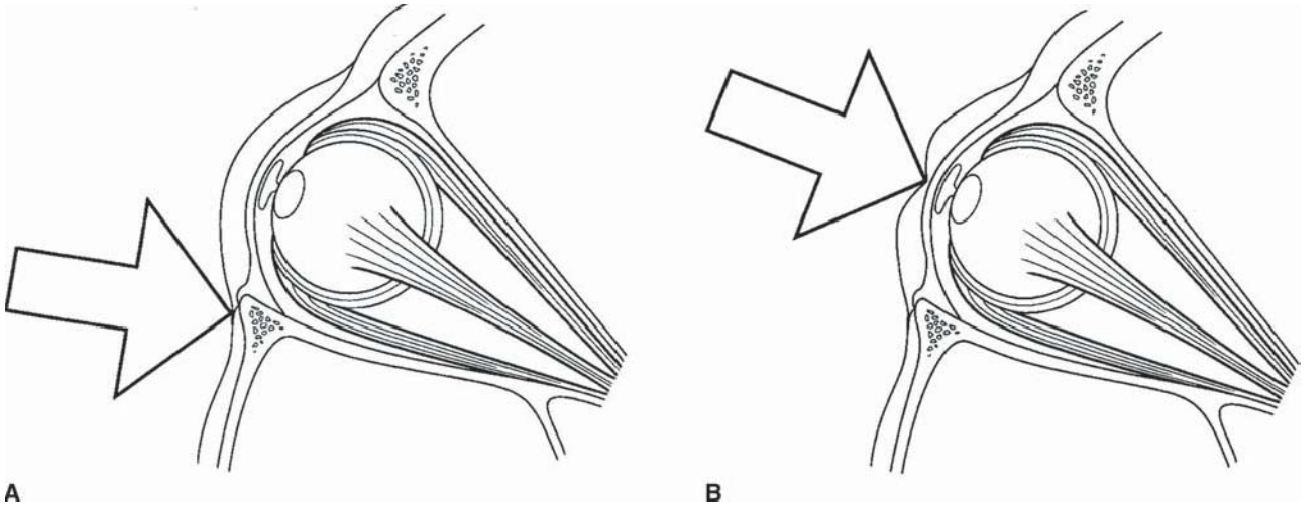

Figure 82.7 Two theories are used to explain the mechanism by which orbital blow-out fractures occur. The bone conduction theory states that force is transmitted through an intact infraorbital rim to the thinner orbital floor **(A)**. The hydrostatic theory suggests that impact to the globe increases intraorbital pressure, causing the orbit to fracture at the weakest point, typically the orbital floor or medial wall **(B)**. (From Waterhouse N, Lyne J, Urdang M, et al. An investigation into the mechanism of orbital blowout fractures. *Br J Plast Surg* 1999;52:607–612, with permission).

Orbital Roof Fractures

Orbital roof fractures are uncommon with an estimated incidence of 1% to 9% of all facial fractures (11). In adults, they are most commonly produced as a result of a high-energy impact such as a motor vehicle accident. In children, fractures may occur as an extension of a linear frontobasal fracture with falls being the most common etiology. One must maintain a high index of suspicion for intracranial injuries manifesting as pneumocephalus, cerebrospinal fluid (CSF) leaks, or encephalocele formation in patients with orbital roof fractures (12).

Biomechanics and Pathophysiology

The pathophysiology for most facial fractures is straightforward in that the fracture occurs at the site of impact. For example, ZMC fractures result from impact sustained at the prominent malar eminence. Orbital blow-out fractures occurring in the absence of an infraorbital rim fracture are unique because the fracture-producing force is transmitted indirectly. Two popular, but not mutually exclusive, theories have traditionally been used to explain the mechanism of these blow-out injuries. The first, bone conduction (or buckling) theory, was originally described by Le Fort (13) and maintains that force is transmitted through the thicker bone of the rim into the thinner bone of the floor, resulting in a fracture of the floor but maintaining an intact rim. The bone conduction theory does not as adequately explain how isolated medial wall blow-out fractures might occur. Alternatively, the hydrostatic theory suggests that impact to the globe results in increased intraorbital pressure that fractures the orbital floor and/or medial wall at the weakest points (14). Figure 82.7 illustrates both theories. A third hypothesis—a modification of the hydrostatic theory—proposes that it is displacement of and direct contact of the globe with the orbital floor or medial wall that results in the fracture. A cadaver study by Rhee et al. in 2002 provides strong support for the hydrostatic theory by demonstrating that increased pressure within the orbit in the absence of rim impact results in blow-out fractures. This study also suggested that direct contact of the deformed globe with the orbital floor or medial wall is not required for fracture (15). Despite this evidence bolstering the pure hydrostatic theory, each of these mechanisms could potentially play at least some role in the clinical setting.

EVALUATION

All trauma patients should initially be stabilized and evaluated according to ATLS protocol by an ED physician or the trauma team. Patients with severe orbitofacial trauma, decreased visual acuity, and/or double vision should be evaluated by the facial trauma surgeon acutely and admitted to the hospital if warranted. Conversely, discharge from the ED and follow-up within 3 to 5 days for outpatient evaluation is appropriate for carefully selected patients. Periorbital edema will decrease in the interval, making the examination less difficult and offering an improved assessment of potential enophthalmos. Comprehensive screening CT scans have become increasingly common in complex trauma cases. Identification of orbital fractures on these screening CT scans is often the impetus for consulting the facial trauma surgeon. In the event that fractures are initially discovered on physical exam or noted on plain films or a head CT, a fine cut (less than 2 mm) maxillofacial scan with axial, coronal, and sagittal reconstructions is indicated. Axial images are useful in evaluating medial

wall fractures. Coronal images provide excellent views of the orbital floor, medial wall, and roof. Sagittal images are helpful in assessing the position of the stable posterior shelf. When available, three-dimensional reconstructions are useful for gaining a broad overview of fracture patterns and fragment orientation.

The availability of a high-quality screening CT scan should not preclude the facial trauma specialist from obtaining a detailed history and performing a thorough physical examination. The historian should inquire about mechanism of impact, previous eye surgery, double vision, numbness, preinjury vision status, and use of anticoagulant medications or other comorbid factors. The physical examination begins with assessing pupillary response and visual acuity. The use of a pocket-sized Snellen chart is helpful for performing an initial vision check. Most smartphones are now able to display such a chart, making the documentation of visual acuity feasible in most circumstances. Color perception is another useful bedside test. Patients with traumatic optic neuropathy may perceive a bright red object (e.g., light shining through the closed eyelid) as a dull brown. While the facial trauma surgeon may not have access to a slit lamp for funduscopic examination, the anterior chamber should be inspected for the presence of hyphema (Fig. 82.8). If available, a Naugle exophthalmometer can easily be used in the clinic to objectively determine the presence and degree of enophthalmos (Fig. 82.9). Extraocular movements (EOMs) are assessed, observing for symmetry and the presence of diplopia during the exam. It is not uncommon to note some diplopia at the extremes of gaze, especially after a fracture causes substantial edema in the affected eye. The status of other cranial nerves, particularly the facial and trigeminal, is determined. Anesthesia or dysesthesia in the distribution of the infraorbital branch of the trigeminal frequently occurs in association with orbital fractures. Likewise, paresis in the buccal branch of the facial nerve can be seen. It is imperative that any neural deficits be documented preoperatively. The combined findings of neurologic injury and an upper eyelid hematoma in a child should raise suspicion for the less common orbital roof fracture (16). The zygomatic arches, zygomaticofrontal sutures, infraorbital rims, and nasal bones are palpated for tenderness or step-offs. The zygomaticomaxillary buttresses are most effectively palpated intraorally. Occlusion and midface stability are also scrutinized.

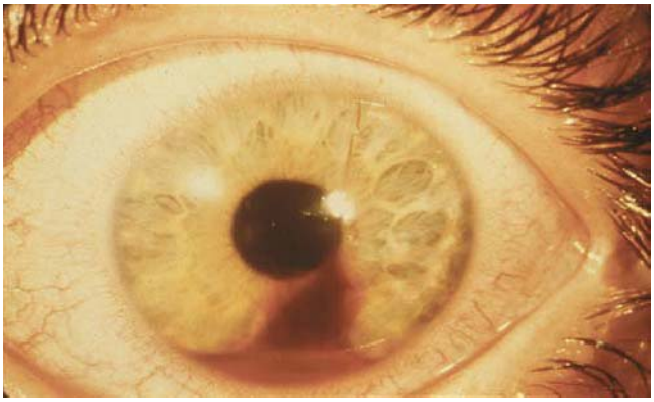

Figure 82.8 Visible hyphema (blood in the anterior chamber of the eye) shown in a patient. Hyphema is most frequently caused by blunt trauma. (Photograph courtesy of Michael P. Grant, MD.)

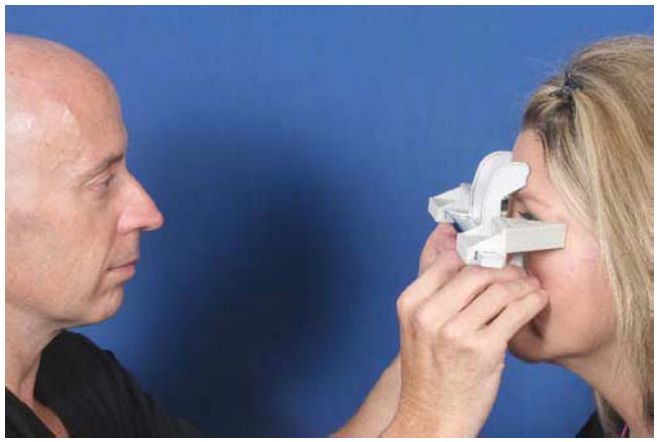

Figure 82.9 A Naugle exophthalmometer can be used to objectively measure enophthalmos. This exophthalmometer is stabilized on the supraorbital and infraorbital rims.

Indications for ophthalmologic evaluation in patients with orbital fractures remain controversial. Some advocate for an immediate and comprehensive ophthalmologic evaluation of every patient with an orbital fracture. In many institutions, this is difficult to achieve and probably unnecessary. At a minimum, it is advisable that the facial trauma surgeon document EOM, pupillary response, and an objective exam of visual acuity prior to any surgical intervention. A prospective study by Grant (17) has demonstrated that up to 30% of patients with orbital fractures have significant ocular injury that could lead to at least partial loss of vision if undiagnosed. Another study by Mellema et al. on the incidence of ocular injuries in patients with orbital fractures demonstrated that severe ocular injuries are extremely uncommon when patients are visually asymptomatic. Surprisingly, changes in visual acuity alone are a poor predictor of ocular injury. Pain, double vision, flashes of light (photopsias), blind spots (scotomata), and floaters are more sensitive indicators. The presence of any of these symptoms including changes in visual acuity is a clear indication for immediate consultation of an ophthalmologist (1).

INDICATIONS FOR SURGICAL MANAGEMENT

Many orbital fractures require intervention to return the patient to preinjury appearance and functional status. Modern approaches are safe and aesthetically acceptable when performed properly. Selecting the most appropriate surgical approach will optimize exposure and increase

the likelihood of successful treatment. Most orbital fractures do not require urgent intervention and can be repaired within 2 weeks. Resolving soft tissue may uncover enophthalmos and allow transient diplopia to resolve (18). Decreased swelling also facilitates improved surgical exposure. If any ocular injury is suspected, we obtain ophthalmology consultation after complex orbital trauma prior to surgical intervention. Evidence of hyphema, ocular rupture, or other globe injury should delay internal orbital approaches until an ophthalmologist can address the injury (19).

Orbital Blow-Out Fractures

Urgent treatment of orbital blow-out fractures is prudent in a select group of fracture patients. Though possible in adults, it is most often children who develop the closed trap door or "white-eyed" fracture that traps periorbital tissues and frequently the inferior rectus muscle (20). Profound entrapment and, rarely, the oculocardiac reflex (OCR) ensue. Even if the OCR is not present, these fractures should be repaired early to prevent irreversible damage to the incarcerated and ischemic inferior rectus muscle.

Indications and ideal timing for repair of more routine isolated orbital floor and medial wall blow-out fractures are unclear in many circumstances. Certainly patients with diplopia secondary to entrapment on the basis of physical examination (positive forced duction testing) or radiologic evidence merit exploration and repair within 2 weeks (18,21). Likewise, enophthalmos that develops immediately after a blow-out fracture will not improve and is likely to worsen without surgical intervention. Surgical candidacy of patients lacking early functional deficits is a greater dilemma. Traditionally, a CT demonstrating a fracture that involves at least 50% or 2 cm^2 of the floor and/or medial wall has been an indication for repair to prevent late enophthalmos. Pronounced rounding of the inferior rectus muscle is also used to identify patients who will benefit from surgery. Rounding of the inferior rectus with a height-to-width ratio greater than or equal to 1.00 on coronal CT scan is predictive of late enophthalmos development (22). Greater than 2 mm of soft tissue prolapse into the maxillary or ethmoid sinus is another proposed indication (5,23). Observing patients with less extensive fractures for 3 weeks or more may help to identify those who do not meet the aforementioned thresholds or criteria but will still develop enophthalmos. Patients in this category can be repaired in a delayed fashion and still have excellent outcomes (24).

Zygomaticomaxillary Complex Fractures

ZMC fracture repair is indicated whenever significant displacement occurs. The least invasive approach to achieve stable anatomic fracture reduction should be utilized. In select cases, a closed reduction alone is adequate. In many cases, multiple open approaches are required for exposure, anatomic reduction, and internal fixation. The most complex cases require a coronal approach to reestablish the contour of a comminuted zygomatic arch. The surgeon should consider intervention for patients with rotation and/or displacement of the body of the zygoma more than a few millimeters. Facial asymmetry will often be perceptible later if a displaced ZMC fracture is left untreated.

Though ZMC fractures involve the orbital floor, orbital floor exploration and repair is not indicated for all patients with ZMC fractures. Ellis reported that patients with preserved orbital contour did not receive orbital exploration at the time of ZMC repair and did not experience long-term sequelae from their orbital injuries. On the other hand, patients with one of the following two criteria were more likely to benefit from surgical exploration of the orbital floor while repairing the ZMC fracture: (a) comminution of the internal orbit sufficient to change orbital shape, increasing the volume of the bony orbit, and (b) significant prolapse of orbital soft tissues into the maxillary and/or ethmoid sinuses through the displaced fracture of the orbital floor even when it is not comminuted (5).

Orbital Roof Fractures

Since the majority of orbital roof fractures are non- or minimally displaced, they are often managed expectantly. Exceptions are blow-in fractures (Fig. 82.10) resulting in exophthalmos, levator dysfunction, or superior rectus entrapment (12). Growing linear fractures requiring repair

Figure 82.10 Orbital roof blow-in fractures are rare but can result in exophthalmos, levator dysfunction, and/or superior rectus entrapment. (Figure courtesy of Dr. Barton Branstetter).

are reported in children (25). Late complications such as encephalocele formation are sometimes cited as indications to uniformly intervene and repair orbital roof fractures. Encephaloceles do not occur routinely, and, if they do develop, delayed surgical management is effective (12,26).

SURGICAL TECHNIQUE

For orbital fractures requiring treatment, adequate exposure facilitates successful repair. A variety of surgical approaches will be described that can be used individually combined gain access to any area of the orbit. Once exposed, ZMC and orbital rim fractures are reduced and if necessary stabilized with low-profile titanium screws and miniplates. Blow-out defects can be successfully repaired with a variety of autogenous and alloplastic materials. While autologous materials, such as cranial bone grafts, were used extensively in the past, the majority of surgeons have switched to alloplastic materials for their ease in use and predictability (i.e., no potential for resorption) (23,27). Popular alloplasts include titanium mesh, porous polyethylene, or composite titanium mesh–porous polyethylene implants (28–30). Titanium mesh plates preformed to simulate the three-dimensional anatomy of the entire orbital floor and medial wall have become available in recent years. These plates are particularly useful for anatomic reconstruction of combined blow-out injuries to these areas. A common error when using any material to replace missing portions of the orbital floor or medial wall is inadequate restoration of the convexity that is present posteromedially (Fig. 82.5). Identifying an intact and stable posterior bony shelf—frequently the orbital process of the palatine bone—during fracture exposure is imperative for proper and anatomical implant positioning. Dissection distances of 40 mm from the infraorbital or medial orbital rim to identify this shelf are often necessary in severe fractures. Dissection to the stable shelf can be accomplished safely with meticulous technique. Still, surgical dissection to this shelf brings the surgeon within millimeters of the optic nerve, especially when dissecting along the medial orbital wall. Medial wall landmarks such as the ethmoid arteries must be utilized to prevent injury to the optic nerve.

New technologies including intraoperative CT scanning, stereotactic guidance, and three-dimensional modeling have bolstered facial trauma surgeons' armamentarium for the treatment of orbital fractures. Confirming anatomic reduction or repair with instant CT images is likely to improve outcomes and can potentially prevent or decrease costly returns to the operating room for revision procedures. The ability to preoperatively and intraoperatively mirror normal contralateral skeletal structure with stereotactic guidance makes restoring normal anatomy a more attainable goal in the most difficult cases where normal landmarks have been obliterated. The production of a three-dimensional model from preoperative CT scans for reconstructive planning can be useful in these circumstances as well. Use of new imaging technologies will increase in coming years as their availability expands and surgeons accumulate more experience with these valuable tools.

Orbital Floor

Transcutaneous approaches to the orbital floor were the mainstay for treatment of blow-out fractures for many years and continue to be in widespread use. Converse originally described the subciliary approach to the orbit in 1944 (31). He and others have also advocated a subtarsal variation of this approach. Both provide access to most of the orbital floor. The orbital rim incision is an alternative that the authors do not use or recommend because of the potential for visible scarring.

For the subciliary and subtarsal approaches, local anesthetic with epinephrine is infiltrated subcutaneously in the lower eyelid and along the inferior orbital rim. A lateral temporary tarsorrhaphy is performed on the operative eye for protection and retraction. The subciliary cutaneous incision is made 2 mm below and parallel to the lash line using a no. 15 blade (Fig. 82.11). The incision should be carried no further medially than the lower lid punctum. Laterally, the incision can be extended up to 15 mm beyond the lateral canthus. If this lateral extension is performed, it should be directed horizontally and not inferiorly to promote an aesthetically acceptable scar. A subcutaneous dissection superficial to the orbicularis oculi is followed inferiorly using either sharp dissection or the Colorado dissector until just inferior to the tarsal plate where the orbicularis is divided parallel to its fibers. It is crucial to preserve this rim of orbicularis over the tarsal plate to maintain lower lid structure and support. A preseptal plane is then followed down to the orbital rim. The

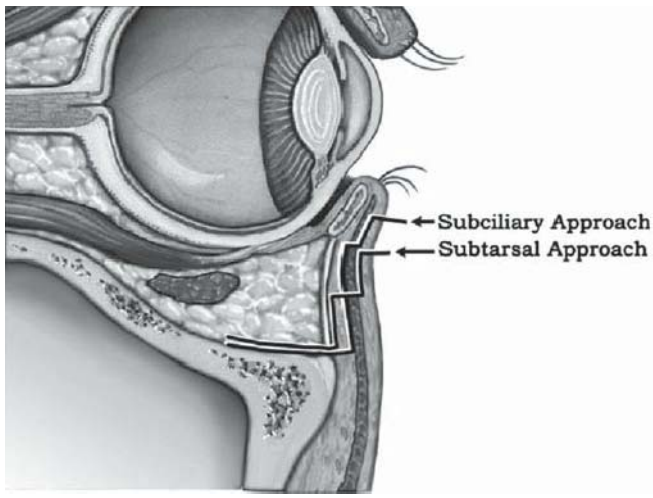

Figure 82.11 Paths traversed by the subciliary and subtarsal approaches through the lower eyelid are shown. It is important to step the incisions as shown to preserve lid integrity and avoid scar inversion. (From Humphrey C, Kriet JD. Surgical approaches to the orbit. *Operat Tech Otolaryngol Head Neck Surg* 2008;19:132–139, with permission).

periosteum is incised on the anterior aspect of the inferior orbital rim, and elevation proceeds posteriorly onto the orbital floor using a periosteal elevator. For the subtarsal variation of this approach, the skin incision is made in the subtarsal fold or 5 to 7 mm below the lash line when the fold is obscured by edema (Fig. 82.11). The orbicularis oculi is divided a few millimeters below the level of the skin incision to discourage scar inversion. Careful layered closure is the rule, taking care to restore orbicularis oculi continuity. A Frost suture is sometimes used to support the lid in the early postoperative period.

Over the past two decades, the transconjunctival approach has supplanted transcutaneous approaches in many surgeons' hands to decrease risks of postoperative lower lid malposition. Bourquett first described the inferior fornix conjunctival or transconjunctival approach for blepharoplasty in 1924 (32). Tenzel and Miller (33) later employed this approach for repair of orbital floor defects in the 1970s. Exposure of most of the orbital floor can be achieved through the transconjunctival approach.

To prepare for the transconjunctival approach, local anesthetic with epinephrine is infiltrated at the lateral canthus, just under the conjunctiva of the lower lid, and transcutaneously down to the orbital rim. Lateral canthotomy and inferior cantholysis is optional and can be performed using curved iris scissors and is optional to increase surgical exposure and minimize retraction of the lower eyelid. If the canthal release is not performed, great care must be taken to avoid excessive retraction that may lead to a higher incidence of lower eyelid malposition. With a Jaeger lid plate protecting the globe, the lower eyelid is everted and an incision is made with a Colorado dissector through the conjunctiva at least 2 mm inferior to the tarsal plate. The incision is continued through the lower lid retractors. Blunt dissection between the orbicularis oculi and orbital septum—a preseptal approach—proceeds using the malleable retractor and cotton-tipped applicators. Alternatively, the orbital septum can be incised to reveal a dissection plane between the orbital septum and periorbital fat—a postseptal approach (Fig. 82.12). A 5-0 silk mattress suture is placed through posterior edge of the conjunctival incision and positioned to passively retract the conjunctiva superiorly such that it covers the globe. Blunt dissection with a malleable retractor over the septum or orbital fat and a Ragnell retractor on the lower lid and orbicularis oculi will reveal the periosteum of the inferior orbital rim. The Colorado dissector is used to incise the periosteum on the anterior surface of the rim. The periosteum is elevated, and the malleable retractor can be used to continually retract the orbital contents and expose the desired portion of the orbital floor. No closure of the conjunctiva is needed so long as it is properly repositioned at the conclusion of the procedure. If canthotomy and cantholysis are performed, the tarsal plate is resuspended to the orbital periosteum near Whitnall tubercle using a single 5-0 polydioxanone suture. The canthus is reapproximated using a single 6-0 fast absorbing gut suture placed through the grey line of the lateral upper and lower lids. Interrupted sutures are used as needed to close any remaining canthotomy defect laterally.

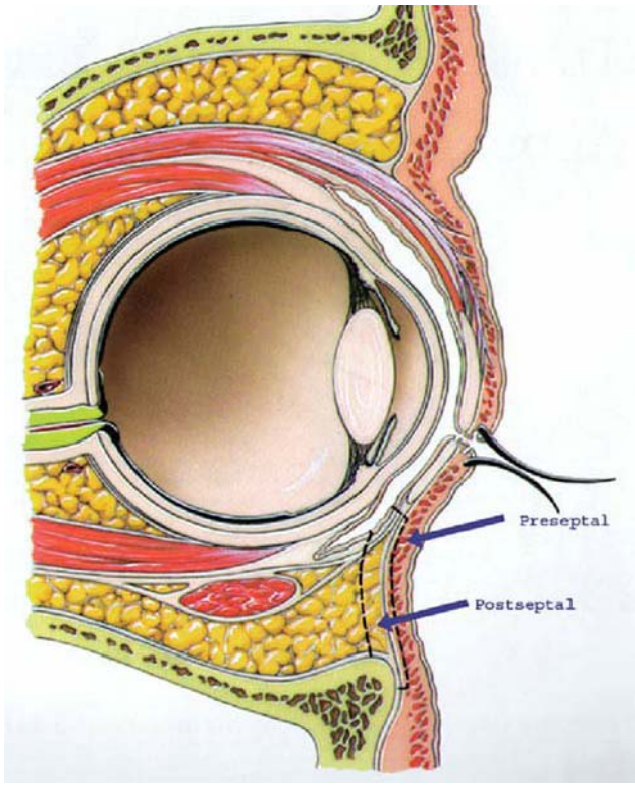

Figure 82.12 Paths traversed by the pre- and postseptal variations of the transconjunctival approach are shown. A hypothetical advantage to the postseptal approach is avoidance of undesirable scar formation between the orbicularis oculi and orbital septum. Such scar formation could contribute to postoperative lower lid malposition. (From Humphrey C, Kriet JD. Surgical approaches to the orbit. *Operat Tech Otolaryngol Head Neck Surg* 2008;19: 132–139, with permission).

Advantages to the subciliary and subtarsal approaches are that they are easy to learn and offer broad access to the orbital floor. Disadvantages are higher rates of postoperative lower lid malposition and visible scarring when compared with the transconjunctival approach (34,35). Technique in a transcutaneous lower lid approach must be flawless to minimize the risk of scleral show and ectropion. Rohrich argues that the subtarsal variation of this approach produces less risk of vertical lid shortening, scleral show, and ectropion but slightly greater risk of visible scarring. Innervation to the pretarsal and much of the preseptal orbicularis is better preserved through the subtarsal variant which may help maintain the preoperative lower lid position (36). Advantages of the transconjunctival approach include no visible scarring and decreased risk of ectropion when compared with the subciliary and other transcutaneous approaches (34,35). While the continually protruding periorbital fat can be an annoyance, a theoretical advantage of the postseptal variant is decreased incidence of postoperative lower lid malposition since the plane between the orbicularis oculi and orbital septum is not violated.

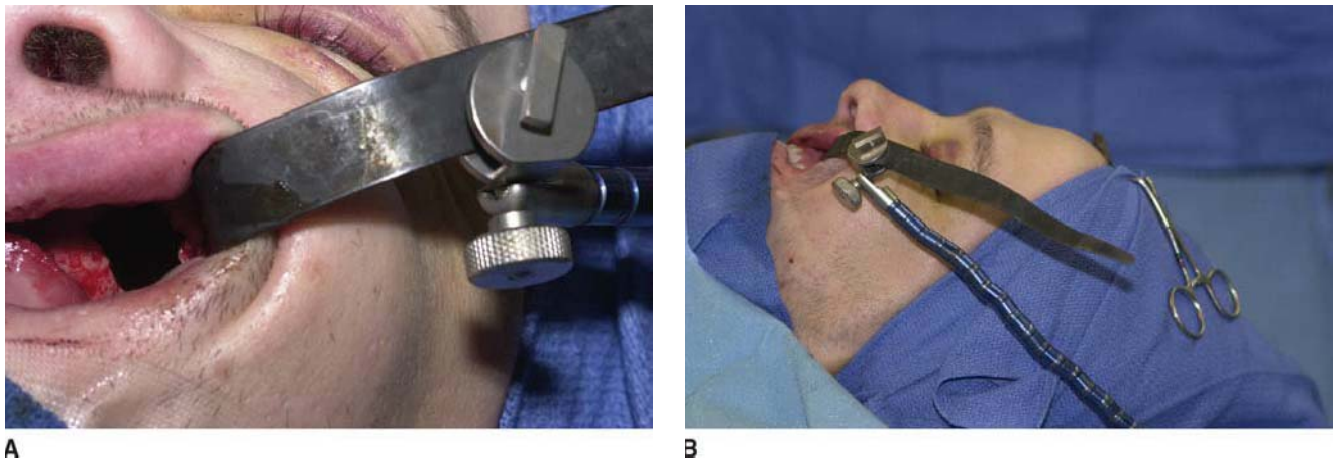

Figure 82.13 A 10- by 20-mm defect is then created in the anterior wall of the maxillary sinus for access to the orbital floor. As shown, the medial buttress, lateral buttress, and inferior orbital rim remain intact **(A)**. A Davida malleable neurosurgical retractor (Flexbar Machine Corporation, Islandia, NY) or similar is positioned to retract the ipsilateral cheek **(B)**. (From Humphrey C, Kriet JD. Surgical approaches to the orbit. *Operat Tech Otolaryngol Head Neck Surg* 2008;19:132–139, with permission).

A transantral endoscopic approach to the orbital floor has been advocated by some surgeons (37). This approach may be used as an isolated technique or combined with a more traditional periorbital approach to assist in fracture visualization and reduction. Endoscopic technique is not indicated for and has lost favor for treatment of routine orbital floor fractures (38).

The transantral endoscopic approach begins with a gingivolabial sulcus incision. The surgeon must preserve a 4- to 5-mm cuff of mucosa on the gingival side for closure. Maxillary periosteum is then incised. The lip is retracted, and a periosteal elevator is used to expose the anterior wall of the maxillary sinus up to the level of the infraorbital nerve. An osteotome and Kerrison rongeur are used to make a 10 by 20 mm defect in the anterior wall of the sinus (Fig. 82.13). Zero- and thirty-degree 4-mm telescopes are then inserted through the antrostomy to visualize the orbital floor (Fig. 82.14). The floor defect is usually obvious and mucosa can be elevated adjacent to the defect for visualization and reduction of the orbital contents.

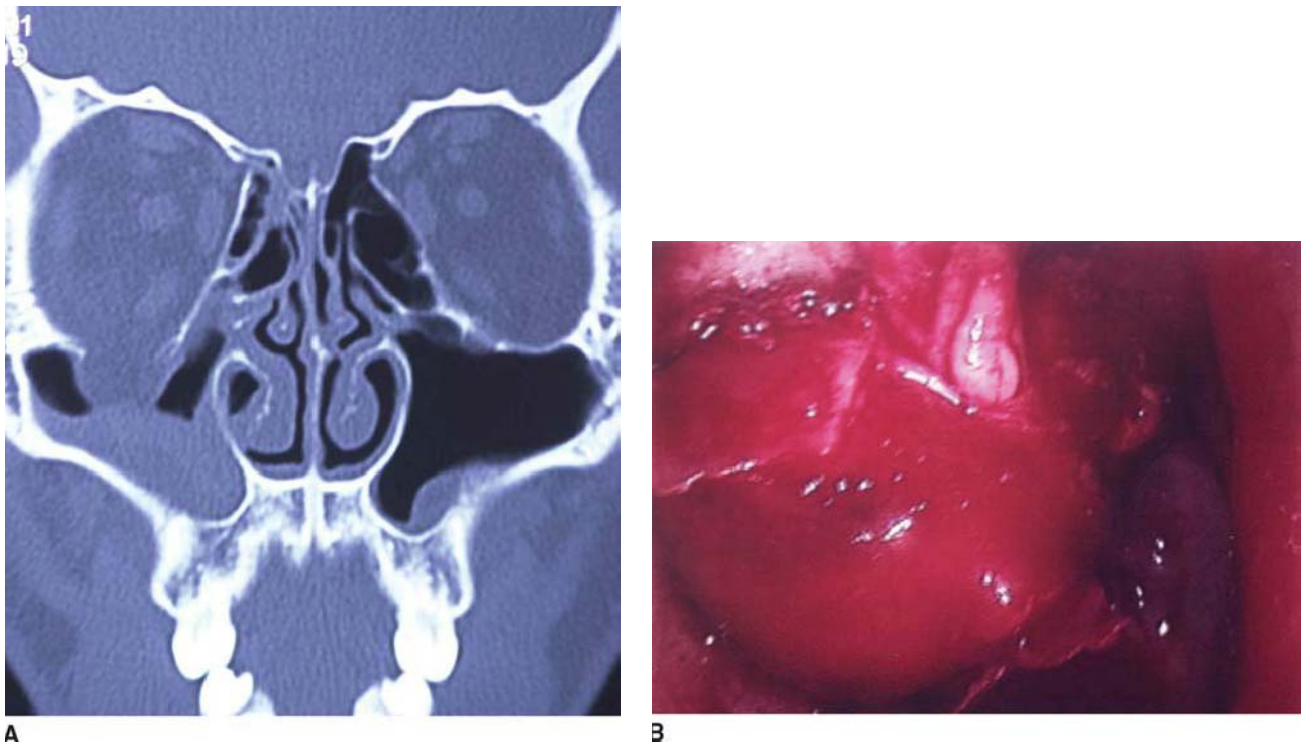

Figure 82.14 A right orbital blow-out fracture as identified with CT **(A)** and as visualized endoscopically via a transantral endoscopic approach with herniation of bone fragments, periorbita, and orbital fat into the maxillary sinus **(B)**. (From Humphrey C, Kriet JD. Surgical approaches to the orbit. *Operat Tech Otolaryngol Head Neck Surg* 2008;19:132–139, with permission).

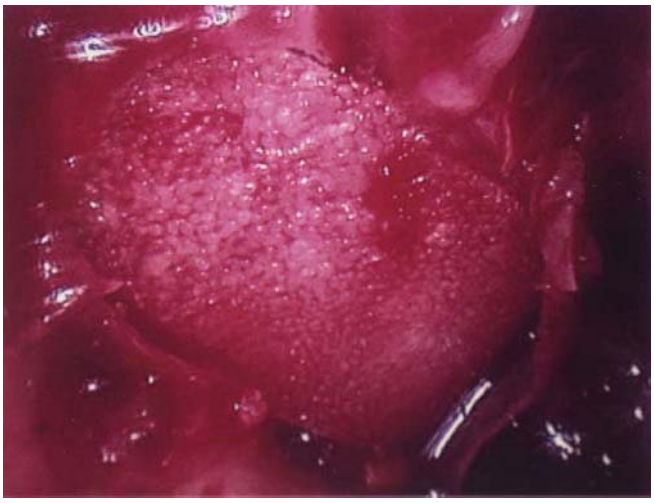

Figure 82.15 Orbital blow-out fracture shown in Figure 82.14 following reduction of herniated orbital fat and placement of a Medpor linear high-density polyethylene implant (Porex Surgical Inc, Newnan, GA) supported by the anterior and posterior shelves of the floor defect. (From Humphrey C, Kriet JD. Surgical approaches to the orbit. *Operat Tech Otolaryngol Head Neck Surg* 2008;19:132–139, with permission).

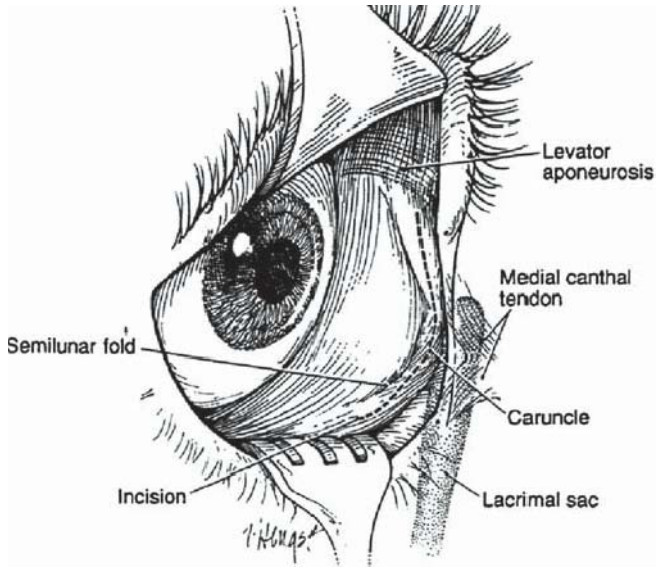

Figure 82.16 The transcaruncular incision is placed either over or just posterior to the caruncle in the sulcus between the caruncle and the semilunar fold. (From Shorr N, Baylis HI, Goldberg RA, et al. Trancaruncular approach to the medial orbit and orbital apex. *Ophthalmology* 2000;107:1459–1463, with permission).

Trap door or greenstick type fractures can occasionally be reduced using this approach alone without need for fixation if the bony floor "locks" into place. An implant can also be inserted if necessary by placing it first onto the posterior shelf and then sliding it up onto the anterior shelf (Fig. 82.15). Closure proceeds by reapproximating the gingivolabial sulcus mucosa using interrupted 3-0 polyglactin suture.

Reported advantages to the transantral approach include improved visibility of the posterior orbit and especially the posterior shelf of a floor defect. Disadvantages include difficulty in reconstructing the orbital floor lateral to the infraorbital nerve, the need to violate the anterior maxillary face in an isolated orbital floor fracture, and the need for specialized endoscopic instrumentation. Though perhaps a useful adjunct for complex cases, the transantral endoscopic approach does not seem to decrease morbidity or improve outcomes for most floor fractures (38).

Medial Orbit

Lynch first described his transcutaneous approach to the medial orbit and frontal sinus for sinusitis in 1921. Though refined somewhat, the approach is relatively unchanged from this original description. Access to most of the medial orbital wall is achievable through this approach (39).

Local anesthetic with epinephrine is injected over the ipsilateral nasal bone and the medial orbital rim. An incision is made with a no. 15 blade over the superomedial orbital rim from a point inferior to the medial brow to the superior aspect of the nasofacial junction. This incision is carried down through periosteum using the Colorado dissector. A periosteal elevator is used to expose the medial orbital wall, staying superior to the medial canthal tendons and lacrimal apparatus until posterior to these structures. If exposing the superomedial orbit, care should be taken to identify and cauterize or ligate the ethmoid arteries. The anterior and posterior ethmoid arteries serve as a useful depth gauge for the surgeon to estimate distance from the optic canal.

An alternative to the Lynch incision is the transcaruncular approach as described by Shorr. It allows access to the entire medial orbital wall posterior to the lacrimal fossa via a conjunctival incision (40). A Colorado dissector is used to make a 12 to 15 mm incision either through or just posterior to the caruncle and anterior to the semilunar fold (Fig. 82.16). The upper and lower lids are retracted with Desmarres retractors, and the globe is protected using small malleable retractors. A plane posterior to Horner muscle is developed with iris scissors until the posterior lacrimal crest is palpated. The Colorado dissector is then used to incise the periosteum posterior to the lacrimal crest, medial canthal attachments, and the lacrimal sac (Fig. 82.17). The periosteum is elevated along the lamina papyracea until the desired exposure is obtained. The anterior and posterior ethmoid arteries are ligated as necessary. If exposure of both the medial wall and floor of the orbit is desired, the transcaruncular approach can be combined with an inferior transconjunctival approach. In most cases, an implant can be placed to reconstruct two-wall defects while working around the inferior oblique muscle. If this is not possible, the inferior oblique can be divided near its insertion and reapproximated at the completion of the case. The surgeon should realize that any manipulation of the inferior oblique may have functional implications.

The transcaruncular approach is replacing Lynch's technique as the standard for access to the medial orbital wall because it eliminates the potential for visible scarring and webbing associated with the transcutaneous incision in this

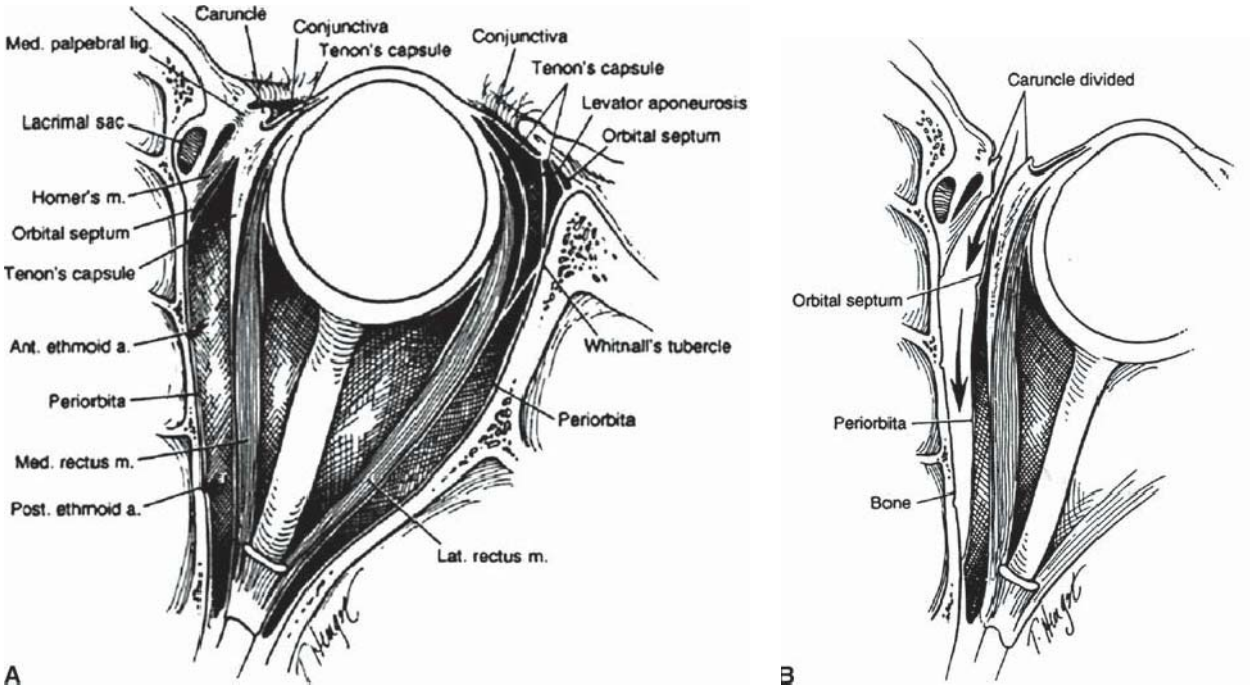

Figure 82.17 The transcaruncular approach follows a plane immediately posterior to Horner muscle down to the periosteum of the medial orbital wall posterior to both the canthal attachments and lacrimal apparatus **(A)**. Periosteal elevation can then proceed without disturbing these structures **(B)**. (From Shorr N, Baylis HI, Goldberg RA, et al. Trancaruncular approach to the medial orbit and orbital apex. *Ophthalmology* 2000;107:1459–1463, with permission).

area. One disadvantage to the transcaruncular approach is that it can be difficult to insert and manipulate an implant through the relatively small incision. Care must be used to avoid injury to the lacrimal apparatus by following the proper dissection plane to the posterior lacrimal crest.

Similar to transantral approaches to the orbital floor, transnasal approaches to the medial orbit have been proposed. Rhee described using a transnasal endoscopic approach either to place stenting material between the middle turbinate and a medial orbital defect or in conjunction with a transcaruncular or transconjunctival approach to facilitate precise placement of an implant for medial orbital wall reconstruction (41).

Prior to inserting endoscopes, the nose is first decongested using oxymetazoline on Cottonoid pledgets. A 4-mm 0 degree endoscope is then advanced into the nasal cavity. The middle turbinate is gently medialized with a Frazier suction or blunt-tipped right angle probe to visualize the uncinate process. Local anesthetic with epinephrine is injected along the uncinate process. A Kerrison rongeur is then used to remove the uncinate, leaving 3 to 4 mm superiorly to prevent formation of nasofrontal recess synechiae. The ethmoid bulla and maxillary os are identified. The majority of medial orbital injuries are associated with nasal trauma, and there may be significant intranasal damage in addition to the prolapsing orbital contents. Care must be taken to bluntly dissect the tissues and definitively identify landmarks as one proceeds to avoid creating or enlarging an orbital or skull base defect. The ethmoid bulla is entered using a small Frazier suction, and the ethmoid cells are opened back to the ground lamella, exposing the lamina papyracea and medial orbital defect. Orbital contents can be carefully reduced using both the transorbital and transnasal approaches at this point. When available, a CT stereotactic guidance system facilitates identification of the orbital defect and skull base.

A combined approach to the medial wall may offer the advantages of superior visualization and improved access during implant manipulation. A disadvantage of the transnasal approach is the potential increased risk for skull base injury and CSF leak. This approach also lacks utility as a single approach because of both limited space for implant introduction and the need to insert an implant blindly toward the eye. No increased morbidity from sinus disease postoperatively has been described (42).

Lateral Orbit and Orbital Roof

The lateral brow and upper blepharoplasty approaches are useful for accessing the zygomaticofrontal and zygomaticosphenoid sutures, most often affected in ZMC fractures. The lateral portion of the superior orbital rim and orbital roof can be exposed as well. Incision placement for each of these approaches is shown in Figure 82.3.

For the lateral brow approach, an incision is made just inferior and parallel to the hair follicles of the lateral 2 to 3 cm of the inferior brow. Some advocate making this incision within the brow, but this may result in undesirable

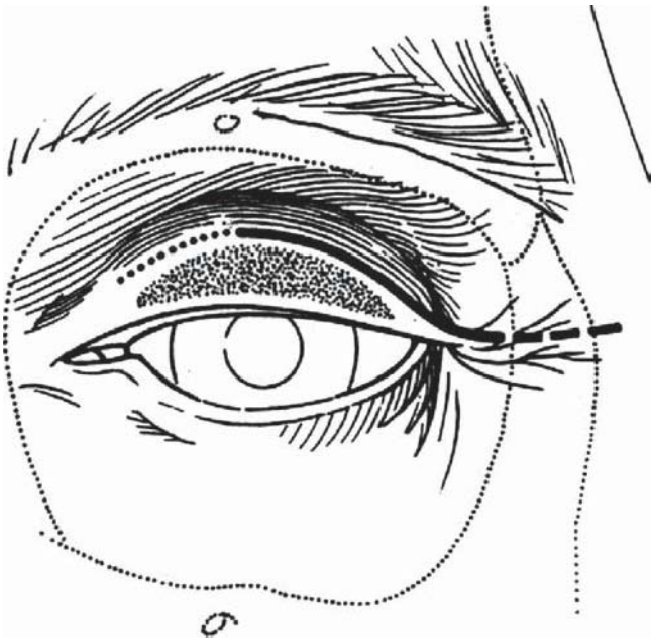

Figure 82.18 The brow incision is placed within or just below the hair follicles of the lateral 2 to 3 cm of the eyebrow. An upper blepharoplasty incision is placed in the lateral one-third to one-half of the supratarsal fold and can be extended as necessary, following a horizontal crease above the lateral canthus. (From Humphrey C, Kriet JD. Surgical approaches to the orbit. *Operat Tech Otolaryngol Head Neck Surg* 2008;19:132–139, with permission).

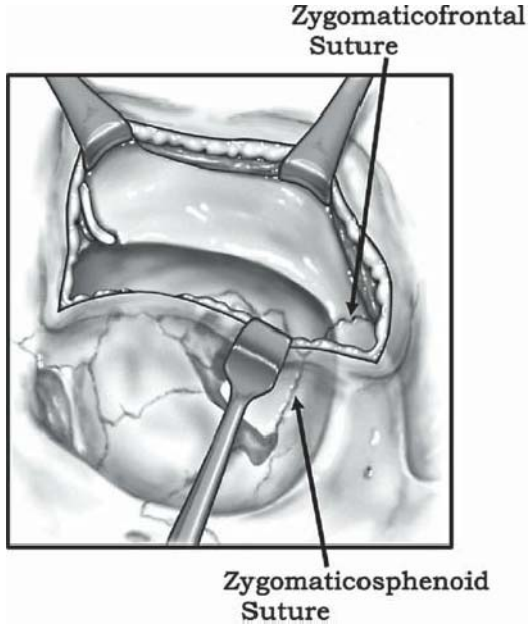

Figure 82.19 Zygomaticofrontal and zygomaticosphenoid sutures are exposed after subperiosteal elevation through an upper blepharoplasty approach. (From Humphrey C, Kriet JD. Surgical approaches to the orbit. *Operat Tech Otolaryngol Head Neck Surg* 2008;19:132–139, with permission).

alopecia. The periosteum over the lateral orbital rim is sharply incised and raised with an elevator to obtain the desired exposure. Meticulous layered closure should reapproximate the periosteum. It is crucial that meticulous layered closure is performed to secure the periosteum over any plates and reestablish orbicularis oculi continuity.

For the upper blepharoplasty approach, the supratarsal fold is marked (typically 7 to 9 mm above the ciliary line). The incision is extended within the fold and horizontally beyond the lateral canthus in a rhytid or skin crease as needed for exposure (Fig. 82.18). Local anesthetic with epinephrine is injected subcutaneously and down to the lateral orbital rim at the zygomaticofrontal suture. The skin is incised, and scissors or a Colorado dissector can then be used to traverse the orbicularis oculi, dividing the muscle parallel to the fibers. Dissection then proceeds to the lateral orbital rim and zygomaticofrontal suture in a plane superficial to the orbital septum and lacrimal gland. The periosteum is elevated over the rim and zygomaticofrontal suture as needed. If necessary, the superiolateral orbital wall can be dissected to assess zygomaticosphenoid suture alignment or gain access to the orbital roof (Fig. 82.19). Closure is performed in layers, again meticulously reapproximating the periosteum, orbicularis oculi muscle, and skin.

The primary advantage of the lateral brow approach is the simplicity of the technique. Disadvantages include the possibility of visible scarring and brow alopecia. It is because of this scarring that this approach has largely been abandoned and replaced by the upper blepharoplasty approach. The advantages of the upper blepharoplasty approach include ample access as well as a cosmetically superior scar (43,44).

For more extensive craniomaxillofacial reconstruction requiring broader access to the superolateral orbit, the coronal approach remains the workhorse. Additionally, it provides access to the medial orbits and zygomatic arches. Access to the lateral aspect of the infraorbital rims is possible by extending the incision along the preauricular creases. The coronal approach has been well described in the literature. For further reading, Frodel provides an excellent discussion of anatomical considerations and surgical technique for this approach (45). The primary advantage of the coronal flap is broad exposure and access to both orbits and the nasal skeleton that is unparalleled by any other approach. Disadvantages include incision length, extensive dissection, and potential morbidity including alopecia, forehead numbness, and potential for injury to the temporal branch of the facial nerve.

POSTOPERATIVE CARE

Forced duction testing should be performed in the operating room following any orbital approach with bony manipulation or implant placement. There should be unrestricted ocular mobility. Following surgery, the authors currently observe most patients undergoing orbital approaches in an inpatient facility overnight. Observation in this setting expedites recognition and treatment of postoperative orbital complications such as expanding hematoma. Vision checks for light perception and acuity are performed every 4 hours.

As previously discussed, color discrimination is a very sensitive indicator of optic nerve injury, and the ability to perceive the color red is a useful bedside test. Pain should also be monitored closely. Corneal abrasion is the most common cause of pain in the early postoperative period. However, an expanding retrobulbar hematoma should be suspected in the presence of progressive pain, visual changes, or increasing proptosis. These findings should prompt physician evaluation. A determination can then be made whether intervention or further observation is warranted.

Ice should be applied to the operative eye for 36 to 48 hours following surgery to decrease swelling and promote vasoconstriction. Tobramycin and dexamethasone ointment is applied to the eye twice daily for 1 week to maintain lubrication and decrease inflammation.

COMPLICATIONS

Diplopia

Diplopia may be the most common complication after surgical treatment of orbital fractures. In many cases, it is documented preoperatively and will persist temporarily because of edema. Forced duction testing showing free ocular mobility at the conclusion of the procedure gives the surgeon confidence that no persistent entrapment is present. Forced duction testing demonstrates clear improvement after release of entrapped rectus or periorbita in early cases but can be much more ambiguous if a delayed repair is performed (8). A postoperative CT scan can also be useful for ruling out entrapped soft tissues. In cases of entrapped rectus muscles that have been released, recovery of function can take many months and may not be complete. If the diplopia is persistent and bothersome to the patient, referral to ophthalmology is indicated for evaluation and treatment.

Vision Loss

Vision loss can occur with direct injury to the optic nerve or its vascular supply. Intraoperative mydriasis is a sign of pressure on the ciliary ganglion (located 1 cm anterior to the annulus of Zinn between the lateral rectus and optic nerve). When mydriasis develops, it should serve as a warning that excessive pressure is being applied to the intraorbital contents; it is not necessarily a direct indication that the optic nerve has been damaged (46). Postoperative hemorrhage can result in blindness if not treated immediately. If the patient develops visual changes such as decreased color discrimination or loss of acuity associated with increased intraocular pressure and proptosis, an expanding retrobulbar hematoma must be suspected. Canthotomy and cantholysis should be performed immediately at the bedside to decrease intraocular pressure. Wound exploration, removal of the implant, and hematoma evacuation in the operating room are also indicated. Immediate ophthalmology consultation should be obtained in any case of decreasing visual acuity but should not delay initial treatment.

Lid Malposition

Lower lid malposition in the form of retraction or ectropion is a complication that develops at least temporarily in 28% to 42% of transcutaneous approaches to the orbital floor (34,35). In transconjunctival approaches, the combined incidence of ectropion, entropion, and scleral show has been reported at less than 0.5% (47,48). Misplaced conjunctival incisions or thermal cautery injury may damage the tarsal plate and increase the risk of entropion and scleral show. There is also potential for symblepharon, or scar formation between the tarsal and bulbar conjunctival surfaces. A theoretical and controversial increased risk of lower lid malposition exists using a preseptal rather than a postseptal approach because of scar which may form between the orbital septum and orbicularis oculi following a preseptal dissection. Some cases of postoperative ectropion and entropion are transient and will resolve with massage and observation over a few weeks. If persistent, surgical repair may be required for correction.

HIGHLIGHTS

- Orbital fractures requiring treatment commonly occur secondary to blunt trauma incurred during violent assaults, accidental injury (falls, sports injuries, work-related), or motor vehicle accidents. These patients must be initially evaluated according to current ATLS protocols. Once stabilized, the facial trauma surgeon performs a focused orbital evaluation.
- Fine-cut CT scanning is the gold standard for radiographic evaluation of orbital injuries. Axial images are useful in evaluating medial wall fractures. Coronal images provide excellent views of the orbital floor, medial wall, and roof. Sagittal images are helpful in assessing the position of the stable posterior shelf.
- Clinical history should document mechanism of injury, previous eye surgery, double vision, numbness, preinjury vision status, and comorbidities. The physical examination should document visual acuity, pupillary response, ocular trauma, globe position, extraocular motility, diplopia, and cranial nerve function.
- Urgent treatment is indicated for closed trap door or "white-eyed" blow-out fractures. These fractures occur most commonly in the pediatric population and may be associated with the OCR.

- Firm indications for repair of orbital blow-out fractures include clinical enophthalmos or diplopia associated with entrapment confirmed by forced duction testing or radiographic imaging. The finding of inferior rectus rounding on CT scanning may identify patients at risk for developing delayed enophthalmos.
- For orbital floor fractures, the transconjunctival approach has largely replaced transcutaneous approaches given a lower incidence of ectropion.
- The transcaruncular approach is a versatile alternative to the Lynch approach for the treatment of medial orbital wall fractures. The former avoids the medial canthal scarring and webbing associated with the Lynch approach.
- The lateral orbital wall can be approached via an upper blepharoplasty incision that avoids brow scarring. Exposure of the zygomaticofrontal and zygomaticosphenoid sutures is readily accomplished with this approach.
- Newer technologies include interoperative CT scanning and navigation, preoperative planning software, and rapid prototype modeling. Increasing availability will assist surgeons in the successful treatment of the most challenging cases.
- While postoperative complications are rare, the clinical finding of progressive pain, increasing proptosis, and visual changes should alert the physician to the possibility of an expanding retrobulbar hematoma. When suspected, emergent bedside canthotomy and inferior cantholysis should be performed.

Nasal Fractures

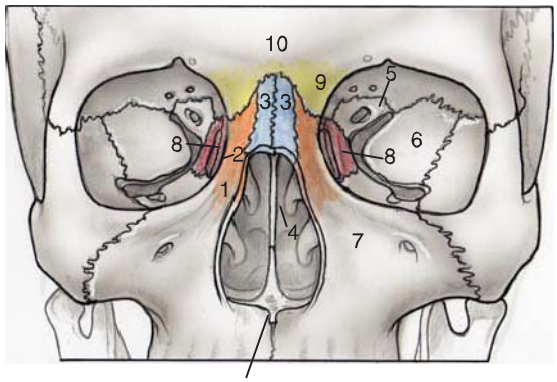
83

Grant S. Gillman *Carlos M. Rivera-Serrano*

INTRODUCTION/PERSPECTIVE

The face is the most visibly apparent feature of the body, and even a subtle alteration or asymmetry may be appreciable to the untrained eye. Due to the thin skin overlying the nasal dorsum, it has been said that a displacement of even as little as a few millimeters may be perceptible (1). Furthermore, beyond the aesthetics of the nose, it is equally important to consider the functional impact that trauma may bring to bear on the nasal airway.

Not surprisingly given the prominence of the nose as a facial feature, the nasal bones are the most commonly fractured of all facial bones and the third most common fracture of the adult human skeleton (2–14). It has been estimated that there are approximately 50,000 nasal fractures per year in the United States though the actual number is likely higher due to underreporting, patients not seeking medical attention, and fractures that are overlooked in the multitrauma setting (7,9). Nasal fractures occur two to three times more frequently in males and are most commonly seen between 14 and 50 years of age (7) with a peak incidence between the second and third decades of life (6).



Of all facial fractures, about 40% involve the nose (3,9,15). When one considers all patients with facial skeletal fractures, about 20% will have multiple facial bone injuries and so even in those cases where only an isolated nasal fracture is suspected, it becomes critical to complete a thorough examination (16). Kim and Yoon (17) have reported that 47% of all nasal bone fractures are associated with fractures of the nasal septum, and in a different study where the septum was explored in all patients undergoing fracture reduction, Rhee et al. (11) reported that septal fractures were actually identified in over 90% of nasal fractures (8).

Individuals with a prior history of nasal fractures have a 15% to 20% chance of sustaining another nasal trauma in the future, as the "lifestyle" of some patients may increase their predisposition to repeated nasal trauma (7). In those who have had a prior rhinoplasty, the nasal bones may fracture more easily and the incidence of nasal bone fractures may also be higher than in the general population (18).

There are multiple considerations, treatments, and differing opinions when it comes to the treatment of nasal fractures but surgeons generally agree that an optimal outcome should address both cosmetic and functional issues. Recommended treatments for nasal fractures range from no intervention at all (if undisplaced and asymptomatic) to extensive surgery using rhinoplasty techniques through open approaches (19,20). One of the most challenging aspects of managing nasal fractures remains the high incidence of a posttraumatic nasal deformity, either externally or in terms of the nasal airway. At a minimum, the goal of nasal fracture management should be to reestablish the preexisting nasal airway and cosmesis. Beyond that, if there was already preexisting pathology, one is very unlikely to attain an optimal nasal airway and cosmetic result with closed reduction techniques alone. The difficulty in the management of nasal fractures is that even when they are recognized, the mechanism of injury and pathophysiology are often poorly understood leading to inappropriate treatment and suboptimal outcomes.

STRUCTURAL ANATOMY

The external nose is pyramidal in shape and mainly composed of the thin nasal bones, the thick frontal (ascending) process of the maxilla, the nasal process of the frontal bone, and the upper and lower lateral cartilages. The paired nasal bones articulate with each other at the midline, with the frontal bone superiorly and ascending process of the maxilla superiorly laterally (Fig. 83.1). The nasal bones tend to be thinner and broader at their caudal end and are therefore more vulnerable to fractures inferiorly than superiorly (21).

Figure 83.1 Structural anatomy of the nose.

The cartilages that contribute to nasal structure are the upper lateral, lower lateral or alar, sesamoids, and the quadrangular septal cartilage. The triangular or trapezoidal-shaped upper lateral cartilages, by virtue of their attachments to the undersurface of the nasal bones superiorly and the dorsal septum medially help provide significant support to the midline location of the septum and the stability of the middle nasal vault (5,22). The lower third of the nose is made up of a complex architecture and relationships between the cartilages, nasal septum, and soft tissue. The lower lateral cartilages are one of the major nasal tip support mechanisms and the strength, resiliency, and orientation of these structures will affect both tip projection, tip symmetry/alignment, and stability of the lower third of the nasal sidewall and the external nasal valve (23).

The nasal septum is made up of the quadrangular cartilage anteroinferiorly, the perpendicular plate of the ethmoid bone superiorly, and the vomer posteroinferiorly. The quadrangular cartilage articulates along its dorsal edge with the upper lateral cartilages and inferiorly along the floor of the nose with the maxillary crest. The septal cartilage acts as a central strut or "tent pole," supporting the middle and lower thirds of the nasal dorsum (20,21). The perpendicular plate of the ethmoid and the vomer articulate with the posterior end of the septal cartilage caudally and the nasal bones anteriorly, but provide less support to the upper third of the nasal dorsum than the quadrangular cartilage does to the lower two-thirds of the nose (20,21).

The nose has a very rich blood supply. The blood supply of the external nose is provided through branches of the internal and external carotid systems—the facial artery anteriorly (which becomes the angular artery superomedially) and the infraorbital and ophthalmic arteries dorsally. Internally, the blood supply to the lateral nasal wall comes from the sphenopalatine artery posteroinferiorly, and the anterior and posterior ethmoidal arteries superiorly (24).

The skin and soft tissue of the nose varies in thickness, being loose and thinner in the dorsum and upper third, and thicker and more adherent at the tip (22). Sensory innervation of the nose is provided by branches of the ophthalmic (V1) and maxillary (V2) divisions of the trigeminal nerve.

PATHOPHYSIOLOGY—MECHANISM OF INJURY

Less force is required to fracture the nasal bones than any other fracture of the facial skeleton (14,25,26). Blunt nasal trauma is a more commonly seen mechanism of injury than penetrating nasal trauma, and lateral forces occur more frequently than frontal or inferior forces. Inherent variations in anatomy as well as the amount and direction of applied forces will influence the fracture pattern and resulting deformity (14,25,26).

With respect to individual anatomic variation, comminuted fractures are more likely to occur in elderly patients because their nasal bones tend to be thinner. In children, dislocations are more common than fractures owing to the fact that the nose has a higher proportion of cartilage to bone in the pediatric population.

In general, the greater the force of impact the more significant the expected nasal deformity. Furthermore, because the caudal end of the nasal bones is thinnest, a fracture of the thicker more cephalic aspect of the nasal bones requires greater force and is therefore more likely to be associated with other facial fractures.

While variability is inevitable with respect to both susceptibility to nasal fractures and nasal fracture patterns, cadaveric studies have enabled some general observations to be made (25,27,28). Although fractures are more commonly caused by a lateral force, a blow from any vector can fracture the nose. A greater force is required to fracture the nose from a frontal impact than lateral impact, because the nasal bones are to some extent buttressed to a frontal blow by the perpendicular plate of the ethmoid bone, the elasticity of the septal cartilage, the anterior nasal spine, and the frontal process of the maxilla.

A less forceful lateral impact may result in undisplaced sidewall fractures, without symptomatic nasal obstruction and should not require any manipulation or treatment. With increasing lateral force an ipsilateral displaced nasal bone infracture first occurs, without affecting either the septum or contralateral nasal bone (Fig. 83.2). This will be apparent externally and can affect the nasal airway as well and as such reduction is recommended. The ipsilateral depression may create the illusion of curvature to the nose (Fig. 83.3), but typically the contralateral bone is not particularly tender, thereby suggesting the diagnosis of a unilateral fracture. As force increases, a lateral impact will break both nasal bones (often an ipsilateral infracture and contralateral outfracture) (Fig. 83.4) as well as the bony and/or cartilaginous septum secondarily with lateral displacement of the entire nasal pyramid and obstruction of the nasal airway (Fig. 83.5).

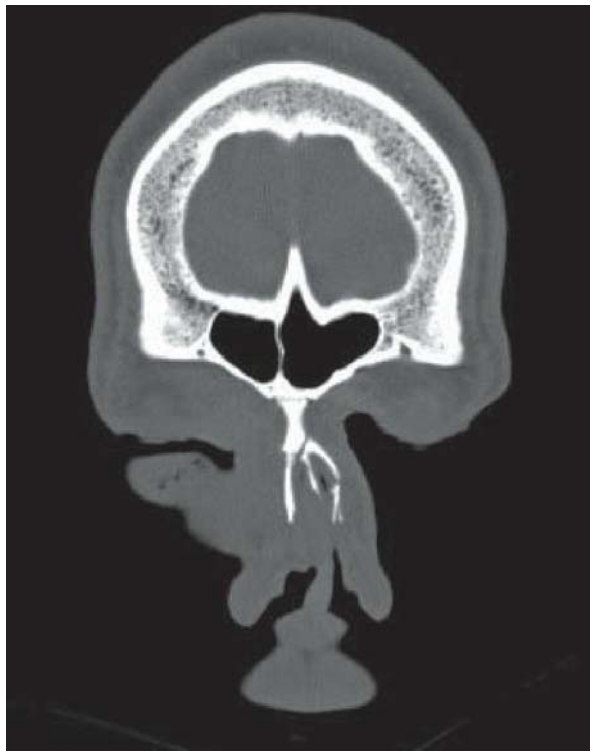

Figure 83.4 Coronal CT scan showing bilateral displaced nasal bone fractures with concomitant nasal septal fracture.

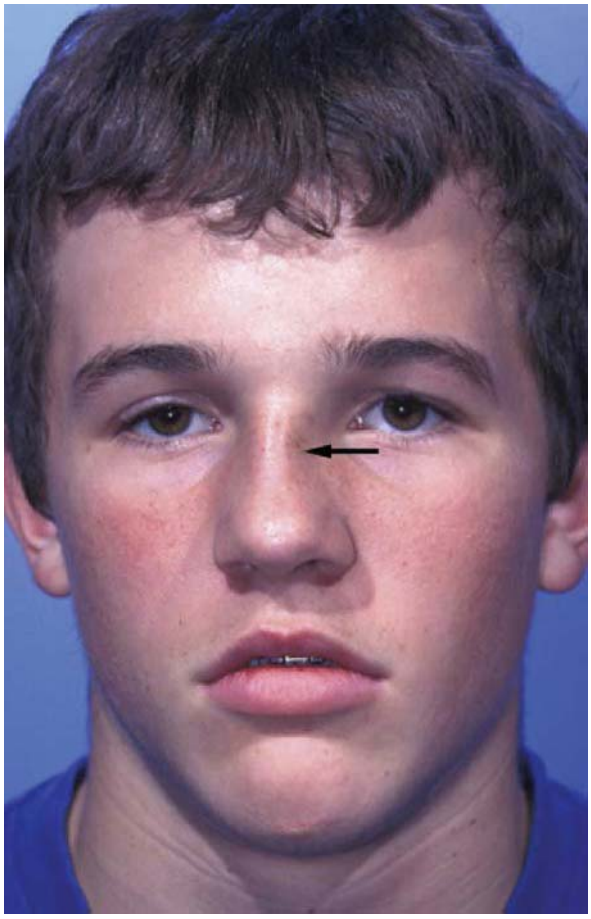

Figure 83.3 Unilateral impacted left nasal bone fracture (*arrow*) generating the illusion of an apparent curvature of the nose to the patient's right.

Similar to the situation with lateral forces, a lesser amount of frontal force may fracture the thinner distal end of the nasal bones without visible displacement or external deviation. If there is sufficient force for displacement of the nasal bones, the upper lateral cartilages, which are attached to the undersurface of the nasal bones may get impacted with the nasal bones or avulsed from the nasal bones with both an external deformity and a reduction in nasal airflow. As the force from a frontal impact increases, the septum may buckle, dislocate, or fracture and the bony nasal cap can be impacted (Fig. 83.6), comminuted, and splayed with widening of the nasal bridge and lateral displacement of the nasal bones. Fracture or dislocation of the septum will inevitably lead to nasal airway obstruction.

A very forceful frontal or central impact to the osseous and cartilaginous nasal structures can be transmitted posteriorly to the nasoorbitoethmoid (NOE) complex leading to nasoethmoidal fractures (8). A NOE fracture is a complex fracture that can involve the nasal, ethmoid, frontal, lacrimal, maxillary, and orbital bones as well as the cribriform plate. A complete review of NOE fractures is beyond the scope of this chapter, but they should be recognized as the treatment is far more complicated and the sequelae, if untreated, much more disabling. These patients will present with additional signs and symptoms that can include marked periorbital edema and ecchymosis, telecanthus, enophthalmos, epiphora, telescoping of the nasal dorsum with a flattened nasofrontal root and midfacial retrusion, and possibly a cerebrospinal

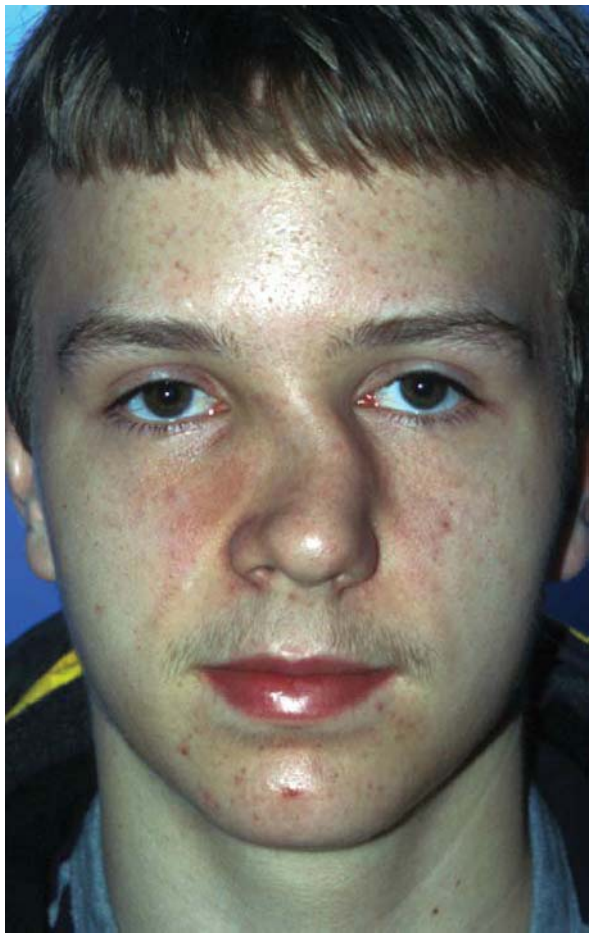

Figure 83.5 Patient with acute, bilateral displaced nasal bone fractures.

fluid (CSF) leak. Further discussion and management is reviewed elsewhere in this text.

Injury to the nose from an inferior vector is more likely to traumatize the cartilaginous septum with or without a fracture of the nasal bones themselves. Sufficient impact from below can dislocate the caudal septum off of the anterior nasal spine or maxillary crest with displacement to one side or the other. This can result in asymmetry of the nostrils and nasal base, inferior septal spurs, and even twisting of the nasal tip because of the proximity of the caudal septum to the lower lateral cartilages. Fractures of the septal cartilage can also occur with telescoping of segments leading to columellar retraction and/or nasal obstruction.

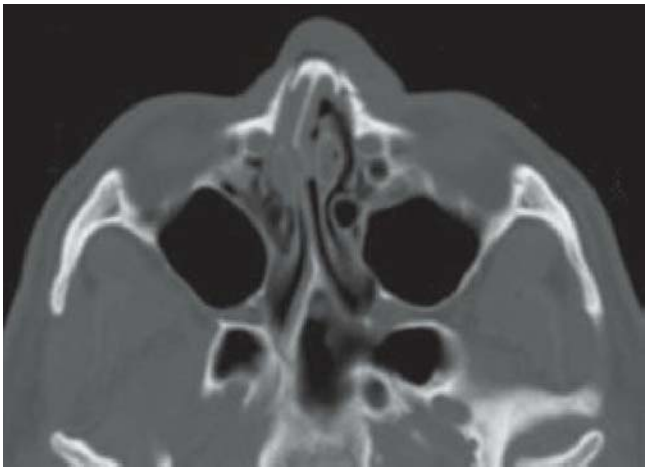

Figure 83.6 Axial CT scan showing impacted fracture of bony nasal cap.

The severity of airway obstruction accompanying nasal fractures depends on the location of the septal fracture and the presence of septal displacement with the latter being the most important variable in nasal obstruction (10). The nasal septum functions somewhat as an energy-absorbing structure (8), with the ability to dissipate a certain amount of force and rebound without significant deformity. Beyond that point, the septum will either dislocate or fracture.

Dislocations, as opposed to fractures, are more commonly seen where the cartilage tends to be thicker and stronger—namely right at the bony–cartilaginous interfaces (28), either posterosuperiorly at the perpendicular plate of the ethmoid bone or inferiorly at the maxillary crest. On physical examination, this would correspond, respectively, to either angulation of the quadrangular cartilage at the junction with the perpendicular plate of the ethmoid or the appearance of a long septal spur inferiorly.

Fractures of the septum on the other hand tend to occur in the thinner central portion of the quadrangular cartilage above the bony cartilaginous interface or through the bony septum (ethmoid and/or vomer) (28). In separate cadaveric studies, Murray et al. (25) and Harrison (28) noted remarkably similar septal fracture patterns with application of sufficient impact force. The fracture line in the cartilaginous septum was typically several millimeters above the maxillary crest, extending posteriorly into the bony septum and curving upward through the vomer into the vertical plate of the ethmoid to yield a C-shaped fracture pattern (Fig. 83.7). Fracture fragments can then either overlap, telescope, or pivot to obstruct the nasal airway. Rohrich and Adams (29) likewise noted that low-velocity injuries tended to occur inferiorly as either dislocations or fractures, while high-velocity injuries or frontal impacts resulted in more extensive fractures in the thin central portion of the septal cartilage extending posteriorly into the ethmoid or vomer.

Another observation of Murray et al. (25) in their cadaveric study of fracture patterns was that if the nasal bones were displaced by more than half the width of the nasal bridge there was inevitably a concomitant C-shaped fracture of the bony and cartilaginous septum as described. Under such circumstances, they concluded that open treatment of the septum with resection of the interlocked or overlapped segments incorporating the fracture inferiorly and posteriorly was required in order to achieve optimal alignment of nasal injuries of this severity. The implication of septal fractures as they relate to success or failure in the management of nasal fractures is discussed at greater length later in this chapter.

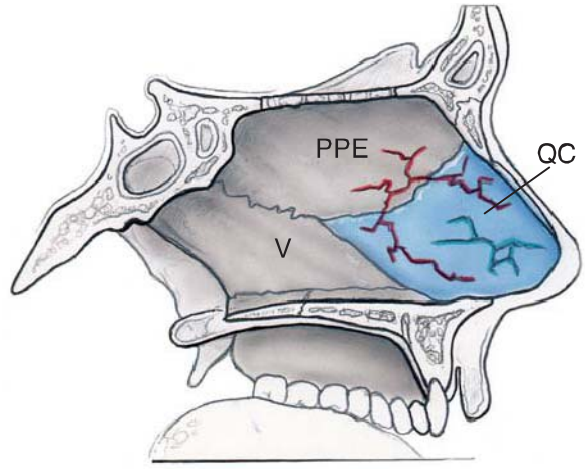

Figure 83.7 Typical nasal septal fracture pattern seen in cadaveric studies. (V = vomer, PPE = perpendicular plate of ethmoid bone, QC = quadrangular cartilage)

DIAGNOSTIC ASSESSMENT

The diagnosis of a nasal fracture is generally made based on the history and clinical exam. Patients who present with nasal trauma may well have additional injuries and should be routinely examined in a comprehensive and orderly fashion as with any other trauma patient to minimize the likelihood of overlooking concomitant injuries.

History

A thorough history is the cornerstone of the diagnosis and will frequently guide the management of nasal fractures as well. It is helpful to know when the incident occurred, the mechanism of the trauma, the direction of the force, patient symptomatology (in particular, whether or not there has been any alteration in alignment or change in the nasal airway), whether or not there is a prior history of nasal trauma or nasal surgery, the patient's medical history and comorbidities, age, and patient expectations. Epistaxis is considered to be a sine qua non for nasal fractures (30) and suggests a disruption of or tear in the nasal mucosa.

Understanding the mechanism of injury is helpful for the workup and management of the patient with nasal trauma, but is not as critical as the physical exam for planning the reduction or surgical technique. As discussed earlier, the velocity and force of impact will influence the pattern and extent of the underlying injury. In general, a greater impact should heighten one's suspicion for additional injuries, for a more complex nasal fracture pattern, and for an associated septal fracture or dislocation.

The timing of the injury is another important variable to know in the scenario of a nasal fracture. Management decisions regarding nasal and septal fractures depend on reliable visual and tactile information that the surgeon interprets when first examining and later manipulating or reducing the nasal complex. Excessive soft tissue edema can mask minor or modest irregularities and preclude an accurate understanding of the fracture pattern and degree of displacement. The classical two windows of opportunity for nasal fracture management described in the literature are therefore based on the rationale of manipulating the nasal complex in the absence of significant edema. Nasal edema is generally limited within the first 2 to 3 hours after the trauma, and has settled to a certain degree 5 to 10 days after the injury. On the other hand, after 2 to 3 weeks of healing a fibrous union is developing across the fracture line making the reduction more challenging and often mandating the use of osteotomies that might have otherwise been unnecessary to enable repositioning of the nasal framework.

As with any surgical patient, the past medical history is relevant. A prior history of nasal and septal trauma or nasal surgery is an important consideration, as it may influence the surgical approach as well as what outcome is potentially achievable. One should also review comorbidities and medications that may contraindicate surgery or influence choice of anesthesia.

It is essential, as much as is possible, to determine the pretraumatic appearance of the nose with respect to alignment and likewise to inquire whether any nasal airway obstruction existed previously. An acute nasal fracture in the setting of an old fracture with secondary deformity is a challenging predicament, as simple closed reduction then becomes unlikely to completely achieve a perfect cosmetic or functional outcome. Patients may not always accurately describe and differentiate between newer and older deformities; therefore, a review of photographs dating from before the injury can be very helpful. On the other hand, most patients are more reliable when it comes to telling the surgeon about the presence or absence of some degree of premorbid nasal airway obstruction. Ultimately, it is perceived changes in alignment and the nasal airway that are the two most important indications for which surgical intervention is warranted.

Questions about rhinorrhea, and new snoring or sleep apnea are also relevant. Persistent clear rhinorrhea after nasal trauma should raise the suspicion of a skull base or frontal sinus fracture and a CSF leak. In these cases, a beta-2 transferrin test is helpful in assisting in diagnosis and more detailed imaging (computed tomography [CT] scan) is warranted. New snoring or apnea may be consistent with new-onset nasal airway obstruction and elevated airflow resistance.

Patient expectations are also very relevant to management decisions. Expectations may vary by age, gender, personality, religion, profession, and education among other variables. In general, there are three types of patients with displaced nasal fractures that are encountered in clinical practice. There are those that are not concerned about minimal or modest change in their nasal appearance or nasal function, those that just want their pretraumatic appearance and/or function restored, and those that see the situation as an opportunity to improve their pretraumatic cosmetic appearance

and/or nasal function. Not uncommonly, older individuals and males tend to be less concerned about changes in nasal appearance or minimal degrees of nasal obstruction.

Those not interested in a reduction when indicated should be advised of the potential for persistent deformity or nasal obstruction, and the possibility of more involved surgery if undertaken once all is healed. As regards cosmetic adjustments (over and above alignment) on the other hand, caution should be exercised before agreeing to undertake any effort to simultaneously implement aesthetic rhinoplasty as swelling and structural instability are likely to thwart such efforts resulting in suboptimal outcomes or a higher risk of needing revision surgery. The fundamental objective of managing nasoseptal fractures is that at a minimum, the surgeon should strive to reduce the fractures to the pretraumatic baseline. In some cases, however, the surgeon may elect to improve the nasal airway at the same time in the patient who had preexisting nasal airway pathology even if not altered by the most recent trauma.

The patient's age is another important determinant in the management of nasal and septal fractures. Nasal fractures in children are discussed later in the chapter. Fractures in elderly people are managed similarly to the rest of adult population. However, owing to different expectations and comorbidities, this patient population will often opt for a less aggressive approach.

Physical Exam

The goal of the physical examination should be to establish a diagnosis, determine whether or not associated injuries may exist, and determine what if any intervention is required. A complete external and endonasal evaluation should be performed. Visual inspection and palpation are equally important.

Physical findings consistent with the diagnosis of a nasal fracture include edema, infraorbital/paranasal ecchymosis, tenderness to touch, bony crepitus, and possibly a palpable step-deformity if new. Any shift or displacement of the nasal pyramid should be noted as well as depressions, ridges, and whether the fracture is unilateral or bilateral. Widening of the midface, telecanthus, restricted extraocular movements, or dental malocclusion are not seen with isolated nasal fractures and should alert one to investigate for additional maxillofacial injuries.

Endonasal examination is performed with a nasal speculum and a headlight (anterior rhinoscopy) and, if available the use of a rigid nasal endoscope enables a more complete evaluation. The endonasal exam is facilitated by the use of a topical decongestant and local anesthetic. Unfavorable functional and aesthetic outcomes are most commonly related to unrecognized septal fractures with significant displacement and accordingly an adequate and complete exam of the nasal septum is critical (5,19,20,29).

Endonasal examination should include an assessment of the septal position and nasal airway, in addition to inspecting for a septal hematoma, abscess, mucosal tears, septal fractures, or dislocation off the maxillary crest. Mucosal tears have been found to be highly suggestive of septal fractures (11). As noted earlier, dislocations or displaced and angulated fractures can be seen anywhere along the septum but occur most commonly at or close to bony–cartilaginous interfaces.

A septal hematoma is characterized by a reddish purple or bluish bulge or fullness along the nasal septum. Septal hematomas can be unilateral or bilateral and typically involve the cartilaginous portions of the septum. If suspected, on palpation of the suspicious swollen area with an instrument or a cotton swab it will feel puffy and compressible. Needle aspiration is frequently diagnostic. If untreated, a septal hematoma can lead to infection, abscess, and secondary septal cartilage necrosis with loss of dorsal support and a supratip saddle deformity (Fig. 83.8). In addition, fibrosis between the perichondrium and septal cartilage can also lead to septal deformities, a thickened septum, and retraction of the columella (31). Small hematomas may be aspirated and observed, but larger hematomas may require incision and drainage, followed by nasal packing to prevent reaccumulation. Systemic antibiotics are recommended while packing is in place.

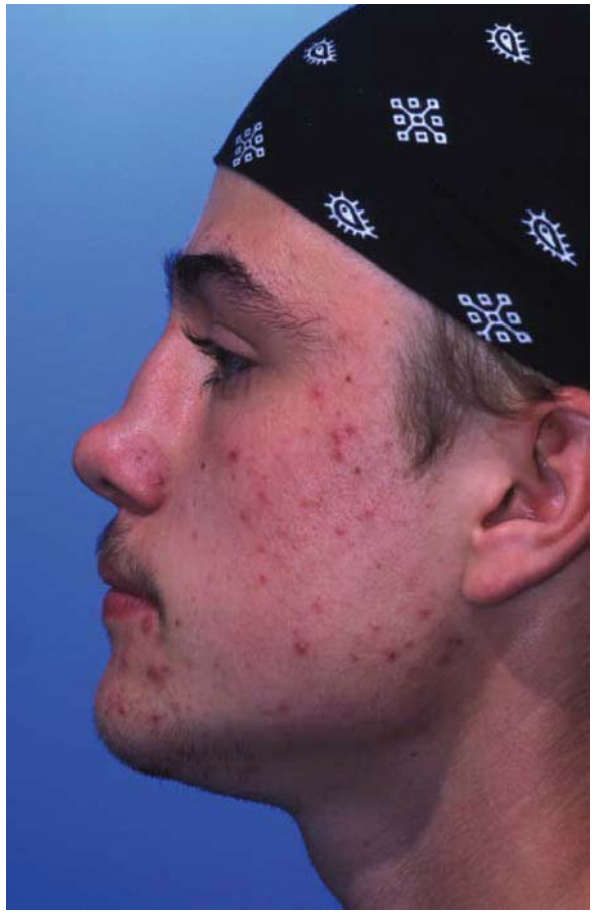

Figure 83.8 Supratip saddle deformity, which developed despite drainage of a septal abscess.

Imaging

Imaging is not routinely required for the diagnosis or clinical management of isolated nasal trauma (32,33). Both false positives and false negatives are commonly seen with plain radiographs and numerous reports have documented their lack of utility in decision making as it pertains to the management of nasal fractures (7,33,34). Old fracture lines, vascular markings, suture lines, and overlapping bone shadows can all be mistaken for fractures on plain x-rays. Furthermore, as most nasal bone fractures heal by a fibrous union, an older fracture line may remain visible and therefore prior or preexisting fractures cannot be reliably distinguished from new ones with imaging. Facial photographs are likely to be of greater benefit both clinically, and if necessary, medicolegally.

If, however, more extensive injury to the facial skeleton is suspected, then a CT scan of the facial bones is warranted. Not infrequently, patients will present to the surgeon with a CT scan ordered for the workup of other injuries, and while this might be helpful to classify or evaluate the characteristics of the fractures, the images are not ultimately necessary for directing the management of isolated nasal injuries.

There are some advocates of ultrasonography as an emerging technology for the assessment and management of nasal fractures. Different authors have suggested that high-resolution ultrasound might be more accurate than a CT scan (35) or plain x-ray (34), and that it may be useful in the evaluation of intraoperative repositioning of the fractures (36). High-resolution ultrasonography has also been reported to be helpful in establishing a diagnosis of nasal fractures in children (37), but ultrasonography is operator dependent and additional studies are required to validate its efficacy.

Ultimately, whereas imaging may confirm a diagnosis or facilitate classification, management decisions for isolated nasal fractures are based primarily on a clinical evaluation. The decision as to whether or not a nasal fracture requires some kind of manipulation or surgical intervention should be based on emergency findings (abscess, hematoma), an alteration of form (alignment), or symptomatic nasal airway obstruction.

MANAGEMENT

Descriptions pertaining to the management of nasal fractures go back over 5,000 years. In the Surgical Papyrus, Edwin Smith outlined treatment methods in ancient Egypt whereby a linen wrap saturated with honey and grease was introduced into each nasal cavity in order to then manipulate the nasal bones for fracture reduction (38). In the fifth century BC, Hippocrates advocated early intervention to reposition the nasal bones, but even at that time, he noted that he was not able to realign the nasal bones appropriately if the septum was deviated (39). Twenty-five hundred years later, debate still exists over the optimal management of the fractured nose and what operation to apply in which circumstances.

Ideally, nasal fractures should be addressed within the first 5 to 10 days of the injury. Beyond about 14 days, the fracture may be less easily mobilized and reduced, and the need for completion osteotomies becomes more likely. Associated lacerations or soft tissue injuries should be repaired within the first 24 hours and routine wound care recommended. Application of ice packs or cold compresses over the first several days is helpful to reduce soft tissue edema and facilitate better evaluation and intraoperative judgment.

If intervention is required, decisions then focus on location (emergency room [ER] vs. office setting vs. operating room [OR]) and anesthesia (local vs. intravenous sedation vs. general anesthetic). Consider that maximal patient comfort will enable the surgeon to apply as much force as is necessary to disimpact and reduce fractures as well as to provide the unhindered ability to progress to more complex intervention (septoplasty, osteotomies etc.) if needed. Treatment in the OR provides the most favorable conditions (patient comfort, instrumentation, lighting, anesthesia options) and as such affords some advantage to the surgeon and possibly therefore patient outcomes as well.

Nasal fracture reduction may be performed under local anesthesia (infiltrative and/or topical), intravenous sedation, or general anesthesia. Both patient factors and intrinsic nasal fracture factors will influence the choice of anesthesia. Patient factors include the age, expectations, tolerance, and comorbidities of the individual. Intrinsic nasal fracture factors include the type and characteristics of the nasal fracture and the status of the septum. Proponents of local anesthesia for closed reduction of nasal fractures, particularly from the United Kingdom and Europe (20,40–48), report that it is faster, uses less hospital resources, is safer in elderly patients, produces minimal discomfort, and has no effect on the result of the reduction (40–49).

The evidence suggests, however, that the debate between local versus intravenous sedation versus general anesthesia is somewhat aimless. It is not that one anesthesia technique is better than the other. In the hands of an experienced surgeon, both techniques are effective if the patient is appropriately selected. In other words, a simple unilateral fracture may be a reasonable candidate for reduction under local anesthesia, whereas a comminuted bilateral displaced fracture with associated displaced septal fractures is likely better managed under general anesthesia. Ultimately, the choice of anesthesia is a matter of surgeon preference but undeniably a general anesthetic (this author's preference) offers safety, a controlled and protected airway, maximum patient comfort, and the uncompromised ability to examine, manipulate, and extend treatment if necessary.

The goal of treating nasal fractures has always been the same—optimize cosmetic and functional outcomes, and minimize revision rates. The traditional technique for

managing acute nasal fractures has been a closed reduction of the fractured nasal bones, and it remains the most widely used today. As far as outcomes are concerned, however, Staffel (50) reviewed 13 reported series of nasal fractures treated with closed reduction alone and found that while patient satisfaction rates in those publications ranged anywhere from 62% to 91%, surgeon satisfaction ranged from only 21% to 65%.

Accordingly, surgeons have sought to improve upon outcomes. Treatment methods have expanded to now include closed reduction, closed reduction with concomitant septoplasty, open reduction, open reduction with concomitant septoplasty, and even early, primary functional septorhinoplasty in select cases. "Closed" reduction implies manipulation of the nasal pyramid with the use of broad instruments and blunt (nonincisional) endonasal techniques. "Open" reduction on the other hand generally implies maneuvers requiring added access through intranasal incisions such as completion osteotomies or bone rasping, for example, but is generally less involved than a formal septorhinoplasty.

If the surgical procedure is well matched to the individual fracture, there is reason to believe that all approaches can have equally good outcomes (19). The challenge then becomes identifying *which* nasal fractures are well managed with a closed reduction and which would merit a more extensive procedure so as to maximize success rates. Clearly, not all patients will do well with a closed reduction alone, and conversely not all patients need an open reduction or primary septoplasty either.

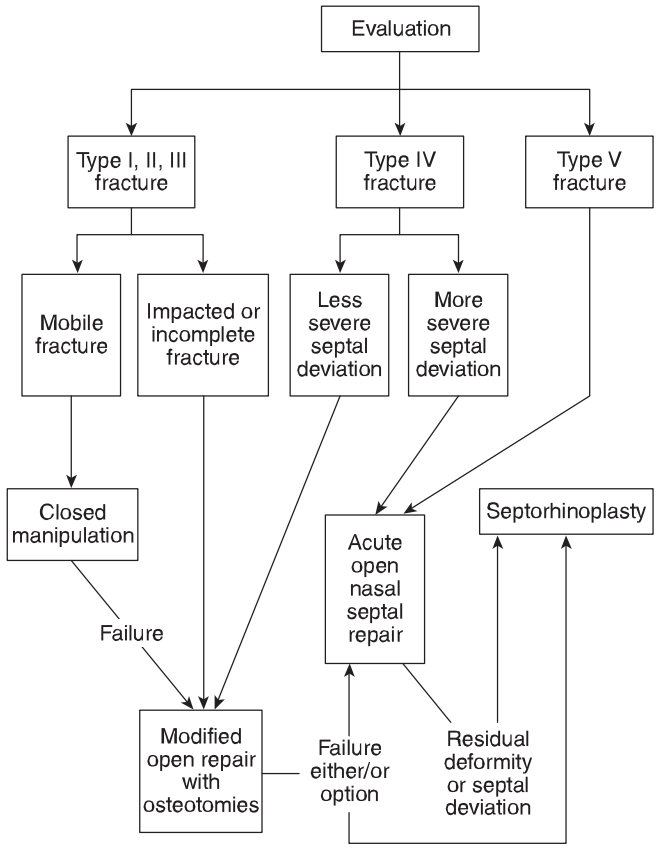
The advantage of a closed reduction lies in the presumed simplicity, shorter operative times, and limited morbidity of the procedure, while the disadvantage may be a suboptimal outcome in more complicated fractures for which an open procedure or septoplasty might have been warranted. On the other hand, an open procedure—surely of outcome benefit to some—involves longer operative times, a greater burden of healing, and arguably the potential for surgical cartilage depletion could make for more challenging revision procedures should they be necessary.

Interpreting published reports within the literature can be difficult. There are many variations from one study to the next in terms of timing of treatment, location of treatment (ER vs. office setting vs. OR), type of anesthetic administered (local vs. sedation vs. general anesthesia), detailed description of technique or lack thereof, inconsistent reporting of assorted variables, unreliable patient follow-up, ill-defined "revisions" (airway vs. alignment vs. both; minor vs. major), and lack of clear fracture classification or treatment stratification among other things.

What has become apparent through various cadaveric and clinical studies is that the greater the force or impact, the greater the disruption and displacement of the nasal bones and that in turn increases the likelihood of associated septal fractures and dislocations. As noted earlier, both Murray et al. (25) and Harrison (28) demonstrated somewhat predictable septal fracture patterns in cadaveric models with application of increasing impact. Murray et al. also noted that if the fractured nasal bones were displaced by more than half the width of the nasal bridge then a fracture of the septum was inevitable and in fact many surgeons have used this as an indication for primary concomitant septal surgery.

Rhee et al. (11), in a prospective study, actually explored the septum through a hemitransfixion incision in all 52 patients with isolated nasal fractures undergoing a closed reduction in their study. They found that only two patients had no septal fracture whatsoever, almost 80% had an identifiable septal fracture with at least mild displacement or more, and 60% were classified as severely displaced or worse (multiple fractures, crushed, comminuted). The presence of a mucosal tear was found to be a statistically significant sign on physical examination for septal fracture. They also found that while a CT scan proved to be helpful in diagnosing septal fractures, it correlated poorly with the severity of the fracture. Their findings would suggest that even with relatively unremarkable nasal fractures, septal fractures are a frequent occurrence. This does not imply that all septal fractures are irreducible or that all fractures require a septoplasty, but rather that the frequency of septal fractures may be underappreciated.

The general consensus within the literature is that unrecognized overlapped, telescoped, or interlocked septal fracture fragments will lead to higher rates of post reduction nasal deformities if unaddressed or if treated with closed reduction alone (9,14,19,29,50). It has been said that "the dorsum follows the septum," meaning that the nasal bones will tend to migrate and heal in the direction of the septal deviation and so if significant septal fractures are not addressed, optimal alignment of the nasal bones is unlikely. With respect to management decisions regarding nasal fractures, it is felt therefore that the single most important determinant would be an accurate evaluation of the septum. Furthermore, a graduated approach beginning with closed reduction and progressing to septoplasty/open reduction if unsuccessful is a reasonable strategy if the patient doesn't have clear indications for one approach or the other.



An "ideal" fracture classification scheme would guide appropriate treatment. A variety of classification systems have been proposed in the literature—based on factors such as impact direction, injury plane, or anatomy (i.e., simple vs. comminuted; closed vs. compound), for example. Unfortunately, these tend to be of academic interest but provide little in the way of clear treatment guidance.

Rohrich and Adams (29) proposed a classification scheme and management algorithm, which enabled them to achieve a revision rate of only 9%. In the case of apparent septal fractures, they recommend either reduction of septal dislocations (using an Asch forceps or Boies elevator) or if the former is unsuccessful, proceeding with acute septal reconstruction for which they generally advocate a limited inferior and posterior resection.

Classification of Nasal and Septal Fractures

Type	Description	Characteristics
I	Simple straight	Unilateral or bilateral displaced fracture without resulting midline deviation.
II	Simple deviated	Unilateral or bilateral displaced fracture with resulting midline deviation.
III	Comminution of nasal bones	Bilateral nasal bone comminution and crooked septum with preservation of midline septal support; septum does not interfere with bony reduction.
IV	Severely deviated nasal and septal fractures	Unilateral or bilateral nasal fractures with severe deviation or disruption of nasal midline, secondary to either severe septal fracture or septal dislocation. May be associated with comminution of the nasal bones and septum, which interfere with reduction of fractures.
V	Complex nasal and septal fractures	Severe injuries including lacerations and soft tissue trauma, acute saddling of nose, open compound injuries, and avulsion of tissue.

Figure 83.9 Nasal fracture classification scheme (**A**) and treatment algorithm (**B**) based on the fracture classification. Reprinted from Ondik, MP et al. The treatment of nasal fractures: a changing paradigm. *Arch Facial Plast Surg* 2009;11(5):296—302, with permission. Copyright © 2009 American Medical Association.

Ondik et al. (19) used a modification of the classification system proposed by Rohrich and then developed a treatment algorithm based on their fracture classification. Their classification and algorithm are seen in Figure 83.9A and B. In their publication, if the septum did not interfere with the bony reduction, then a closed reduction alone was used. On the other hand, if the septum was sufficiently dislocated or fractured so as to compromise midline support with severe deviation or disruption of the nasal midline, then an acute septal repair was performed together with completion osteotomies (if indicated). By classifying patients and stratifying treatment accordingly, they reported an overall revision rate of 6% (2% for closed reduction patients and 9% for those requiring open treatment, which is indicative of a more substantial fracture). They concluded that if the choice of procedure is based upon the type of fracture, both closed reduction and open procedures can have high measures of success.

Staffel (50) also developed and proposed a graduated protocol for the treatment of nasal fractures, which begins with closed reduction and progresses as needed to include a septoplasty (for persistent drift and/or preoperative nasal airway obstruction), completion osteotomies (for persistent drift or memory), release of the upper lateral cartilages (if the nose was crooked before the fracture or remains so despite completion osteotomies), fracturing of the perpendicular plate of the ethmoid bone and lastly, camouflaging onlay grafts for any residual defects. The challenge with this approach might be making some of the finer decisions regarding drift or residual defects when confronted with post-traumatic and intraoperative edema.

Over an 8-year period, Defatta et al. (14) studied only those patients undergoing closed reduction for a nasal bone fracture in whom there was a persistent significant (not defined) septal deformity identified intraoperatively after closed reduction. Under such circumstances, those undergoing concomitant primary septoplasty had lower rates of residual septal deformity at follow-up (12.5%) than those who did not (60% residual deformity). The number of patients over that same time period who underwent closed reduction alone, in whom there was not a persistent septal deformity identified intraoperatively, and their success/failure rates with those patients was not mentioned however so a broader sense of perspective (i.e., what percentage of patients are likely to fall into their treatment group) is not possible.

The treatment dilemma or the difficulty of choosing the correct operation for a given patient is well expressed by Fernandes (15) who commented that "although it is

possible to predict the closed reductions that will definitely fail, I am unable to predict those closed reductions that will definitely succeed despite the patient having a straight nose on the operating table."

Reasonable general recommendations therefore begin with a full evaluation of the injury with particular attention paid to the possibility of septal fractures warranting open treatment. A septal injury more likely to warrant primary repair should be suspected with overlying mucosal tears on physical examination, a collapsed or buckled septum (often associated with acute loss of dorsal height—Fig. 83.10), severe septal angulation posteriorly or inferiorly with symptomatic new-onset nasal airway obstruction, displacement of the external nasal framework by an amount greater than half the width of the nasal bridge, and nasal bones that prove to be irreducible with closed reduction or continue to drift. Primary septal repair, when indicated, should be as conservative as is possible, with particular attention focused toward inferior displacement over the maxillary crest and posterosuperior fractures and angulation or telescoping at the junction of the quadrangular cartilage with the perpendicular plate of the ethmoid bone. Completion osteotomies are indicated for nasal bones, which are displaced and impacted, thereby limiting closed reduction or in situations where early treatment has been delayed (beyond about 2 weeks) and the nasal bones are somewhat immobile.

To summarize, because the untreated post-traumatic nasal deformity—the crooked nose—can be one of the most difficult of all septorhinoplasty procedures, effort should be directed toward minimizing the need for revision procedures when treating an acute, displaced nasal bone fracture in need of reduction. There is a place for both closed and open procedures and properly applied, both can be successful. At the very least, the treating physician should consider the need for extending treatment beyond a closed reduction alone, obtain proper consent to proceed as necessary, and apply a graduated approach as dictated by the circumstances. In all cases, patients should be made aware preoperatively of the possible need for a secondary surgery in the future.

Figure 83.10 Acutely buckled septal fracture leading to septal collapse, nasal airway obstruction, and supratip depression seen before open reduction with acute septal repair.

NASAL FRACTURES IN CHILDREN

The facial bones are much less commonly fractured in children than in adults, with children accounting for only 5% to 10% of all facial fractures (51–53). Falls, blunt trauma, and sports-related injuries are among the more frequent causes, and facial fractures are more common among older teens. Nasal septal deviations and nasal deformities can also be seen in newborns in 1.25% to 23% of cases in association with intrauterine trauma, forceps-assisted deliveries, and breech deliveries (54).

The low incidence of facial fractures in children is a by-product of the elasticity of the bones, craniofacial disproportion, and underdevelopment of the facial skeleton in preadolescent children (51,53,55). With respect to nasal fractures in particular, the child's nose is more cartilaginous than bony and thus more resilient than that of an adult. Fractures of the nasal bones are thus less common, while the cartilage, rather than fracture is more likely to buckle, twist, or dislocate. In such cases, septal mucoperichondrium may separate from the underlying cartilage, even in the absence of mucosal tears or nasal bone fractures. This creates a potential space in which rupture of smaller vessels supplying the mucoperichondrium may lead to a septal hematoma, which is thus more commonly seen in pediatric nasal trauma than in adults (56). Should a hematoma evolve into a septal abscess, the likelihood of septal cartilage destruction and long-term sequelae increases dramatically (57). For that reason, any child with a history of acute nasal trauma complaining of nasal obstruction must be carefully examined with that in mind.

Nasal fractures in children are often overlooked or untreated, leading to adult nasal pathology (7,58). The septum serves as one of the growth centers of the face until about 12 to 13 years of age and as a result, nasal trauma at a younger age may significantly affect subsequent growth, form, and function (5,59). This underscores the importance of establishing a diagnosis and administering treatment when warranted, despite the inherent challenges in both.

Physical findings are often less striking, particularly in the very young child, and radiographs are of even less value than in an adult due to the primarily cartilaginous nature of the nasal structures in children. Substantial septal and mucosal trauma can occur even in the absence of grossly apparent external nasal deformity (58).

In the setting of nasal trauma in children, a history of associated epistaxis, nasal obstruction, and/or subtle physical findings such as nasal dorsal edema, dorsal tenderness, periorbital ecchymosis, and bony crepitus should elevate the examiner's index of suspicion as well the more obvious finding of a visible external deformity or grossly abnormal radiographs. A suspicious or inconsistent history, associated

unexplained injuries, or a history of repeated trauma should prompt consideration of possible child abuse. Given the sequelae that can develop as a result of undiagnosed nasal or septal fractures/dislocations in children, a proper and thorough intranasal examination is required for a complete evaluation and to rule out septal pathology. This can be challenging in the noncompliant child, and in some cases a general anesthetic may be necessary to do so.

Pediatric fractures begin to heal and unite much quicker than those of adults so when intervention is necessary. It should be undertaken within the first week if at all possible. The general approach to the surgical treatment of nasal fractures in children is one that emphasizes conservatism.

A septal hematoma or abscess should be drained in all cases. For fractures, a closed reduction is the preferred approach for all pediatric nasal fractures to decrease the possibility of interference with the bone growth centers—only highly displaced fractures should undergo open reduction and/or primary septal surgery (53). If closed reduction is unsuccessful and open reduction is indicated, the objective at that point should be maximal tissue preservation while optimizing nasal airway function and external alignment. Dissection and excision of tissue should be minimized to whatever extent possible.

TECHNIQUE

Closed Reduction

As mentioned earlier, closed reduction implies manipulation of the nasal pyramid with the use of broad instruments and blunt (nonincisional) endonasal techniques.

Once the patient is anesthetized or the field is blocked, the nose is decongested with pledgets soaked with a topical vasoconstrictor (e.g., oxymetazoline) to open the nasal airway, improve visualization, and decrease bleeding with manipulation. Injection of lidocaine and epinephrine can also be used if desired, but is not absolutely necessary.

The typical instrumentation needed for a basic closed reduction is seen in Figure 83.11. Simple, unilateral depressed nasal bone fractures can be easily reduced using a broad, flat elevator such as a Boies elevator. In such cases, measuring the distance from the nostril rim to the medial canthus externally will give the surgeon a sense of how far into the nasal cavity the elevator must be passed to rest beneath the nasal bone in question. With the elevator thus positioned endonasally, the thumb (for a right nasal bone fracture) or the index and long fingers (for a left nasal bone fracture) of the opposite hand is placed over the ipsilateral nasal bone, in order to maximize fine control and provide tactile feedback to the surgeon as the nasal bone is repositioned (Fig. 83.12).

The nasal bone is then elevated along a vector opposite the direction of impact or bone displacement. A palpable if not audible repositioning of the bone should be evident. Typically, unless severely comminuted, the edges of fracture fragments will interdigitate sufficiently to hold the reduced bone in position. The Boies elevator can also

Figure 83.11 Typical instrumentation needed for a closed reduction—(left to right)—Walsham forcep, Boies elevator, Asch forcep, nasal speculum, nasal suction, bayonet forceps.

be used to reduce a septum, which is dislocated inferiorly back onto the maxillary crest or into the vomerine groove. A Walsham forcep is another instrument that can be used for unilateral nasal bone fracture reduction in lieu of the Boies elevator—it too is designed for manipulation of the nasal bone of one side. With the Walsham forcep, one blade rests in the nasal cavity while the other rests externally on the skin overlying the nasal bone for complete control of the nasal bone during reduction.

While the Boies elevator is well suited for reduction of a simple unilateral nasal bone fracture, it is less well applied to bilateral displaced nasal bone fractures. The Asch forcep offers ideal control of the entire nasal pyramid, in contrast to the Boies elevator or Walsham forceps, which limit the manipulation to one side. The Asch forceps is inserted

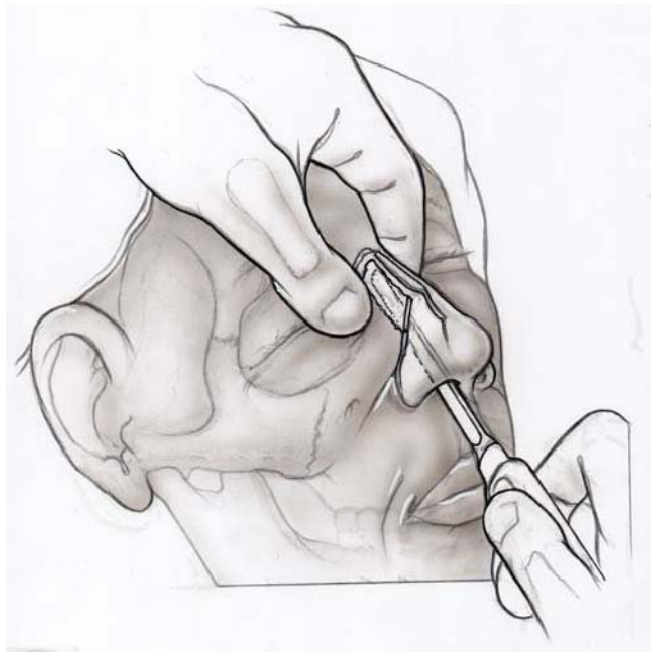

Figure 83.12 Bimanual closed reduction technique using Boies elevator to reduce unilateral depressed nasal fracture.

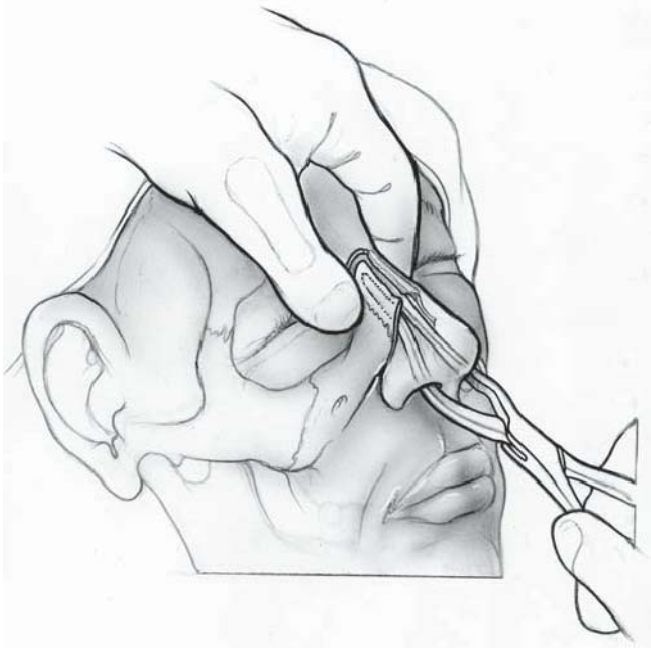

Figure 83.13 The Asch forceps is positioned astride the nasal septum to enable disimpaction and manipulation of the entire nasal pyramid.

straddling the septum, with one blade in each nostril in order to "hug" the nasal septum (Fig. 83.13). Thin pledgets can be left in place on each side, between the tine of the reduction forcep and the septal mucosa to protect the mucosa from further trauma during reduction.

The septum and the nasal pyramid are carefully disimpacted, elevated, and repositioned by manipulating the forcep in the direction opposite that of the fracture impact. The Asch forcep has the distinct advantage of giving the surgeon control over both nasal bones simultaneously and as a single unit. As an added advantage, the Asch forcep serves as a septal reduction forcep as well and some septal fractures may be reduced concurrent with the movement of the nasal bones. In the case of bilateral nasal bone fractures, if the bone on the side opposite the direction of displacement has been noticeably impacted, once the entire nasal framework is repositioned to the midline with the Asch forcep, the impacted nasal bone can be gently elevated into position with the Boies elevator.

Both nasal bone and septal reposition maneuvers are repeated as necessary to obtain the best results; however, excessive manipulation and trauma should be avoided. Once properly positioned, a standard external nasal splint can be applied. Packing the nose is not generally needed although it may help to provide early intranasal support to a badly comminuted or unstable fracture. If a concomitant septoplasty is performed, Doyle splints are used postoperatively to stabilize the septal alignment. External and any internal splints are removed the week following surgery. Prophylactic antibiotics are used in cases where internal splinting or packing is used.

Open Reduction

Open reduction involves the repositioning of the nasal structures via different mucosal and skin incisions, with techniques fundamentally similar to the ones used in functional and cosmetic rhinoplasty techniques. Open reduction techniques, from septoplasty to osteotomies to functional primary septorhinoplasty can be of such range that they are beyond the purview of this chapter but are referenced in part or whole elsewhere in this text. It is worth, however, emphasizing once again the importance of septal reduction to enable satisfactory repositioning of the nasal bones—an inadequate reduction of the nasal septum impedes appropriate repositioning of the external nasal framework.

COMPLICATIONS

Complications of nasal fractures may present in an early or a delayed fashion. A list of more commonly encountered early and late complications is provided in Table 83.1.

Early

Edema and ecchymosis are typically seen early and are more expected than indicative of a complication. Both should resolve spontaneously within 1 to 2 weeks.

Epistaxis is not at all uncommon, and most cases will resolve spontaneously. Less commonly, cauterization or/and intranasal packing may be required, and surgery (electrocautery or vessel ligation) and/or embolization is reserved for the very rare refractory cases. When packing a nose in the setting of a nasal fracture, care should be taken to not to overpack for fear of interfering with blood supply to the already damaged septum. In the setting of suspected skull base fractures, packing is relatively contraindicated and should be performed only under direct visualization and with total control in order to avoid inadvertent intracranial complications.

Wound infections are uncommon, although they can develop with contaminated nasal lacerations (compound fractures). A higher incidence of wound infection can be seen in smokers, diabetics, immunocompromised patients, and those with autoimmune diseases and with poorer nutritional status (60).

TABLE 83.1 COMPLICATIONS NASAL FRACTURES

Early	Late/Delayed
• Epistaxis	• Nasal airway obstruction
• Wound infection	• Synechiae
• Septal hematoma	• Septal perforation
• Septal abscess	• Crooked nose/external deformity
• CSF leak	• Saddle deformity
	• CSF leak

As discussed earlier, a septal hematoma should be suspected with abnormal bluish–purplish compressible swelling over the septum and complaints of nasal pain or congestion that seem beyond the norm for a nasal fracture. Clinical examination establishes the diagnosis, and treatment, whether by aspiration or formal drainage, is essential. Failure to recognize a septal hematoma can result in progression to a septal abscess with secondary cartilage necrosis and saddling of the nasal dorsum.

A CSF leak may be associated with fractures of the cribriform plate or posterior wall of the frontal sinus, and usually present with clear fluid rhinorrhea. This may be evident early but in some circumstances may not manifest for months or even years after the initial traumatic event. As noted earlier, if suspected a beta-2 transferrin test is helpful in assisting in diagnosis, and more detailed imaging (CT scan) is warranted. Smaller leaks often go undetected and may in fact resolve spontaneously. Otherwise, management will depend on etiology and may require neurosurgical consultation.

Late

Late complications are often preventable with proper early evaluation, diagnosis, and appropriate management. Delayed complications may be either functional or cosmetic, and are generally secondary to anatomic displacement and deformity of nasal structures, or tissue loss. Delayed presentation of a CSF leak is noted above.

Delayed complications can include external nasal deformities (a crooked nose or saddle deformity), or endonasal deformities such as nasal airway obstruction (deviated septum, valve collapse), intranasal synechiae, and septal perforations. Disruption of facial growth centers in children can also lead to delayed functional or cosmetic problems. Treatment of delayed complications ranges from primary septoplasty to functional and/or cosmetic rhinoplasty, which are discussed elsewhere in this text.

HIGHLIGHTS

- The nasal bones are the most commonly fractured facial bone and the third most commonly fractured bone in the body
- A complete evaluation should take into account the possibility of other facial skeletal fractures
- The greater the impact resulting in a nasal bone fracture the higher the likelihood of associated nasal septal fractures
- Closed reduction and open reduction are both reasonable treatment options—successful management is predicated upon carefully considering which approach is necessary for a given patient's fracture
- Physical findings may be more subtle in children and the incidence of septal hematoma is higher—both of which mandate greater vigilance

Frontal Sinus Fractures

84

E. Bradley Strong

BACKGROUND

While frontal sinus injuries are relatively uncommon, the potential for long-term sequelae is significant. It is therefore critical to have a comprehensive treatment strategy. Unfortunately, optimal management of frontal sinus fractures remains controversial (1–8). Most authors would agree that a hierarchical treatment strategy would include: treatment of any intracranial injury, avoidance of short- and long-term complications such as mucoceles, reestablishment of an aesthetic facial contour, and return of normal sinus function if possible. This chapter provides an anatomically based treatment algorithm for the management of frontal sinus fractures, highlighting the key steps to surgical repair.

ANATOMY

The frontal sinus is not present at birth. The anterior ethmoid air cells invade the frontal bone at age 2; developing into a full size frontal sinus by age 15 (Fig. 84.1). The floor of the sinus forms the medial portion of the orbital roof. The posterior table forms a portion of the anterior cranial fossa. The anterior table forms part of the forehead, brow, and glabella (Fig. 84.2). The size and shape of the adult frontal sinus is highly variable. It is commonly asymmetric and may be divided by one or more septations. Less frequently, patients will have a unilateral (10%), rudimentary (5%), or no frontal sinus (4%). Average frontal sinus dimensions are: height 30 mm, width 25 mm, depth 19 mm, and volume 10 mL. The anterior table is much thicker (average 4 mm, but up to 12 mm) than the posterior table (0.1 to 5 mm) (9,10). The nasofrontal recess is the sole outflow tract for the frontal sinus. The ostia are approximately 1 to 3 mm in diameter and located posteriorly, inferiorly, and medially on the floor of the sinus (9,10). They are the narrowest point of an hourglass configuration, with the frontal sinus infundibulum above, and the nasofrontal recess below (Fig. 84.3).

PATHOPHYSIOLOGY

The frontal sinus is protected by thick cortical bone and is more resistant to fracture than any other facial bone (11) (Fig. 84.4). Consequently, frontal sinus fractures account for only 5% to 15% of maxillofacial injuries (1,11). The use of seat belts and airbags has significantly decreased the incidence of frontal sinus fractures (1,12). The majority of these fractures involve young males (average age 30 years) involved in high-velocity injuries such as motor vehicle accidents (52%), assaults (26%), and recreation or industrial accidents (14%) (1,5–6). Greater than 75% of patients will have associated facial fractures (1,7). Isolated anterior table fractures occur approximately 33% of the time. Combined fractures of the anterior table, posterior table, and/or the nasofrontal recess account for approximately 67% of frontal sinus injuries. Isolated posterior table injuries are rare (~2% of injuries) (1,4).

DIAGNOSIS

Physical Examination

Due to the high velocity nature of these injuries, associated intracranial, spinal cord, thoracic, abdominal, and long bone injuries must be ruled out in all patients. A thorough history and complete head and neck examination are critical. Common physical findings include forehead abrasions/lacerations, contour irregularities, tenderness, paraesthesias, epistaxis, and hematoma. Exploration of forehead lacerations should be performed with sterile technique, if there is any question of intracranial violation. Through-and-through injuries of the frontal sinus have a high morbidity and prompt surgical treatment is indicated.

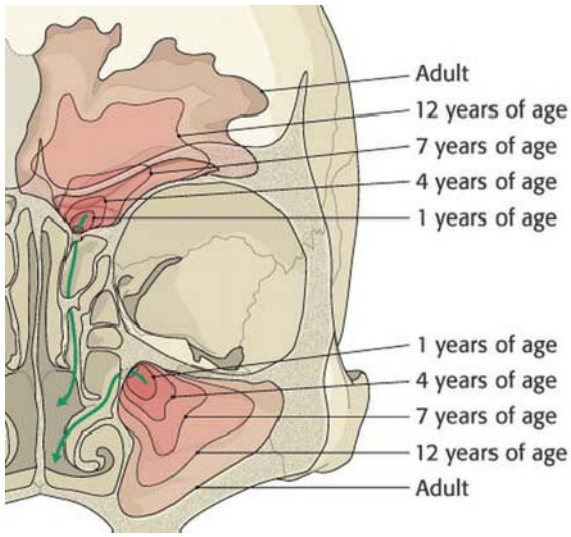

Figure 84.1 Frontal sinus development. The anterior ethmoid air cells invade the frontal bone at age 2. The sinus is fully developed by age 15. (From AO Surgery Reference Cranial Vault & Skull Base, www.aosurgery.org. Copyright by AO Foundation, Switzerland with permission).

The presence of associated facial fractures must be ruled out, with special attention to examination of the orbits and nasoorbitoethmoid complex. Conscious patients should be questioned regarding the presence of watery rhinorrhea or salty tasting postnasal drainage suspicious for a cerebrospinal fluid leak. Such fluid should initially be evaluated with a "halo test." The bloody fluid is allowed to drip onto filter paper. If cerebrospinal fluid is present, it will diffuse faster than blood and result in a clear halo around the blood. Beta-2 transferrin is the definitive test to confirm a cerebrospinal fluid leak; however, it is generally a "send out" test and may take 5 to 7 days to receive results.

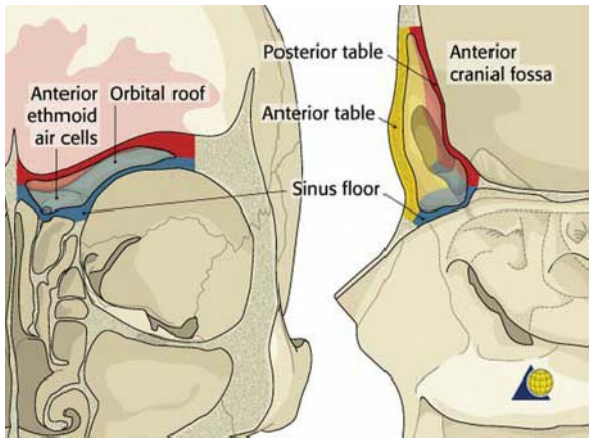

Figure 84.2 Frontal sinus anatomy. The anterior table of the frontal sinus is thick bone and provides forehead contour. The posterior table is thinner and constitutes a portion of the anterior cranial fossa. The floor or the sinus makes up a portion of the orbital roof. The frontal sinus ostia is located in the medial, posterior, and inferior portion of the sinus floor. (From AO Surgery Reference Cranial Vault & Skull Base, www.aosurgery.org. Copyright by AO Foundation, Switzerland with permission).

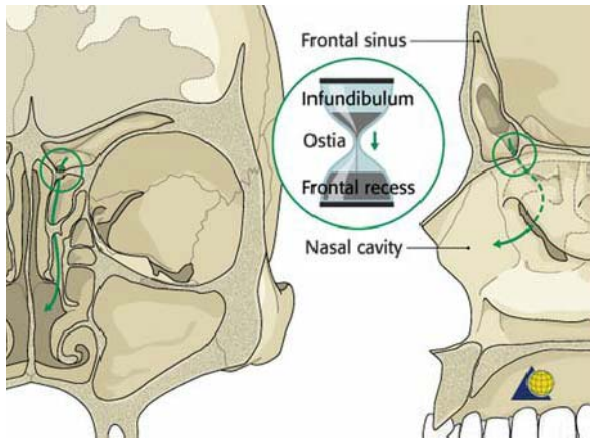

Figure 84.3 Frontal sinus drainage. The frontal sinus drainage pathway has an hourglass configuration with the infundibulum above and the frontal recess below. (From AO Surgery Reference Cranial Vault & Skull Base, www.aosurgery.org. Copyright by AO Foundation, Switzerland with permission).

Radiography

Plain radiographs are of little use in the diagnosis of frontal sinus fractures. A thin cut (1.0 to 1.5 mm), axial computed tomography (CT) scan is the gold standard. It is recommended to obtain coronal, sagittal, and three-dimensional (3-D) reconstructions for diagnostic accuracy. The axial images are used to evaluate the anterior and posterior tables (Fig. 84.5); coronal images for the sinus floor and orbital roof (Fig. 84.6). Sagittal images can be useful in assessing the patency of the frontal recess (Fig. 84.7) (13), while 3-D reconstructions help define the shape, location, and orientation of individual bone fragments that are seen less clearly on 2-D views (Fig. 84.8). The 3-D information can reduce the need for surgical dissection, because the surgeon knows the number, location, and orientation of the larger bone fragments. It can also help the patient and/or family to understand the bony anatomy and severity of the injury.

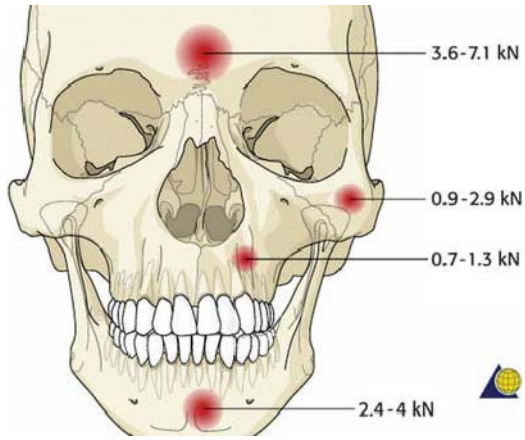

Figure 84.4 The anterior table of the frontal sinus is thick cortical bone. It is more resistant to fracture than any other facial bone. (From AO Surgery Reference Cranial Vault & Skull Base, www.aosurgery.org. Copyright by AO Foundation, Switzerland with permission).

Figure 84.5 Axial CT scan demonstrating a frontal sinus fracture involving both the anterior and posterior tables. **A:** Marked anterior table disruption. The *white arrow* points out a displaced posterior table bone fragment. **B:** Disruption of the nasofrontal recess. (From Strong, EB. Frontal sinus fractures: current concepts. *Craniomaxillofac Trauma Reconstr* 2009;2(3):161–175, figure 2.)

TREATMENT ALGORITHM

The appropriate treatment strategy for the management of frontal sinus fractures can be made by assessing *four* anatomic parameters (Fig. 84.9). These parameters include the presence of: (a) an anterior table fracture, (b) a posterior table fracture, (c) a nasofrontal recess fracture, (d) a dural tear (cerebrospinal fluid leak). These findings can be applied to the algorithm presented to determine appropriate treatment (Table 84.1). The treatment options include: observation, endoscopic repair, open reduction and internal fixation, sinus obliteration, sinus cranialization, and rarely sinus ablation (Reidel procedure). The indications and techniques for each of these procedures are discussed below.

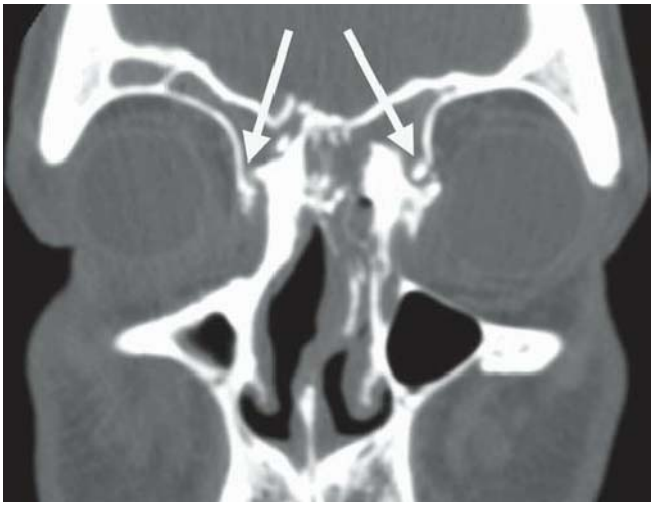

Figure 84.6 Coronal CT scan demonstrating disruption of the medial orbit and frontal recess (*arrows*). (From Strong, EB. Frontal sinus fractures: current concepts. *Craniomaxillofac Trauma Reconstr* 2009;2(3):161–175, figure 3.)

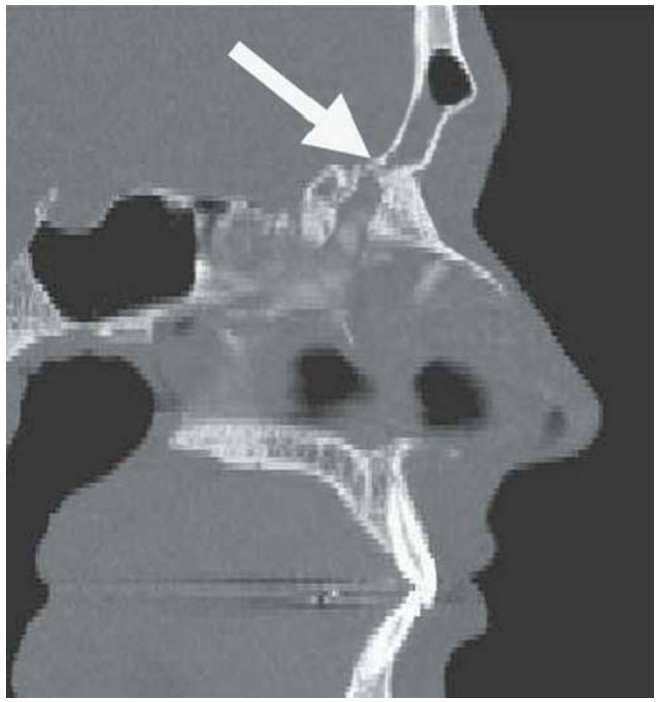

Figure 84.7 Sagittal CT scan demonstrating a frontal sinus fracture. The *arrow* demonstrates narrowing and obstruction of the frontal sinus outflow tract. (From Strong, EB. Frontal sinus fractures: current concepts. *Craniomaxillofac Trauma Reconstr* 2009;2(3):161–175, figure 4.)

Frontal Recess Fractures

Frontal recess fractures result in disruption of the sole frontal sinus outflow tract (Fig. 84.10 and Table 84.1). Frontal recess

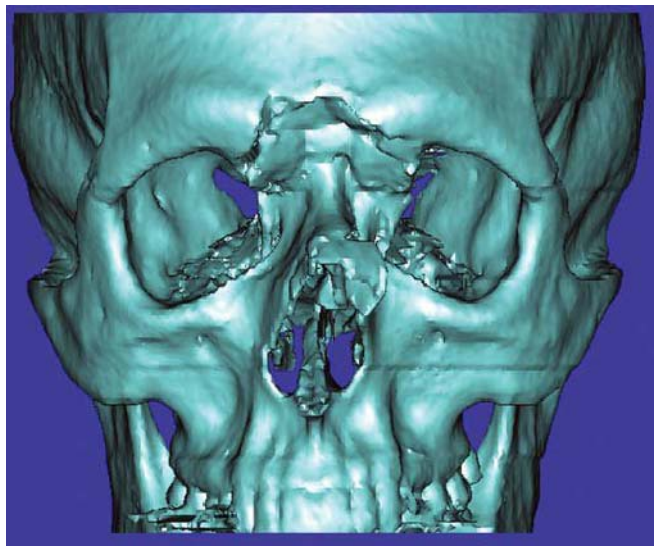

Figure 84.8 3-D CT scan of a frontal sinus fracture. The 3-D reconstruction can be helpful in delineating the position of bone fragments to be located intraoperatively. (From Strong, EB. Frontal sinus fractures: current concepts. *Craniomaxillofac Trauma Reconstr* 2009;2(3):161–175, figure 5.)

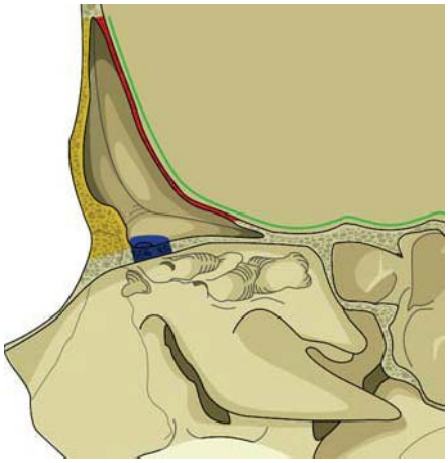

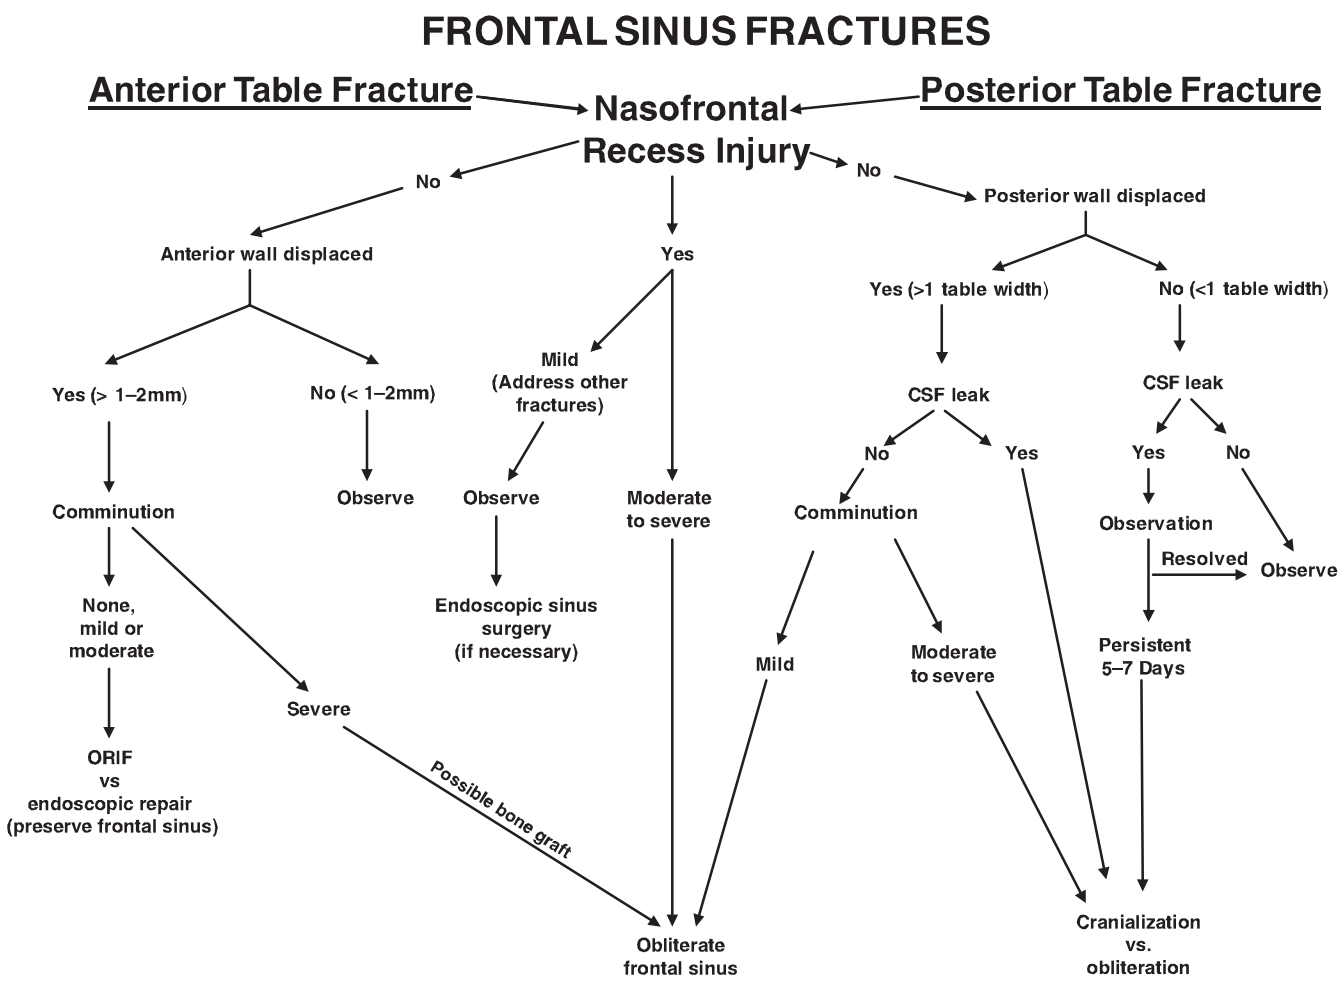

Figure 84.9 Illustration of the anatomic parameters that need to be assessed when developing a treatment plan for frontal sinus fractures. *Yellow*—anterior table; *Red*—posterior table; *Blue*—frontal recess; *Green*—dural integrity. (From Strong, EB. Frontal sinus fractures: current concepts. *Craniomaxillofac Trauma Reconstr* 2009;2(3):161–175, figure 6.)

fractures that result in sinus outflow obstruction will generally require frontal sinus obliteration. Unfortunately, the compact anatomy of the frontal recess makes accurate diagnosis challenging. One option is to perform a frontal sinus trephination to visualize the recess endoscopically. This does, however, require a general anesthetic. Some authors have proposed infusion of dye into the sinus to document frontal recess patency. Unfortunately, the passage of dye into the nose does not confirm or refute the presence of a fracture and has no documented prognostic value for the ultimate patency of the frontal recess. Therefore treatment decisions are generally based on thin cut CT scans. If the frontal recess patency remains in question (and there are no other significant sinus injuries) patients may be followed with sequential CT scans at approximately 1 and 12 months to assure that the frontal recess is patent. If the frontal recess becomes obstructed an obliteration is indicated. A more recently described technique involves observation of limited frontal sinus fractures (with serial CT scans), followed by endoscopic frontal sinusotomy for management of frontal recess stenosis (14). While

TABLE 84.1 FRONTAL SINUS FRACTURES

this approach shows some promise, it should be reserved for surgeons with extensive experience in both endoscopic sinus surgery as well as open approaches to the frontal sinus.

Anterior Table Fractures

Nondisplaced (0 to 2 mm) anterior table fractures can be observed with little risk of long-term morbidity (Fig. 84.11 and Table 84.1). Fractures with greater displacement (2 to 6 mm) present little risk of mucocele formation; however, the risk of an aesthetic deformity increases with the degree of displacement (Fig. 84.12). In these situations, the decision for an open reduction should *not* be based on the long-term risk of sinusitis/mucocele formation. Most sinuses will heal adequately. The decision for surgery should be carefully weighed against the risks of general anesthesia and the long-term iatrogenic sequelae from a coronal incision (i.e., alopecia, paresthesias, facial nerve injury, etc.). Historically, these sequelae have been downplayed, but they can be more severe than the injury itself. Alternatively, minimally invasive approaches may be indicated with mildly displaced fractures. Transcutaneous upper eyelid approaches have been described, but have not gained significant popularity (15–16). Endoscopic fracture reduction in the acute setting has also been described, but is technically

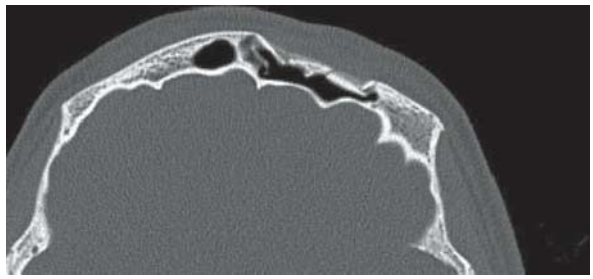

Figure 84.12 Axial CT scan demonstrating a mild to moderately displaced anterior table fracture. These fractures have a more significant risk of long-term aesthetic deformity.

challenging (17–21). The author feels it is not a viable technique for the majority of patients. Therefore, if an endoscopic approach is chosen, the author prefers a camouflage technique (17,18,20). Surgery for camouflage of the external deformities is performed 2 to 3 months after the injury when all facial swelling has resolved. This allows the patient to assess the degree of deformity and make an accurate decision as to whether they desire surgical intervention. Patients with thicker skin are better candidates for this approach because any subtle defects will be more easily camouflaged. If the patient is seen acutely, the rationale and indications for a delayed approach must be clearly explained (i.e., risk of iatrogenic injury may be greater than the traumatic deformity itself); and the patient must understand that a fracture reduction cannot be performed once the fracture has healed. While the risk of mucocele formation is very low, this should also be discussed. In the author's experience, many patients with minimally displaced fractures will desire no surgical intervention due to the lack of significant deformity. More complex anterior table fractures (greater than 6 mm or with comminution) will likely require open reduction using a coronal incision (Fig. 84.13). Uncommonly frontal sinus obliteration may be required when severe mucosal injuries are present.

Posterior Table Fractures

The treatment algorithm for posterior table fractures is complex due to the risk of CSF leak, meningitis, and mucocele formation (Table 84.1) (2,4–7). The primary decision criteria for surgical intervention are the fracture severity (displacement/

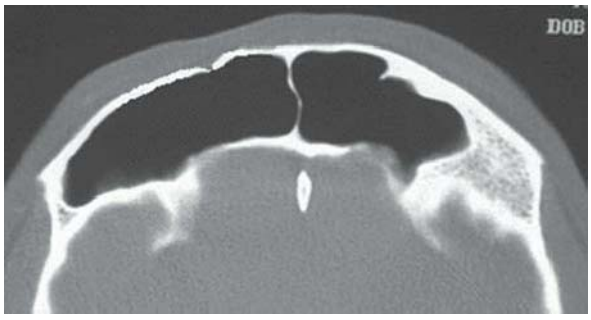

Figure 84.11 Axial CT scan demonstrating a minimally displaced anterior table fracture. These injuries have a low risk of mucocele formation or aesthetic deformity.

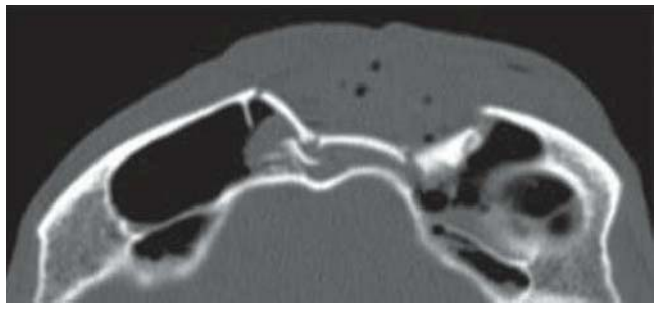

Figure 84.13 Axial CT scan demonstrating a severely displaced anterior table fracture requiring open reduction and internal fixation.

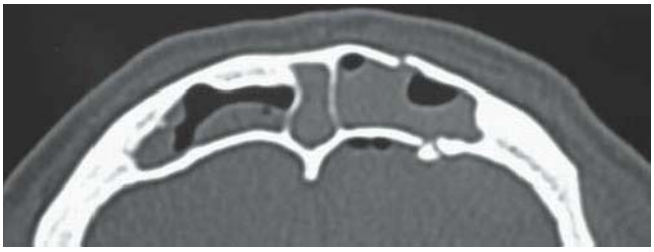

Figure 84.14 Axial CT scan demonstrating a minimally displaced (less than 2 mm) posterior (and anterior) table fracture.

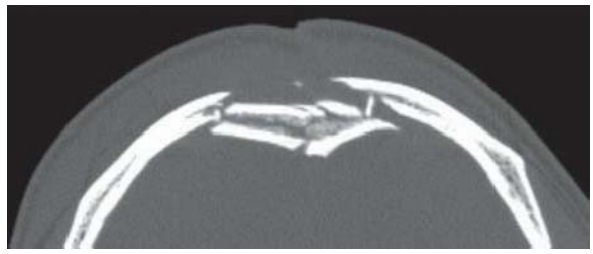

Figure 84.16 Axial CT scan demonstrating a severely displaced and comminuted fracture of the posterior (and anterior) table.

communition) and the presence of a CSF leak. While the degree of displacement that requires surgical intervention is "subjective" and controversial, the author prefers to use 2 mm of displacement as a rule of thumb. Two millimeter is often very close to the thickness of the posterior table, which has been used by some authors as an indication for intervention (5).

Less than 2 mm of Displacement: (Fig. 84.14)

Patients with posterior table displacement less than 2 mm, and no CSF leak, may be observed. Long-term follow-up with repeat CT scans at 1 month and 1 year is appropriate to rule out mucocele formation. If a CSF leak is present at the time of injury, 1 week of observation is indicated; approximately 50% will resolve spontaneously (6). If the leak is persistent, open reduction, dural repair, and sinus obliteration are indicated.

Greater than 2 mm of Displacement: (Fig. 84.15)

Patients with posterior table displacement greater than 2 mm, no CSF leak, and mild comminution should be treated with sinus obliteration. More severe injuries, with a frank CSF leak and moderate to severe comminution, will likely require removal of some posterior table bone to repair the dural tear. If the injury or surgical repair results in disruption of more than 25% to 30% of the posterior table, sinus cranialization should also be considered (Fig. 84.16) (22).

SURGICAL TECHNIQUE

Frontal Sinus Trephination

Trephination and endoscopic visualization of the frontal sinus can be useful to assess the frontal recess as well as the extent of any posterior table injury. After infiltration of local anesthesia, a 1.0 to 1.5 cm skin incision is placed midway between the medial canthus and the glabella, approximately 1 cm inferior to the brow (Fig. 84.17). The incision is best hidden by placing it inferior and deep to the curve of the forehead. A small "V" shaped relaxing incision may be added to reduce the risk of scar contracture and webbing. The incision should NOT be placed within the eyebrow, because it may result in alopecia, and place the supratrochlear neurovascular pedicle at risk. A guarded micro-point, monopolar electrocautery can then be used to dissect through the soft tissues and onto the frontal bone. The location and depth of the sinus should be confirmed on the CT scan or with intraoperative navigation. A depth of at least 7 mm is recommended to avoid injuring the posterior table. A small cutting burr is used to open a 4 to 5 mm frontal sinusotomy (Fig. 84.17 inset). The mucosa is incised and the sinus can be suctioned free of any blood or mucous. A 30 degrees endoscope is used to examine the posterior table and frontal recess for any evidence of injury. A Valsalva maneuver can assist with the diagnosis of a CSF leak (Fig. 84.18). While flexible pediatric bronchoscopes are more cumbersome, they can be used to examine the lateral aspects of the sinus. Once the examination has been completed, the skin and soft tissue are closed meticulously in layers.

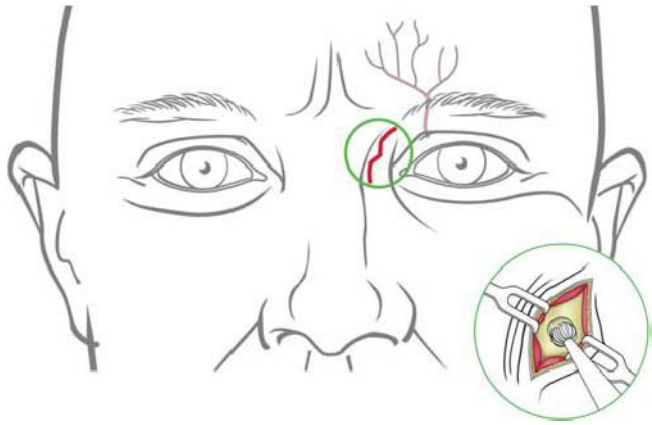

Figure 84.17 Illustration demonstrating the incision for a frontal sinus trephination. The incision should be midway between the medial canthus and the glabella, and approximately 1 cm inferior to the brow. The incision is best hidden when placed inferior to the forehead curvature. Inset: A small cutting burr is used to trephinate the sinus taking care to avoid injury to the posterior table. (From Strong, EB. Frontal sinus fractures: current concepts. *Craniomaxillofac Trauma Reconstr* 2009;2(3):161–175, figure 9.)

Endoscopic Anterior Table Repair

This technique is appropriate for isolated anterior table fractures above the orbital rim. Several authors have described endoscopic reduction of these fractures; however, the author finds this to be technically challenging (19–21). The repair described below is a camouflage technique. It is performed approximately 2 to 4 months after the injury when all forehead swelling has resolved and an accurate assessment of the deformity can be made. Prior to surgery, appropriate consent is obtained for the procedure including the risks of bleeding, infection, paraesthesias, alopecia, poor aesthetic result, and possible need for open approach if an endoscopic repair cannot be performed. The surgical technique is similar to a brow lift and uses the same instrumentation (23). Local vasoconstriction agents should be used liberally to minimize the need for electrocautery, and reduce the risk of alopecia at the incision site. A 3 to 5 cm parasagittal "working" incision should be placed above the fracture, 3 cm behind the hair line, and carried through the periosteum onto bone (Fig. 84.19). The actual length will vary depending on the size of the fracture and implant to be inserted. A 1 to 2 cm subperiosteal "endoscope" incision is then placed at the same height, 4 cm medial to the working incision. In patients with a prominent forehead or receding hair line, the incisions may need to be moved closer to the hairline, allowing visualization around the forehead curvature.

The initial subperiosteal elevation is carried down to the level of the fracture using an endoscopic brow lift elevator. The dissection is rapid and does not require the use of the endoscope (Fig. 84.20). Caution should be used to maintain the integrity of the periosteal envelope. Tears in the periosteum will "catch" the endoscope when it is inserted and make visualization more difficult. A 4.0 mm, 30-degree endoscope (with a rigid endosheath and camera) is then inserted through the endoscope incision. A large endosheath guard helps to maintain a generous optical cavity (Fig. 84.21). Dissection over the fracture is then carried out under direct visualization. A fibrous scar layer prevents entry into the sinus (Fig. 84.22). The supraorbital and supratrochlear neurovascular pedicles are commonly visualized at the orbital rim. Excessive traction on the pedicles should be avoided as it can result in postoperative paresthesias. Once the limits of the fracture have been visualized, a 0.85 mm thick porous polyethylene sheet is trimmed to approximate the defect (using the depression in the forehead skin as a template) (Fig. 84.23). The superior edge of the implant is marked with a pen to maintain the orientation endoscopically during insertion. The implant is

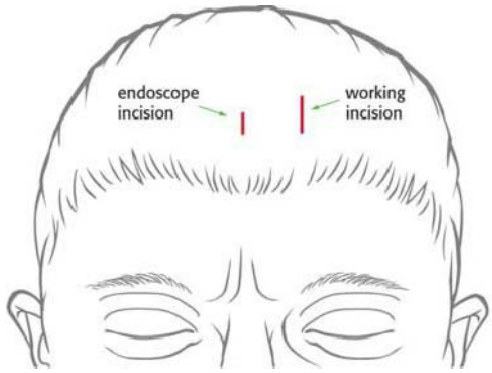

Figure 84.19 Illustration demonstrating the incision used for the endoscopic approach to an anterior table frontal sinus fracture. The "working incision" is placed directly above the fracture, while the "endoscope" incision is placed approximately 4 cm medial. Both incisions are placed 3 cm above the hairline. (From Strong, EB. Frontal sinus fractures: current concepts. *Craniomaxillofac Trauma Reconstr* 2009;2(3):161–175, figure 10.)

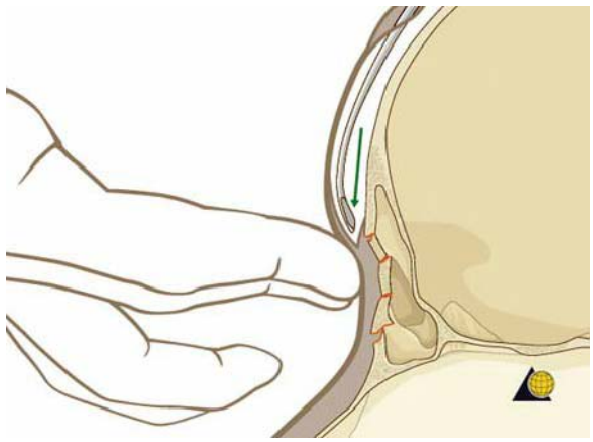

Figure 84.20 Illustration of a subperiosteal dissection used for exposure of an anterior table fracture. inserted through the working incision and manipulated both internally (with instruments) and externally (with fingers) over the defect (Fig. 84.24). Once the implant is in place, the size and shape are evaluated endoscopically and the implant is removed, trimmed, and refined. The process is repeated until the diameter of the implant is approximately 2.0 to 3.0 mm larger than the defect. If necessary for stability, the implant can be sutured together in two to three layers as an inverted pyramid shape to more accurately fill deeper defects (Fig. 84.25). Patients with very thin skin may require a smaller implant that sits flush within the defect. Once the implant is appropriately fashioned, a 25 gauge needle is passed through the skin over the fracture and endoscopically visualized to determine the best site for a percutaneous incision and screw placement. Optimal incision placement will allow screws to be placed on either side of the implant through a single incision (Fig. 84.26). However, some larger implants may require two separate stab incisions. Once the site has been determined, a no. 11 blade is used to make a 2 mm, through-and-through stab incision. A small self-drilling screw (4 to 7 mm

in length) is passed through the stab incision, through the edge of the implant (at least 1 mm from the edge to avoid tearing of the implant), and into stable bone at the periphery of the fracture (Fig. 84.27). The screw must be securely attached to avoid dislodging it from the screwdriver as it passes through the soft tissue. If the implant remains unstable after the first screw is placed, a second screw is applied on the contralateral side. The scalp incisions are then closed in layers and a pressure dressing is applied.

Open Reduction and Internal Fixation

Anterior table fractures that cannot be observed or managed endoscopically may require open reduction and internal fixation. The patient consent should include the risks of bleeding, infection, paresthesia, headache, CSF leak, orbital

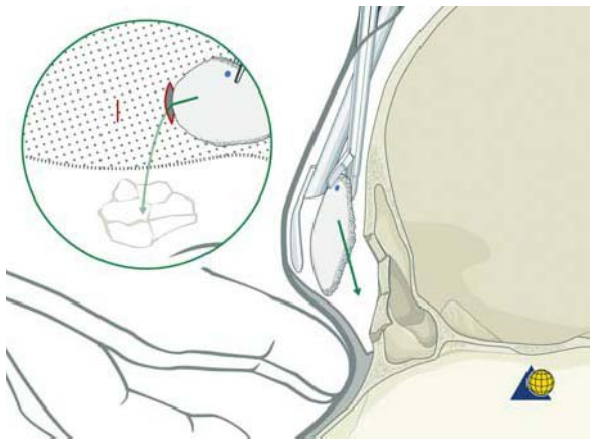

Figure 84.24 Once the implant has been trimmed to size, the superior edge is marked to maintain orientation after insertion. injury, diplopia, meningitis, external deformity, and late mucocele formation. In the operating room, the bed is turned 180 degrees away from the anesthesiologist and corneal shields or temporary tarsorrhaphies are placed. The hair need not be shaved, but patients with longer hair will require banding to delineate the incision line (Fig. 84.28). Application of a water-based lubricant to the hair facilitates separating the hair and rapid application of the rubber bands. Surgical towels are stapled to the scalp just behind the incision line. An adherent plastic suction pouch is applied at the leading edge of the towel to collect blood and minimize spillage.

The greatest blood loss occurs with the initial incision and wound closure. When possible, generous amounts of a vasoconstrictor agent should be injected in a subgaleal plane prior to surgery. In patients who will wear their hair longer than 3 to 4 cm, the author prefers a "zig-zag" incision, starting *behind the ear* and running 4 to 6 cm behind the hair line (Fig. 84.29). Postoperatively when the patient is upright, the zig-zag pattern allows gravity to pull the hair inferiorly,

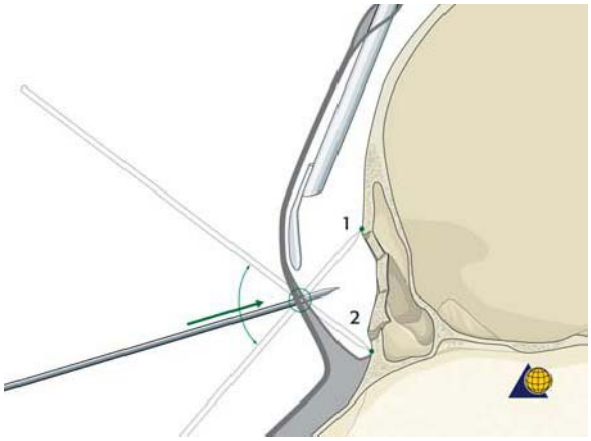

Figure 84.26 Illustration depicting the location of the stab incision used for insertion of a fixation screw to stabilize the implant. A 25 gauge needle is passed through the skin and visualized internally. The ideal location allows for a screw to be placed on either side of the implant through one stab incision. (From AO Surgery Reference Cranial Vault & Skull Base, www.aosurgery.org. Copyright by AO Foundation, Switzerland with permission).

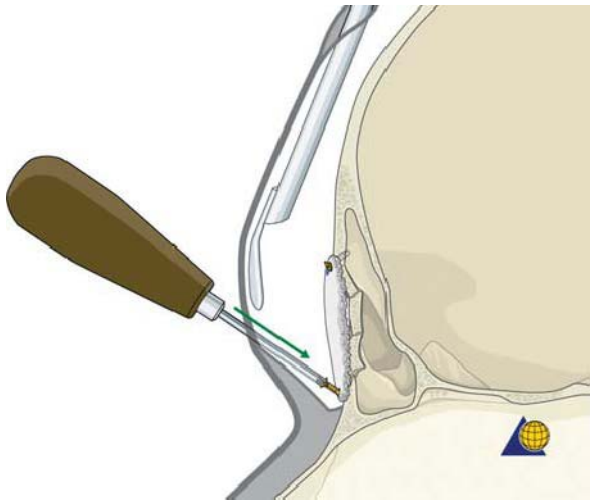

Figure 84.27 A self-drilling screw is passed through the edge of the implant and into stable bone. (From AO Surgery Reference Cranial Vault & Skull Base, www.aosurgery.org. Copyright by AO Foundation, Switzerland with permission).

covering the transverse arms of the scar. Excessive trauma to the "tips" of the zig-zag incision should be avoided, as it may increase the risk of alopecia. If the patient wears very short hair, a zig-zag pattern only lengthens and accentuates the incision. In this situation, a traditional straight line incision (with a central "widow's peak" or a methylene blue tattoo for realignment) is more rapid and provides adequate cosmesis (Fig. 84.30). In patients with male pattern baldness, the incision can be moved posteriorly to camouflage it within in the hair. This will necessitate a slightly more extensive lateral dissection to allow forward rotation of the scalp flap. All hair-bearing skin should be handled carefully, to avoid postoperative alopecia. While forehead lacerations can be used to assist with the repair, midforehead, brow, and "gull wing" incisions should be avoided due to the prominent scar and associated forehead paresthesias.

Figure 84.28 Photograph of banding hair to keep it away from the incision. (From AO Surgery Reference Cranial Vault & Skull Base, www.aosurgery.org. Copyright by AO Foundation, Switzerland with permission).

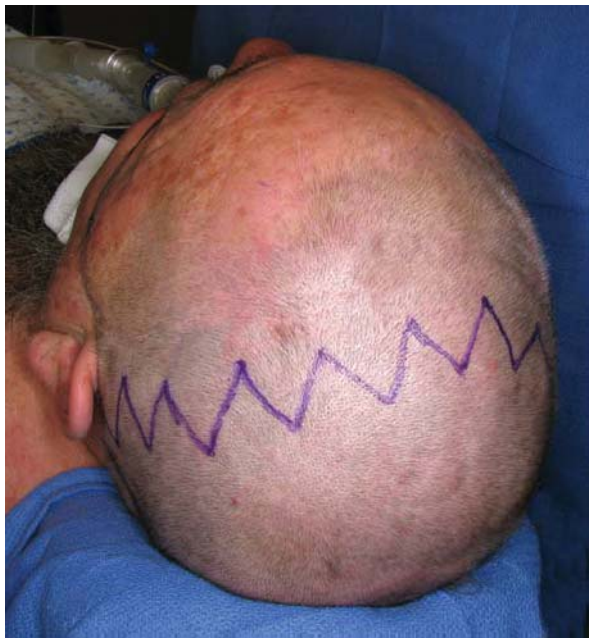

Figure 84.29 Photograph of a "zig-zag" coronal incision. (From Strong, EB. Frontal sinus fractures: current concepts. *Craniomaxillofac Trauma Reconstr* 2009;2(3):161–175, figure 14A.)

The scalp is opened in thirds. This allows time to control of bleeding and minimize blood loss. The central one-third (temporal line to temporal line) is initially incised down to the level of the galea aponeurosis. Electrocautery is avoided to protect the hair follicles. Larger vessels should be tied off individually. If necessary, Raney clips may be applied judiciously, depending on surgeon preference. Double-pronged skin hooks are used to retract the scalp away from the skull and protect the underlying pericranium. Once the galea

Figure 84.30 Photograph of a straight line incision with a "widows peak" at the top for alignment and wound closure. (From Strong, EB. Frontal sinus fractures: current concepts. *Craniomaxillofac Trauma Reconstr* 2009;2(3):161–175, figure 14B.)

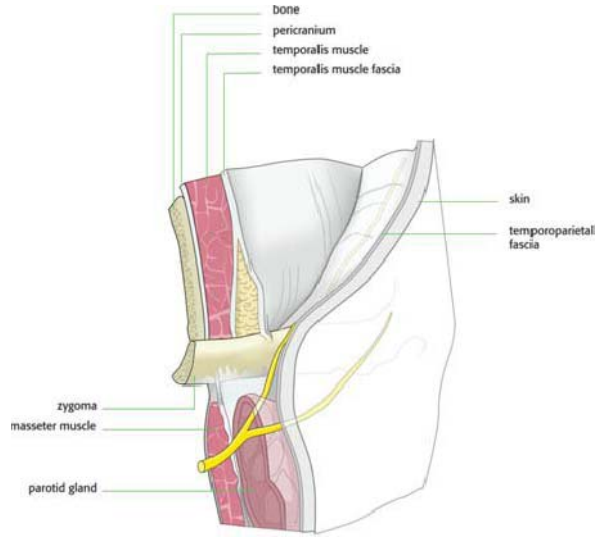

Figure 84.31 Illustration of a coronal incision in the temporal region. (From Strong, EB. Frontal sinus fractures: current concepts. *Craniomaxillofac Trauma Reconstr* 2009;2(3):161–175, figure 15.)

aponeurosis is incised, air will rapidly enter into the subgaleal space, developing an excellent dissection plane just above the pericranium. If there is a need for use of the pericranial flap during the surgical repair, the pericranium is left intact on the calvarium. It is more readily separated from the scalp when it is left attached to the bone. If there is no need for a pericranial flap, it is incised and elevated in one layer with the scalp.

Next, the lateral thirds of the scalp are individually incised. This dissection demands a thorough understanding of temporal anatomy (Fig. 84.31). The incision is extended from the temporal line inferiorly behind the helix (Figs. 84.29 and 84.30). The retroauricular incision is easily extended inferiorly behind the ear as necessary for flap rotation, while remaining completely hidden. A preauricular incision offers no real advantage, and results in a visible scar. The temporal incision should then be carried through the temporoparietal fascia (superficial temporal fascia) and onto the temporalis muscle fascia (deep temporal fascia), traversing the temporal artery and vein, which can be controlled using a suture ligature or bipolar cautery. The appropriate level of dissection can be confirmed by placing a small (1 to 2 mm) nick in the temporalis muscle fascia, exposing dark temporalis muscle beneath. The flap is then elevated anteriorly using blunt finger dissection or gauze, with limited use of the scalpel. The integrity of the temporoparietal fascia must be maintained, as it contains the frontal branch of the facial nerve (Fig. 84.31). As the temporal flap is elevated, it is joined with the central dissection that was performed initially. The fibers along the temporal line are incised sharply.

If the posterior table of the frontal sinus is intact and the surgeon has left the pericranial flap attached to the galea aponeurosis, the central dissection is carried forward in a subperiosteal plane using a wide elevator. The dissection is carried around the fracture taking care to protect the integrity of the bone fragments when possible. As the supraorbital rims are reached, care is taken to avoid injury to the

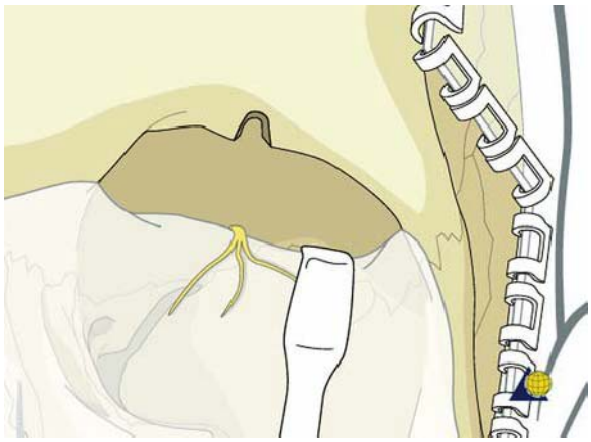

Figure 84.32 Illustration depicting the supratrochlear neurovascular pedicle after being removed from the supraorbital fissure with an osteotome. This provides exposure to the entire orbital roof. (From AO Surgery Reference Cranial Vault & Skull Base, www.aosurgery.org. Copyright by AO Foundation, Switzerland with permission).

supraorbital and supratrochlear neurovascular pedicles. If greater exposure is required, the dissection can be carried around the orbital rims into the orbits. The supraorbital neurovascular pedicle can be released, if necessary, using a small osteotome placed at the medial and lateral aspect of the foramina and down-fracturing the bone (Fig. 84.32). Once the pedicle is released, a careful dissection following the internal concavity of the superior orbit will avoid violation of the orbital periosteum and prolapse of orbital fat.

If the periosteum has been maintained on the calvarium, the soft tissue dissection is generally carried to the level of the orbital rims, while attempting to protect the integrity of the pericranium over the fracture site. At this point, the pericranial flap is incised and elevated off the calvarium down to the level of the orbital rims. Lateral incisions are placed 2 cm cephalad to the temporal line (Fig. 84.33). If necessary,

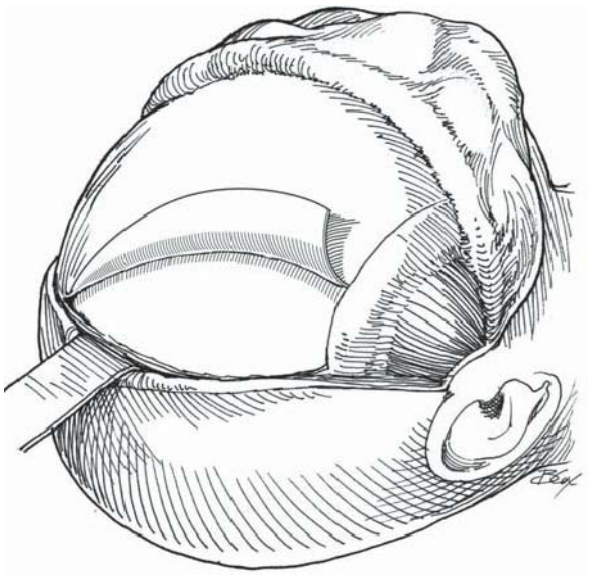

Figure 84.33 Illustration showing elevation of a large pericranial flap. (From Strong, EB. Frontal sinus fractures. *Oper Tech Otolaryngol* 2008;19(2):151–160, figure 9)

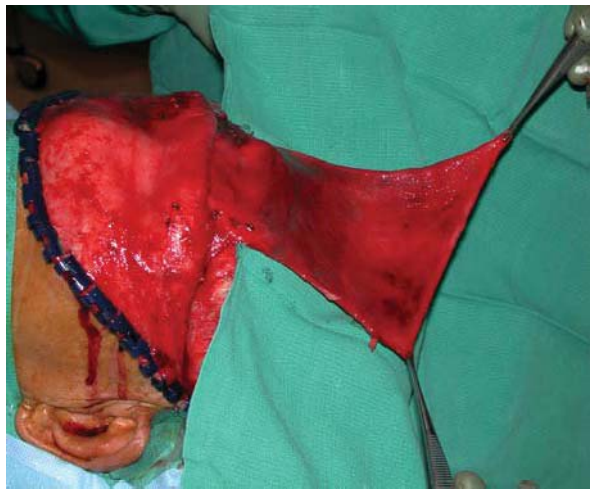

Figure 84.34 Photograph of a large pericranial flap harvested for repair of a dural defect. (From Strong, EB. Frontal sinus fractures. *Oper Tech Otolaryngol* 2008;19(2):151–160, figure 10)

2 to 4 cm of extra length can be obtained by joining the lateral periosteal incisions *behind* the initial skin incision. As the dissection is carried inferiorly, periosteal lacerations may be noted at the fracture site. A careful dissection will usually maintain an intact vascular supply and provide a lengthy flap that can be used for repair of CSF leaks or obliteration of the sinus itself if it is small (Fig. 84.34).

Reduction of noncomminuted fractures can be extremely challenging. When the convex surface of the frontal bone fractures, it goes through a compression phase, before becoming concave (Fig. 84.35). Fracture reduction requires enough force to pull the bone fragments back through the compression phase (Fig. 84.36). It may be necessary to

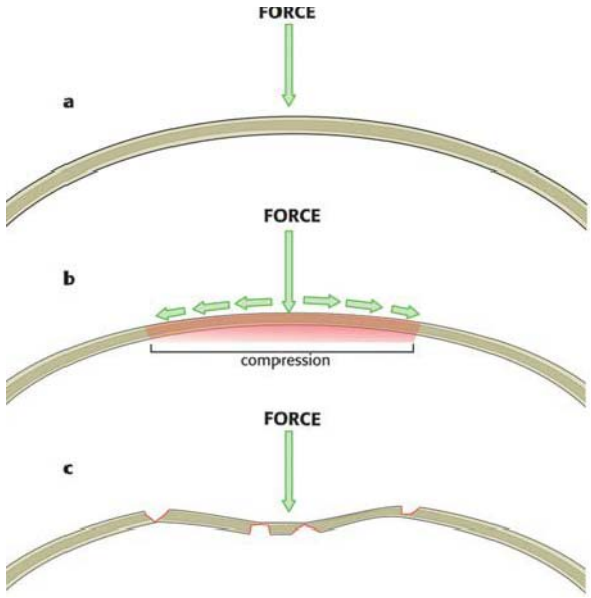

Figure 84.35 Illustration of the forces on the frontal bone when a frontal sinus fracture occurs. Note that as the bone goes from convex to concave that there is a compressive phase the bone must pass through. (From Strong, EB. Frontal sinus fractures: current concepts. *Craniomaxillofac Trauma Reconstr* 2009;2(3):161–175, figure 17A.)

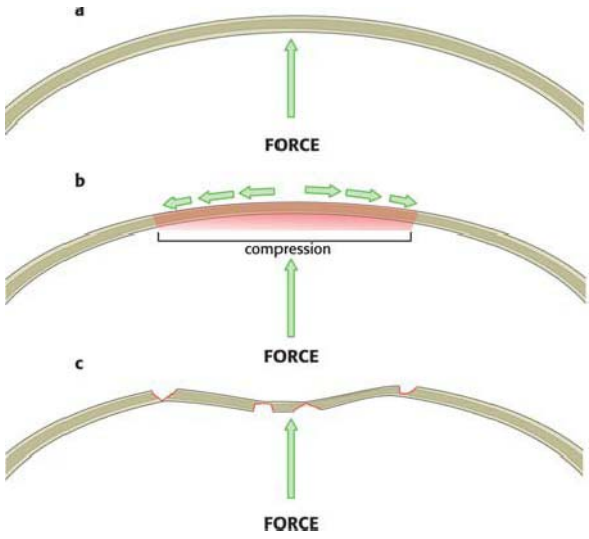

Figure 84.36 Illustration of the forces that must be applied to return the frontal bone in order to reduce a fracture. Note that as the bone goes from concave to convex, it must pass through the same compressive phase seen during fracture. This may require the surgeon to apply significant amount of force or remove a bone segment to release the pressure. (From Strong, EB. Frontal sinus fractures: current concepts. *Craniomaxillofac Trauma Reconstr* 2009;2(3):161–175, figure 17B.)

remove a bone fragment to release the tension and reduce the fracture. If comminution exists or bone segments overlap, a small bone hook may be insinuated between the fragments to assist with elevation. Another technique is to place a 1.5 to 2.0 mm screw in the depressed segment, grasp the screw with a heavy hemostat, and pull upward (with controlled force) to reduce the bone fragments (Fig. 84.37). Once the bone fragments are mobilized, the sinus mucosa should be evaluated. A 30-degree endoscope can be helpful to visualize the sinus and the nasofrontal recess through a limited bone defect. Every attempt should be made to keep the majority of the fragments in place, allowing for a more accurate repair. If bone fragments are removed, arranging them atop a drawing

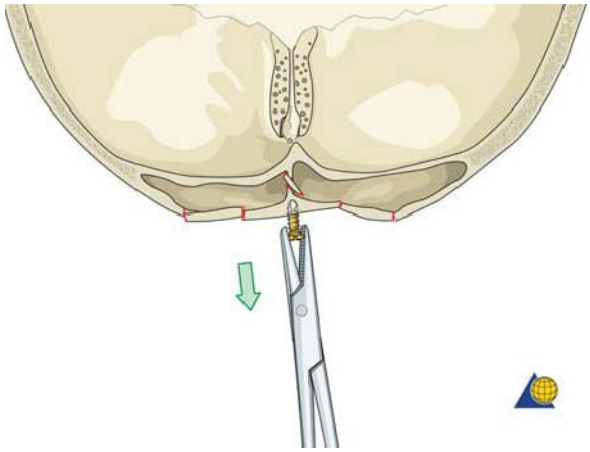

Figure 84.37 Illustration of a bone screw to assist with fracture reduction. (From AO Surgery Reference Cranial Vault & Skull Base, www.aosurgery.org. Copyright by AO Foundation, Switzerland with permission).

Figure 84.38 Any bone fragments that are removed should be kept moist atop a drawing of the fracture. This will help maintain the anatomic orientation for the final reconstruction. of the fracture helps to maintain the anatomic orientation for the final reconstruction (Fig. 84.38). The fracture is then reduced and plated with 1.0 to 1.3 microplates. Small gaps (4 to 10 mm) can be reconstructed with titanium mesh. Hydroxyapatite bone cement should *not* be used to fill bone defects. It has an unacceptably high-risk infection and extrusion. During wound closure, it is important to resuspend the temporal soft tissues to avoid long-term ptosis of the forehead and upper midface. Two, 2-0, monofilament sutures are passed through the temporoparietal fascia and suspended up to the temporalis muscle fascia (Fig. 84.39).

Frontal Sinus Obliteration

More severe injuries may require frontal sinus obliteration. A coronal incision is used to expose the fracture as previously described. A pericranial flap should be maintained for any unanticipated injuries that might be found intraoperatively (CSF leak, dural tear, etc.). After complete exposure of

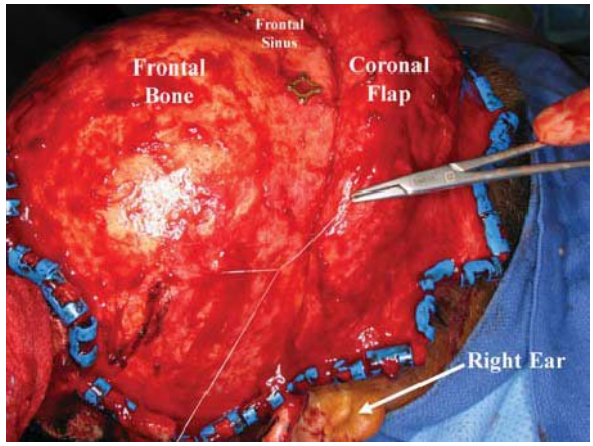

Figure 84.39 Photograph demonstrating resuspension of the coronal flap to the temporalis muscle fascia. (From Strong, EB. Frontal sinus fractures: current concepts. *Craniomaxillofac Trauma Reconstr* 2009;2(3):161–175, figure 18.)

the frontal bone, all anterior table fragments should be carefully removed, kept moist on a side table, and oriented on a drawing to assist with the final repair (Fig. 84.38). In some instances, it may be necessary to perform a frontal sinusotomy to remove the remaining anterior table bone and visualize the entire sinus cavity. Localization of the sinusotomy cuts can be performed in several ways. Historically a "6 foot penny Caldwell" x-ray was used (i.e., anterior–posterior Caldwell x-ray with the patient placed 6 feet from the x-ray tube). However, current digital radiograph technology has made these films very difficult to obtain. Intraoperative navigation is effective but requires a specialized scan and navigational hardware. Alternatively, one tine of a bipolar cautery can be placed through a defect in the frontal bone, while the opposite tine remains visible outside the sinus. The internal tine is then "walked" around the periphery of the sinus, while the outer tine is used to mark an outline the

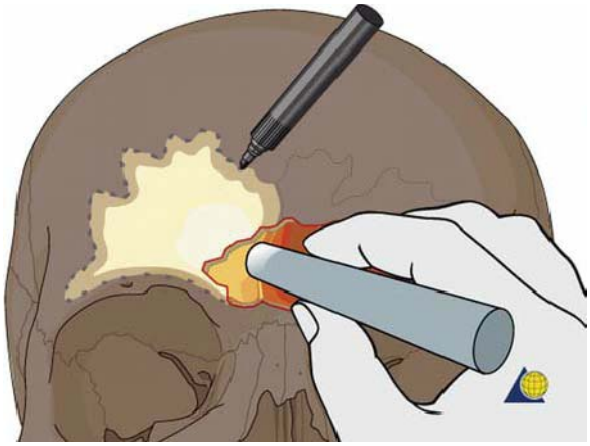

Figure 84.41 Illustration depicting the use of a light source to transilluminate the borders of the frontal sinus in preparation for a completion frontal sinusotomy. (From AO Surgery Reference Cranial Vault & Skull Base, www.aosurgery.org. Copyright by AO Foundation, Switzerland with permission).

sinus with a drill or ink (Fig. 84.40). Another technique involves insertion of a light source into the sinus through a fracture line; this transilluminates the periphery of the sinus and guides the osteotomy (Fig. 84.41).

After the limits of the sinus have been marked out, two to three microplates (1.0 to 1.3 mm) are "pre-applied" spanning the proposed osteotomy sight (Fig. 84.42). This allows the surgeon to accurately reposition the osteotomized bone even after it is removed. The plates are then rotated superiorly away from the osteotomy, with one screw left in place (Fig. 84.43). A drill is used to "postage stamp" perforations around the periphery of the sinus (Fig. 84.44). It is angled toward the sinus cavity to avoid intracranial penetration (Fig. 84.45). A side-cutting burr is then used to join the perforations and complete the osteotomy (Fig. 84.46). Care should be taken to avoid disruption of the predrilled miniplate holes while performing the osteotomy. Inferiorly, the orbital rims are

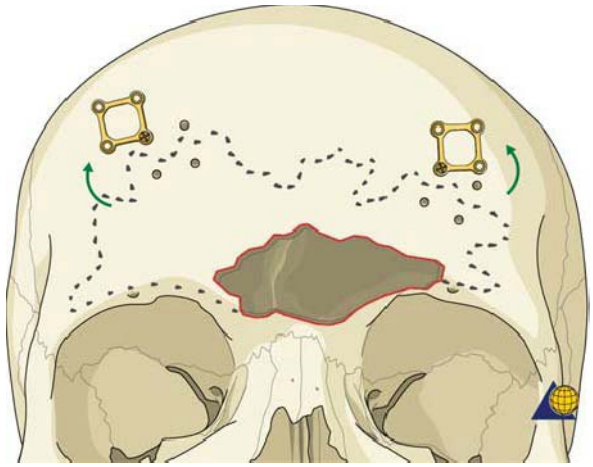

Figure 84.43 Illustration depicting rotation of the miniplates to allow for osteotomy. (From AO Surgery Reference Cranial Vault & Skull Base, www.aosurgery.org. Copyright by AO Foundation, Switzerland with permission).

osteotomized at the periphery of the sinus. The glabella is osteotomized approximately 5 mm above the junction with the nasal bones. No osteotomy is placed in the orbital roof. Particular attention must be paid to avoid injury to the supraorbital/supratrochlear neurovascular pedicles. A curved 4-mm osteotome (curved away from the posterior table) is then inserted into the sinus from above, and used to fracture the intersinus septum (Fig. 84.47). Finally, a hand is placed on the anterior table and the osteotome is gently elevated to out fracture the anterior table.

Once the sinus is completely exposed, the posterior table integrity is evaluated. If the bone is stable and free of significant defects, sinus obliteration is acceptable. However, *all* sinus mucosa must be meticulously removed from the entire sinus, including the anterior table bone. Initially a 4 to 6 mm cutting burr is used, followed by a 1 to 4 mm diamond burr for the periphery of the sinus. Access to the deepest portions of the sinus can be challenging, and particular attention must be paid to the scalloped areas above the orbits and at the periphery of the sinus (Fig. 84.48). After complete removal of the sinus mucosa, attention is turned to the frontal recess. The mucosa of the frontal sinus infundibulum is elevated and inverted inferiorly occluding the ostia. A small plug of temporalis muscle is then placed above the inverted mucosa. A *sharp* 5 mm osteotome is then used to obtain two 5 × 5 mm bone chips from the calvarium (Fig. 84.49). These are inserted to block the frontal sinus infundibulum (Fig. 84.50).

Many different autologous materials have been successfully used for sinus obliteration. These include abdominal fat, cancellous bone, muscle, pericranium, and spontaneous osteoneogenesis with "auto-obliteration" (2,6,7). While different authors may advocate a specific material having the "best" success rate in their hands (or at their institution), the success rate is more likely related to the complete removal of all sinus mucosa and meticulous attention to surgical technique

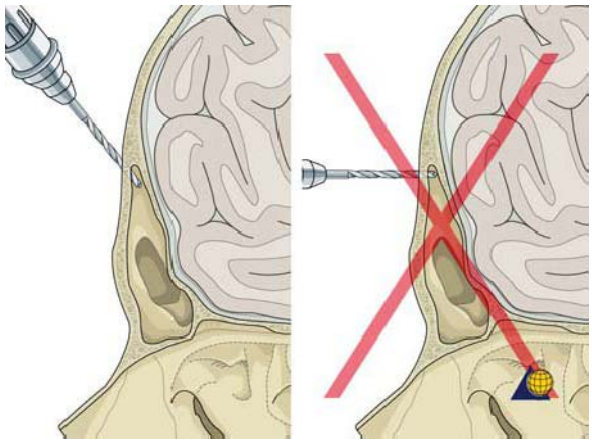

Figure 84.45 Illustration depicting the appropriate angle of approach to safely enter the frontal sinus and avoid violation of the posterior table. (From AO Surgery Reference Cranial Vault & Skull Base, www.aosurgery.org. Copyright by AO Foundation, Switzerland with permission).

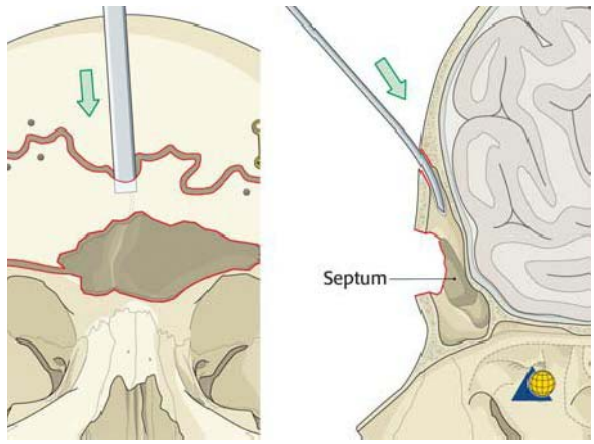

Figure 84.47 Illustration of curved osteotome used to fracture the intersinus septum and release the osteotomized frontal bone. (From AO Surgery Reference Cranial Vault & Skull Base, www.aosurgery.org. Copyright by AO Foundation, Switzerland with permission).

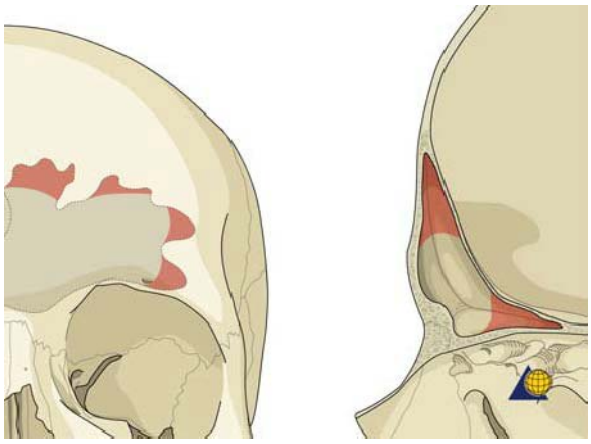

Figure 84.48 Complete removal of the frontal sinus mucosa is imperative to successful sinus obliteration. The areas above the orbits and at the periphery of the sinus (i.e., darkened areas) require special attention as they are more difficult to visualize. (From AO Surgery Reference Cranial Vault & Skull Base, www.aosurgery.org. Copyright by AO Foundation, Switzerland with permission).

rather than the type of autologous material used for obliteration. Overall, the success rates are quite high, but there is always small risk of late mucocele formation. The author prefers abdominal fat. Alloplastic materials, such as hydroxyapatite bone cement, should be avoided due to the risk of infection and extrusion. A fat graft is obtained through a left lower quadrant (or periumbilical) incision using a separate, sterile instrument set. The fat graft should be harvested in a single piece if possible, without the use of electrocautery. The fat graft is then inserted into the sinus cavity and trimmed to size. The anterior table fragments are replaced. Anterior table stabilization and wound closure are completed as described above under "closed reduction."

Frontal Sinus Cranialization

The most severe injuries result in disruption of the posterior table. Consultation with a neurosurgical colleague

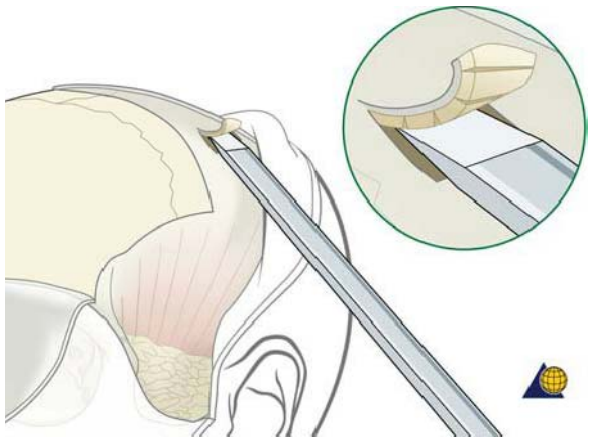

Figure 84.49 Illustration of outer table bone graft harvested from the parietal region. Note the bone graft is taken at a location where the periosteum remains intact. (From AO Surgery Reference Cranial Vault & Skull Base, www.aosurgery.org. Copyright by AO Foundation, Switzerland with permission).

is recommended. While the exact indications for cranialization of the sinus can be controversial, injuries that: (a) disrupt greater than 25% to 30% of the posterior table wall, (b) result in significant comminution and instability of the posterior table, and/or (c) require repair of a large dural laceration should be considered for cranialization. The surgical approach is described above (see "Frontal Sinus Obliteration"). It does not require a craniotomy and can be performed through the sinus itself. However, maintaining the integrity of the pericranial flap becomes more critical for dural repair and control of CSF leaks. All free bone fragments from the anterior *and* posterior table are removed. Fragments that are adherent to the dura should be freed with Penfield elevators (Fig. 84.51). The dura is then elevated from behind any stable bone at the periphery of the sinus and retracted with malleable brain retractors. Kerrison rongeurs are used to remove any remaining posterior table

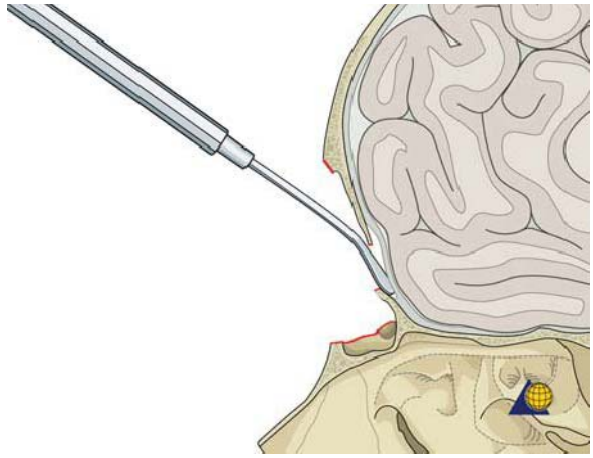

Figure 84.51 Illustration of dural elevation prior to removal of posterior table bone for a frontal sinus cranialization procedure. (From AO Surgery Reference Cranial Vault & Skull Base, www.aosurgery.org. Copyright by AO Foundation, Switzerland with permission).

bone (Fig. 84.52). A drill should be used to smooth the posterior table edge flush with the anterior sinus walls, floor, and anterior cranial fossa (Fig. 84.53). The frontal recess is occluded as previously described in "Frontal Sinus Obliteration." Simple dural lacerations can be repaired with interrupted 5-0 nylon sutures. More complex injuries may require neurosurgical debridement and closure with a pericranial flap. When a pericranial flap is used, a small bony defect must be fashioned just above the orbital rims to allow passage of the flap intracranially without strangulating it. The anterior table is then reconstructed using 1.0 to 1.3 microplates and mesh. The bony disruption of the anterior table can be so severe that posterior table fragments are required for reconstruction. The incision is closed as described under "Open Reduction and Internal Fixation."

SUMMARY

Optimal management of frontal sinus fractures remains a controversial topic. While there is a paucity of evidence to support a uniform approach to treatment, it is critical that each surgeon have a well thought out strategy for management of these injuries. The author provides an anatomically based, hierarchical treatment strategy for frontal sinus fractures. Differences in materials use for reconstruction, obliteration, or cranialization of the sinus are likely less important to a successful outcome than meticulous surgical technique. There is a long-term risk of mucocele formation in all patients sustaining frontal sinus fractures, even years after treatment. Patients must therefore be informed of this risk, educated about the signs and symptoms of a mucocele, and encouraged to actively participate in long-term follow-up.

HIGHLIGHTS

- The majority of frontal sinus fractures involve young males (average age 30 years) involved in high velocity injuries such as motor vehicle accidents (52%), assaults (26%), and recreation or industrial accidents (14%).
- A thorough history and physical examination is critical for patients with frontal sinus fractures. The majority of patients will have associated facial fractures and commonly have other non-head and neck injuries.
- The hierarchy of surgical management for frontal sinus fractures includes: management of any intracranial injury, avoidance of short- and long-term complications such as mucoceles, reestablishment of an aesthetic facial contour, and return of normal sinus function if possible.
- The gold standard for diagnosis is a thin cut (1.0 to 1.5 mm), axial CT scan with coronal, sagittal, and 3-D reconstructions.
- The appropriate treatment strategy for the management of frontal sinus fractures can be made by assessing *four* anatomic parameters. These parameters include the presence of: (a) an anterior table fracture, (b) a posterior table fracture, (c) a nasofrontal recess fracture, (d) a dural tear (cerebrospinal fluid leak).
- Nondisplaced (0 to 2 mm) anterior table fractures can be observed with little risk of long-term morbidity.
- Coronal incisions carry with them a moderate risk of alopecia. When recommending a coronal incision for mildly displaced fracture (2 to 6 mm), the risk of alopecia must be weighed against the risk of a cosmetic deformity if nothing is done.
- Patients with mildly displaced anterior table fractures that do not extend into the inferior orbital rim are potential candidates for endoscopic fracture treatment.

- Posterior table fractures are the result of higher velocity injuries and carry with them greater risk of long-term complications.
- If sinus obliteration is to be performed, it is absolutely critical that all sinus mucosa be meticulously removed to avoid long-term mucocele formation.
- Because mucoceles form very slowly, it is critical that the patient be informed of the associated symptoms, and that long-term follow-up is stressed.

85 Pediatric Facial Fractures

Peter C. Revenaugh *Paul Krakovitz*

The last 25 years have seen dramatic changes in the diagnosis and treatment of facial fractures driven by advances in imaging and the advent of internal rigid fixation. Rapid acquisition of high-resolution images with three-dimensional (3-D) reconstruction techniques has facilitated more accurate definition of fracture patterns and precise preoperative treatment planning. Advances in biocompatible materials with high tensile strength, low profile, and absorbable characteristics have allowed rigid fixation of complex injuries with minimal morbidity. These refinements in technology, along with increased understanding of facial biomechanics and growth patterns, have rendered complex injuries consistently amenable to precise 3-D reconstruction. However, controversy still exists regarding the suitability of rigid fixation for the developing pediatric craniofacial skeleton.

Despite controversies, the fundamental principles of pediatric traumatology are similar to those in adults. Goals include stable restoration of preinjury architecture with minimal functional and aesthetic impairment. A unique challenge to pediatrics is the need to reconcile acute injury and functional limitations with the potential long-term growth consequences. Fortunately, there is an increasing wealth of literature in this arena and this knowledge can be used to formulate a reasonable treatment plan. The evaluation and treatment of pediatric facial trauma should include consideration for the differential injury mechanisms and patterns as well as the potential growth implications on the developing facial skeleton.

EPIDEMIOLOGY

Trauma is the leading cause of death and major contributor to long-term morbidity among children in the United States (1). There are approximately 15,000 deaths annually from trauma and 100,000 children are permanently disabled (2). The estimated national health care cost for the treatment of pediatric injuries is over $15 billion (2). Despite the high prevalence of pediatric trauma, facial fractures in this age group are relatively rare, accounting for 5% to 14% of all facial fractures (1,3,4). This percentage has remained stable despite advances in motor vehicle and sport safety and accounts for a significant health care cost at an average charge of $22,510 for pediatric patients hospitalized with facial fractures (4).

An age differential is generally noted, where patients younger than 5 years of age are less likely to sustain facial fractures. Younger male patients are disparately affected at a rate of 1.5 to 3.1:1 versus females (1,4,5).

Nasal bone fractures likely account for the most frequently fractured facial bone, but precise statistics are not available as the majority of nasal fractures occur in isolation and are treated in the outpatient setting. More routinely, large studies report fracture incidence based upon emergency department and hospital admissions. Mandible fractures comprise the majority of these fractures accounting for 20% to 50% of facial fractures in the pediatric age group (5,6). The condyle is the most vulnerable and hence, most commonly involved site in 40% to 70% of mandible fractures (1,6). Rarely seen in young children, fractures of other mandible sites increase as children approach adolescence, reflecting adult frequency and anatomic location. Dentoalveolar trauma and fractures occur often in children but due to the same limitations in data gathering, frequency may be higher than reported. Midfacial fractures are less common in children, but orbital fractures are the next most frequent midfacial fracture after nasal bone fractures accounting for 15% to 39% or pediatric facial fractures (1,5,7). Isolated zygomaticomaxillary fractures occur in 10% to 20% of patients (1,5). Even less commonly, complex midface fractures account for 5% to 10% of pediatric facial fractures. Panfacial and Lefort fracture patterns are rarer still and the scarcity and diverse fracture patterns highlight the challenge in gaining experience in the treatment of such injuries.

Pediatric maxillofacial trauma frequently involves associated injuries due to mechanism and force variability. An estimated 30% to 75% of children with facial fractures have additional injuries (3,8). Frequently, pediatric patients hospitalized with facial fractures have concomitant brain injuries (32.3%), skull base fractures (27.7%), cranial vault fractures (13% to 30%), ocular injuries (7.2%), and cervical injuries (3.3%) (1,3). Orthopedic, thoracic, and abdominal injuries are also encountered, reinforcing the need for comprehensive initial assessment of pediatric trauma patients. Further, it may be necessary to delay fracture management in lieu of neurologic stabilization. This delay can complicate future treatment in the rapidly healing pediatric facial skeleton.

EMERGENCY MANAGEMENT AND PHYSICAL EXAMINATION

Initial assessment of all patients who have experienced trauma should adhere closely to advanced trauma life-support protocols (Table 85.1). Airway management can be approached using a variety of methods based upon the patient's injury profile and mental status. For the majority of isolated maxillofacial injuries, adequate positioning of the patient is sufficient for airway management, given appropriate consideration for cervical injuries. In addition to positioning, oral suctioning to remove saliva, blood, and tooth fragments can be beneficial. In some severe cases of bilateral mandibular fracture with tongue retrodisplacement, manual traction or midline tongue traction suture can help maintain airway patency until definitive airway management.

Orotracheal intubation may be necessary in situations where positioning is inadequate to maintain the airway, there is neurologic impairment, significant oral bleeding, or complicated maxillary fractures. Again, cervical spinal injures should be considered and airway management would ideally follow proper stabilization of the spine.

If oropharyngeal or laryngeal injuries are present, intubation should be approached in the operating room with rigid instrumentation available. Emergent cricothyroidotomies or tracheotomies are avoided in favor of orotracheal intubation. However, elective tracheotomy may be beneficial in patients with panfacial fractures or when fractures are accompanied by severe neurologic injuries.

TABLE 85.1 EMERGENCIES PEDIATRIC FACIAL TRAUMA

Adherence to the Airway, Breathing, Circulation (ABCs)
Emergent tracheotomies and cricothyroidotomies are ideally avoided
Septal hematoma requires urgent drainage

TABLE 85.2 DIAGNOSIS AND EVALUATION

Injuries inconsistent with the history should raise suspicion of child abuse
Secondary survey proceeds in an orderly fashion; neurologic assessment, manual palpation, inspection of the neck, spine, eyes, nose, face, and oral cavity
Periorbital edema and hypoesthesia, ecchymoses, subconjunctival hemorrhage, diplopia, and mobility reduction are indicative of orbital injury
Suspected orbital trauma warrants an ophthalmologic evaluation
Trapdoor or "white-eyed" fracture can be subtle with limited supraduction mobility
Malocclusion is indicative of mandibular fracture
Intranasal examination is essential for septal injury, particularly septal hematoma
CT has revolutionized the evaluation of pediatric trauma

Once the patient has been stabilized according to trauma protocols, the secondary survey should proceed in an orderly fashion, keeping in mind that portions of the exam may be difficult to accomplish in an uncooperative or neurologically injured child (Table 85.2).

Full neurologic evaluation should be pursued, followed by examination of the neck and cervical spine. Attention to overall level of consciousness and cranial nerve integrity is crucial in this assessment. Particular attention to sensation of all divisions of the cranial nerve V and the motor function of the facial nerve are paramount. Ophthalmologic examination should focus on overall visual integrity, pupillary evaluation, range of motion examination, ophthalmoscopy, or presence of diplopia or ophthalmoplegia. Forced duction testing may be performed, usually under anesthesia in cases of suspected orbital trauma. Otoscopy may reveal hemotympanum or cerebrospinal fluid (CSF) otorrhea associated with temporal bone fractures. External auditory canal lacerations associated with mandibular condylar fractures or displacement may also be seen on otoscopy. Anterior rhinoscopy should focus on ruling out nasoseptal injuries, particularly hematomas and CSF rhinorrhea. Full oral examination is crucial to assess occlusion, dentoalveolar injuries, missing or broken teeth, tongue injuries, or palatal fractures associated with midface injuries.

The facial skeleton should be approached in a systematic fashion with observation followed by palpation. Facial asymmetry, ecchymosis including "raccoon eyes" or Battle sign, edema, periorbital edema, conjunctival chemosis, epistaxis, malocclusion, trismus, and gingival laceration all are signs of potential underlying fractures. Once the face has been thoroughly inspected, palpation of the buttresses follows, usually beginning at the zygomatic arches or supraorbital rims and proceeding caudally. Asymmetry, tenderness, mobility, or crepitus should be

noted wherever present. Areas of frequent fracture should be examined including the nasal bones, orbital rims, and malar eminences. Assessment of midface stability is accomplished with attempted movement of the premaxilla with one hand while stabilizing the head with the other hand. Maxillary buttressing can also be palpated intraorally. Bimanual palpation of the mandible should focus on loose teeth or tooth segments, and attempted elicitation of mobility in multiple vectors. Any missing teeth should be catalogued and considered as a potential source of airway foreign body. As with the facial skin, oral mucosa and all oral structures should also be inspected.

As time and witness availability allows, an accurate history should be obtained. Injury mechanism and assessment of velocity may predict potential fracture patterns or concomitant injuries. Any suspicious stories or inconsistent injuries should raise the threshold of concern for child abuse or nonaccidental injury.

RADIOGRAPHIC EXAMINATION

Computed tomography (CT) has revolutionized the diagnosis and treatment of facial fractures. Contemporary scanners allow rapid image gathering, ultrafine cuts (1 mm), multiplanar and even 3-D reconstructions for fracture identification and treatment planning, especially in the multiply injured children. Axial cuts provide a reasonable starting point for overall facial assessment and are particularly useful in the mandible, midface, nasal bones, and frontal sinuses. Coronal cuts are necessary for evaluating the orbital floor and may provide valuable information regarding the mandibular condyle. Sagittal cuts can provide additional information about the orbital floor, roof, and overall facial and mandibular projection.

Though CT is regarded as the "gold standard" for facial skeletal assessment, mandible panoramic x-rays (Panorex) are still useful in the evaluation of the isolated mandible fracture. Care should be taken to ensure condyle inclusion and the clinician should understand that Panorex may be inferior to helical CT in evaluation of the condyle or multiply fractured mandible (9). Plain films are now of little use in facial fracture workup and may delay diagnosis or miss facial fractures (5,10). However, nasal plain films are still commonly encountered in the emergency department setting. One should recognize the potential inadequacy of facial plain films and the subsequent need for CT in cases of nasal fracture where there is significant deformity and flattening of the dorsum or a history of significant contributing force. However, imaging in the vast majority of isolated pediatric nasal injuries is unnecessary.

ETIOLOGY/MECHANISM OF INJURY

The variable structural characteristics of the developing face and skull in relation to the mechanism of trauma determines the risk and pattern of facial fractures. Young children are generally spared from facial fractures due in part to their protected environment and minimal engagement in activities known to be risk factors for fractures. When considering all types of pediatric facial fractures, including nasal and dentoalveolar, childhood play may account for the greatest percentage (11). However, motor vehicle collisions account for the vast majority of serious facial fractures (1,5). The risk of serious facial fracture is doubled by inappropriate motor vehicle restraint in children (1,12). Falls, interpersonal violence, and sporting injuries are all common causes of fractures and vary in percentage based upon the age group of the patient. Bicycles have remained a common cause of pediatric facial fractures. Though helmets have contributed to a reduction in intracranial injuries and midfacial injuries, they do not protect against mandibular and dentoalveolar trauma (13). Fractures in young, especially preambulatory patients, or fractures of the mandible should be remembered as a possible indication of child abuse (3).

The anatomic development of the face is important to understand the different patterns of fracture seen between adults and children. At birth, the ratio of cranial to facial volume is approximately 8:1 with the face set in a recessed position. The relative protection of the skull contributes to a lower incidence of facial fractures, but a higher incidence of skull fracture and intracranial injury in young children (14). Facial growth generally occurs in a downward and forward direction and begins to outpace cranial growth after the second year of age. The orbit and brain near completion of growth by age 7, but facial growth continues well into the second decade of life. In the developing face, the bones have less mineralization with a greater proportion of cancellous bone, thinner cortices, and the sutures are not fused in infants. These factors, combined with the presence of multiple tooth buds and the lack of paranasal sinus development, make the infant craniofacial complex a solid yet elastic structure, resisting fracture. These factors also contribute to the higher proportion of greenstick fractures observed in pediatric patients. Likewise, suture ossification, sinus pneumatization, tooth eruption, and greater independence contribute to the transition from pediatric to adult fracture patterns.

FACIAL GROWTH AND TRAUMA

Understanding of craniofacial growth and its relation to trauma is limited. Coordination mechanisms of facial growth and the exact genetic and environmental contributions are unclear. A complete discussion of the various theories of facial growth and regulation is beyond the scope of this chapter. However, it is fairly accepted that facial skeletal growth and development consists of remodeling and displacement combined with inner table resorption and outer table deposition (15). Factors contributing to bony growth undoubtedly include finely regulated local and systemic factors as well as vector forces acting on the bones.

Figure 85.1 **A:** 3-D CT reconstruction of a 3-year-old child with mandibular hypoplasia, retrognathism, and right temporomandibular ankylosis. The child had a history of crush injury to the right mandibular condyle in the first year of life. **B:** 3-D CT scan of the child depicted in **(A)** shows a normal left condyle and an abnormal, hyperplastic right condyle with a foreshortened condylar neck ankylosed in the right temporomandibular joint.

The facial skeleton can be divided into two independent, yet related growth areas—the nasomaxillary complex and the mandible. Alterations in growth and remodeling within and between these areas due to trauma contribute to the deformities and dysfunction observed.

Mandible growth has long been associated with the condyle, although it is likely there are a series of growth centers that contribute to overall growth. As an area of continued growth throughout childhood the condyle seems to have an ability to remodel quickly (less than 12 months) under the strains of mastication (16,17). However, crush injuries to the condyle and injuries involving condylar head can lead to mandibular and maxillary growth asymmetries or ankylosis (Fig. 85.1) (18). Norholt et al. (19) demonstrated that younger children have fewer deformities following trauma suggesting that growth may compensate for the injury. Contrary, Rowe (2) found that injuries occurring before 3 years of age generally produced more severe deformities. Despite these apparent disparities, there is consensus that early return of mandibular mobility in pediatric patients is desirable to limit the risk of ankylosis and to stimulate normal growth and remodeling.

The nasomaxillary complex appears more sensitive to the effects of trauma on normal growth. This may be due to the multiple suture sites, limited functional restorative movement compared to the mandible, or the importance of the septum as a regional growth site. Numerous animal studies involving septectomies and septoplasties in the last three decades have continued the debate into the role of the septum as a growth center for the midface (20–22). Small case series and twin studies in humans have demonstrated midfacial hypoplasia following trauma to this area (23). Surgical manipulation of the nasoseptal area in the pediatric population carries the same concerns for midfacial or nasal growth alteration; however, evidence is limited (24). Unless functional limitation or gross deformity exists, minimal surgical manipulation of the area is recommended, especially in the area where the septal cartilage contacts the bony septum (25).

The potential effects of trauma on growth should be a counseling point with parents following injury and care should be taken wherever possible to minimize additional growth alteration risk during treatment. Minimizing additional risk would include careful restoration of the periosteum and other soft tissues with minimal periosteal elevation, attention to realignment of the septal cartilage where possible, and accurate reduction with correct suture realignment. Long-term follow-up for pediatric trauma patients is essential in identifying alterations in growth and initiating appropriate orthodontic treatment if necessary.

RIGID FIXATION

The role and best use of rigid fixation in children is still controversial, given the aforementioned concerns regarding facial growth and other potential complications of internal fixation (Table 85.3).

As with traumatic injuries, animal studies have investigated the potential growth retardation related to plating. Plating across suture lines and elevation of the periosteum has demonstrated restricted growth in several animal models (26,27). Laurenzo et al. (27) observed an equivocal amount of growth restriction between rabbits that had

TABLE 85.3 COMPLICATIONS FACIAL FRACTURES

The nose, nasoethmoidal complex, and maxilla are susceptible to growth abnormalities as a result of trauma
More severe types of pediatric facial trauma are associated with concomitant injuries— especially neurologic in up to 60% of patients
Fracture complications can include delayed sinus infections, malunion, malocclusion, TMJ dysfunction, and delayed growth disturbances
Inadequate treatment of upper and midfacial injuries may result in serious alterations of facial growth
Bone growth can cause translocation of metallic implants

trauma and those that had trauma and subsequent fixation. They concluded that plating offers no additional growth restriction beyond that of the initial trauma. Their group then reported that subsequent removal of the plates had additional detrimental effects to growth in rabbits (26).

Human studies have also demonstrated growth restriction in the setting of plated fractures (28). These data have caused some clinicians to recommend plate removal, although detractors would cite the animal evidence that removal may further traumatize growth centers and less than 8% of patients who are observed eventually require plate removal (28). Independent of growth considerations, metallic hardware can be complicated by palpability, hypersensitivity, bone atrophy, tooth bud injury, and potential interference with future imaging. Plate displacement, plate and screw migration (even intracranial), and plate isolation are also complications to consider when planning rigid fixation (29).

To avoid the complications associated with permanent plates and screws in the developing face, absorbable plating systems have been developed. The safety and efficacy of these systems have been established and this technology gained U.S. Food and Drug Administration (FDA) approval in 1996. High molecular weight polyalphahydroxy acids are the most commonly used craniofacial bioabsorbable materials including polylactic acid (PLA) (both L and D enantiomers), polyglycolic acid (PGA), polydioxanone (PDS), and their copolymers. Biodegradation of PLA and PGA occurs in two phases; a hydrolysis phase where water molecules cleave the larger macromolecules, and a metabolic phase where macrophages phagocytize the polymer fragments (30). Substantial strength loss occurs during the hydrolysis phase and the space occupied by the absorbable screws is eventually obliterated by bony ingrowth (30). During degradation, PLA and PGA are metabolized into carbon dioxide and water and eliminated through respiration whereas PDS degradation products are primarily excreted in the urine (30). Pure polymers have disadvantageous properties in regard to strength, degradation time, and local tissue reactions.

Currently available plating systems utilize copolymers of PLA and PGA allowing a variety of strength profiles and degradation times from 6 months up to 6 years (30). Physical and biomechanical studies have demonstrated that available absorbable plates provide flexural and tensile strength comparable to available titanium microplate systems (31). Ideally, plate resorption should occur after the 4 to 6 weeks necessary for full fracture healing and indeed, commercially available systems retain 60% to 80% of their strength at 10 weeks (30).

Complications observed with absorbable plating commonly include peri-implant edema, temporary visibility, and palpable hardware (30). Degradation appears to elicit only a mild foreign body reaction in the surrounding tissue. As in permanent fixation, some controversy exists regarding the potential growth restrictive properties of absorbable plating procedures. To date there have been few long-term studies to address this possibility.

Currently, resorbable plating systems are recommended for "non–load-bearing" areas of the upper face and midface. Although plating of mandible fractures and saggital split osteotomies have been described, their use in these contexts is still investigational in children with limited long-term data (32). The somewhat larger screws, thicker plates, and limited malleability of absorbable systems can limit use in areas of thinner skin or in severely comminuted fractures. As technology improves, changes in product properties and indications are expected.

While it has been demonstrated that open reduction and internal fixation (ORIF) for the treatment of mandibular and complex midface fractures is safe and efficacious, especially in children older than 13 years, the risks and benefits of internal fixation must be weighed prior to intervention (Table 85.4) (3).

Many minimally displaced or greenstick fractures can be managed conservatively. Management of moderately displaced fractures requires higher clinical acumen and can be guided by postreduction stability. However, in certain complex cases, or load bearing segments, rigid fixation cannot be avoided. Whether rigid or absorbable, plates should be as small as possible without compromising stability, as

TABLE 85.4 TREATMENT PEDIATRIC FACIAL FRACTURES

Orotracheal intubation is ideally accomplished after securing the cervical spine
Careful restoration and resuspension of injured soft tissue
Reduction of fractures into stable anatomic locations
ORIF is indicated in unstable fractures
Correct realignment of suture lines
Minimal periosteal elevation
3-D, stable fixation
Use of bone grafts in areas of bone loss
Mandibular fractures with normal occlusion and mobility treated with soft diet
Malocclusion or movement limitation treated with MMF or ORIF
Traumatic telecanthus associated with nasoorbitoethmoid fractures is best treated with transnasal wiring

short as possible, and ideally not placed over more than one suture. Periosteal elevation should be minimized and dissected tissues reapproximated precisely.

SURGICAL APPROACHES

Despite advances in rigid fixation, it is important to remember that many pediatric fractures can be managed with closed techniques. In cases of displaced or complex fractures where fixation may be necessary, much of the facial skeleton can be exposed through a single incision or combination of several incisions.

The upper third of the face can be approached through a coronal incision to access the upper orbital rims, forehead, and nasoorbitoethmoid (NOE) complex. Subfascial release of the temporalis fascia allows complete exposure of the zygomatic arches. Exposure of the orbital rims can be accomplished using a subciliary or more popularly a transconjunctival incision with or without a lateral canthotomy. The medial orbit and apex can be approached via a transcaruncular incision (33). For important realignment of the midfacial nasomaxillary and zygomaticomaxillary buttresses, an upper gingivolabial sulcus incision can provide access to the entire maxilla and zygoma with care taken to identify the infraorbital nerve. In the case of especially complicated fractures requiring wide exposure, a midfacial degloving approach can be used.

Fractures of the mandibular symphysis, body, and angle can be approached through a lower gingivolabial sulcus incision. Rarely, plating of ramus fractures or comminuted fractures of the angle and body can be reduced through an external approach.

As always, tenets of limited periosteal dissection with careful restoration of soft tissue should be observed. In complex fractures, accurate reestablishment of facial buttresses to provide preinjury occlusion, facial width, and height is fundamental.

NASAL FRACTURES

Visual examination of the pediatric nose reveals the differences in anatomy from the adult nose. Children have limited nasal projection and the projecting tissue comprises soft cartilage that is compliant to physical forces. As a result, the pediatric nose deforms readily, dissipating force across the maxillary soft tissues and lateral buttresses. Rarely are the nasal cartilages injured. However, the underlying septum is relatively rigid and prone to injury with trauma of significant force. Three types of septal injuries are observed in children. The perichondrium can be sheared from the septum creating a potential space for blood and resultant hematoma. Secondly, a dislocation of the caudal septum can lead to nasal deformity and obstruction. Lastly, separation of the bony and cartilagenous septum can be observed, leading to nasal obstruction and growth abnormalities.

Nasal bones have limited projection in young children and therefore are rarely fractured in this age group. Fracture risk increases with age and if present in younger children, they can be of the greenstick variety. In addition to limited projection, the nasal bones are not fused in the midline in young children, resulting in "open-book" fractures where the nasal bones are separated in the midline and splayed over the maxilla. Clinicians should have an index of suspicion for occult nasoorbitoethmoid fractures in children with fractures of the nose with "open-book" fractures or a history of direct trauma to the nasal bridge.

Initial examination is often of limited utility due to the presence of midface edema from force dissipation and the lack of external deformity. Several days of observation may be necessary before the true cosmetic deformity can be appreciated. Initial examination must focus on evaluation for septal injury and hematoma. Nasal obstruction and unilateral septal bulging are hallmarks of a hematoma. A septal hematoma will classically appear purplish and compress with manipulation but not resolve with decongestion. Untreated and even treated hematomas can lead to a variety of complications including a fibrotic septum or loss of cartilage and resultant saddle-nose deformity (34).

Treatment of a septal hematoma is best approached under anesthesia in the pediatric population. The hematoma is incised via a Killian incision, allowing exploration of the septum and limited reduction of cartilaginous fragments. Through-and-through quilting suture should reapproximate the mucoperichondrial flaps. Septal splints can be used for 2 to 3 days to prevent reaccumulation. Packing can be poorly tolerated and only advised if there is strong justification for its use. Perioperative antibiotics are recommended. Closed reduction can be accomplished in the same setting if dorsal nasal fractures are encountered.

If no hematoma is encountered and there is no notable nasal deformity, the patient can be reevaluated in 3 to 5 days once edema has resolved enough to reveal any deformity. If bony or septal injuries are discovered causing a fixed nasal obstruction or poor cosmesis, definitive management is recommended. Usually, closed reduction is sufficient. Greenstick fractures and septal fractures may require open approaches to adequately reduce. Injuries presenting 2 to 3 weeks postinjury may require open reduction due to rapid ossification. Timing of open reduction is debated and should take into account the deficit or defect, patient age, and potential for altered growth.

NEWBORN NASAL DEFORMITY

Occasionally newborns may be born with a grossly asymmetric nasal tip. Intrauterine positioning and trauma while traversing the birth canal are two potential etiologies. Classically, the septum is deviated to the same side of the nasal tip and the nasal dorsum is unaffected. Since neonates are obligate nasal breathers, nasal obstruction would be an indication for early septal relocation. Otherwise, the nasal tip and septum eventually straighten in the majority of cases and reassurance is all that is needed (35).

FRACTURES OF THE MANDIBLE

Fractures of the mandible account for 13% to 48.8% of pediatric facial fractures with increasing frequency as patients age (1,5,7). Concerns over the developing face and dentition dictate management decisions, which are somewhat different in pediatric versus adult patients. Although treatment modalities may differ, the overall goal is accurate alignment and reduction with restoration of preinjury occlusion.

Unique to the pediatric mandible are concerns presented by the developing dentition. Until age 2 there is incomplete eruption of the deciduous teeth. In this age group traditional methods of immobilization may be inadequate. Age 2 to 5 years, the deciduous incisors and molars have firm roots for fixation if needed. From age 5 to 9 there is mixed resorption of the deciduous roots and incomplete eruption of the secondary dentition. Once children are 10 to 12 years old, an adequate compliment of secondary teeth for fixation is present.

Maxillomandibular fixation (MMF) is used more sparingly in the pediatric population given concerns for joint ankylosis, tooth development, and general airway concerns. If deemed necessary, 2 to 3 weeks of immobilization in children less than 12 years of age is adequate. When used, differences in dentition phase may dictate MMF type. Patients who have no teeth or limited deciduous teeth, an acrylic splint can be fabricated using plaster casts of the upper and lower dentition positioned in estimated occlusion to cast the final splint. The acrylic splint can be secured using circum-mandibular and transnasal wires (Fig. 85.2). Alternatively, screws can be placed in the zygoma and inferior mandibular border and secured with monofilament suture. However, this is

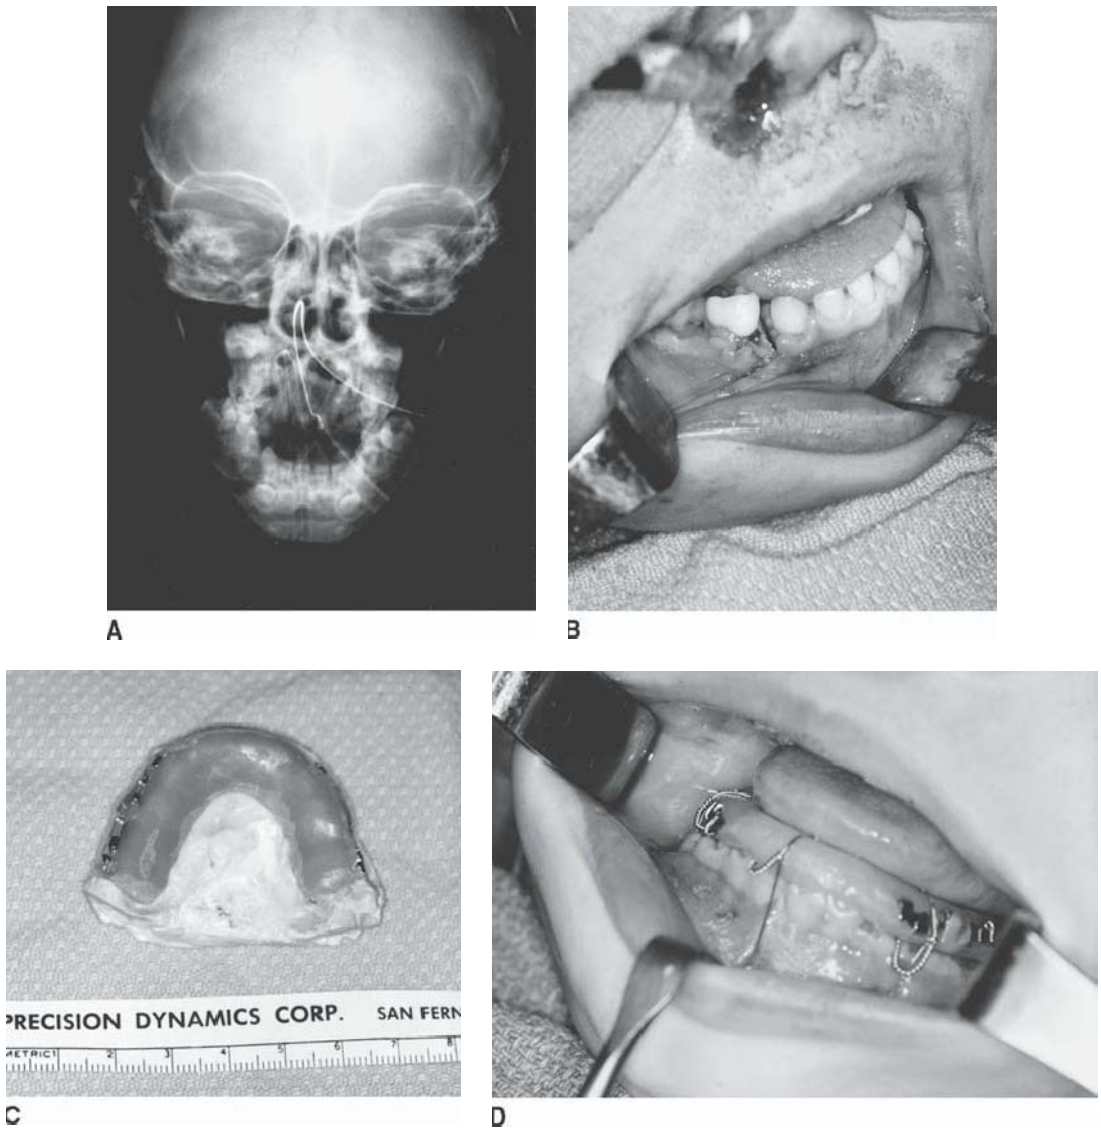

Figure 85.2 **A:** Towne view shows right parasymphyseal mandibular fracture in a 3-year-old girl. **B:** Clinical photograph shows the fracture depicted in **(A)**. **C:** Acrylic splint fabricated on a plastic cast of the mandible. The original impression of the mandibular arch was cut and the occlusion established to the maxillary impression before fabrication of the splint. **D:** Acrylic splint wired into place with circummandibular wires.

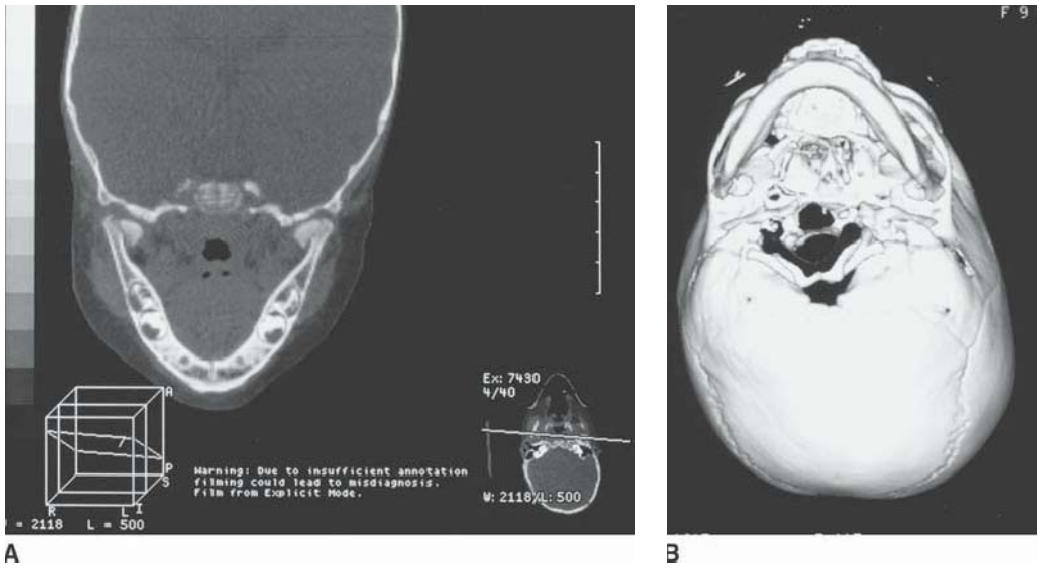

Figure 85.3 Coronal **(A)** and 3-D reconstruction **(B)** CT images of a 10-month-old infant with bilateral displaced subcondylar fractures. Coronal view shows symphyseal greenstick fracture of the lingual cortex. This child was treated expectantly.

inadvisable in older patients as the masticatory muscles may be strong enough to resist the fixation. Once patients are 2 to 5 years old, the deciduous teeth have firm enough roots for cap splints and arch bars. Arch bars may be difficult to secure, however, due to the shape of the teeth. If using MMF from age 2 to 5, augmentation of fixation may be obtained using pyriform aperture and circum-mandibular wiring. After 10 years of age, children generally have enough permanent dentition to securely place arch bars.

Consideration for the growing face cannot be overemphasized in fracture management. Complications of pediatric mandibular fractures in general can include malocclusion, malunion, nonunion, infection, tooth loss, and temporomandibular joint (TMJ) dysfunction. Greenstick fractures are common and teeth are often encountered in the fracture line and should not be removed unless devitalized (36). Prolonged MMF places the patients at risk for TMJ ankylosis, which can be difficult to treat and result in growth abnormalities.

FRACTURES OF THE CONDYLE

Fractures of the condyle account for the majority of mandibular fractures in children (6). These can be classified into three anatomic types: intracapsular crush fracture of the condylar head, high condylar fracture above the sigmoid notch, and low subcondylar fracture. The low subcondylar fracture is the most common type with many being greenstick fractures. Although the condylar head has rapid resorption capabilities, there is evidence to suggest that trauma to this growing area can result in growth arrest or functional or radiologic deformity in up to 20% of patients (37). Therefore, long-term follow-up and possible orthodontic intervention is advised.

Most clinical and experimental data support a conservative closed approach to the majority of condylar fractures. A primary clinical decision point is usually whether or not to immobilize the patient. Often, unilateral condylar fractures with normal range of motion and normal occlusion, a soft diet and movement exercises are all that is necessary. If there is good occlusion, but deviation with movement, arch bars with elastic guiding bands may be helpful. Commonly, an open bite may be a sign of unilateral or bilateral condylar fracture (Fig. 85.3). If there is an open bite, mandibular retrusion, or movement limitation, a short course (2 to 3 weeks) of MMF may be helpful followed by elastic bands if needed. Open surgical repair of the condyle is rarely indicated except in instances of displacement into the middle cranial fossa or severely restricted mandibular movement. Preauricular and submandibular approaches can be used.

FRACTURES OF THE ARCH OF THE MANDIBLE

Fractures of the arch of the mandible can range from greenstick fractures to displaced bicortical fractures and are commonly associated with fractures of other mandibular site in up to 30% of cases. Often, masticatory muscles exert unfavorable forces on fractures of the anterior arch causing displacement that can be carefully reduced under anesthesia.

Treatment of arch fractures ranges from soft diet to MMF or ORIF with miniplate fixation. Arch bar placement can be complicated by dentition stage and unfavorable splaying of the inferior border of the fracture. If rigid fixation is used, monocortical screws should be placed with cognizance of the underlying developing tooth buds

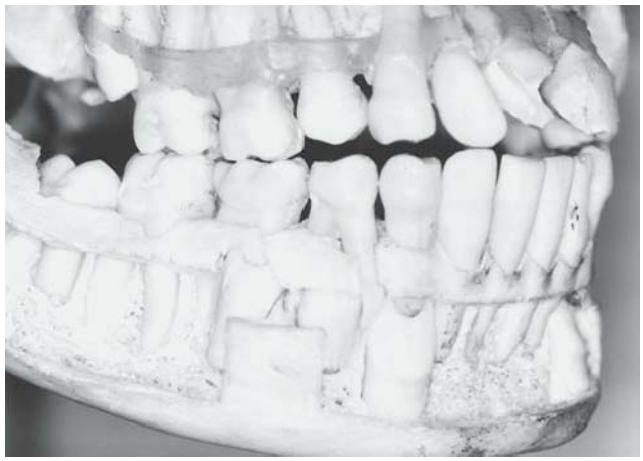

Figure 85.4 Proximity of the unerupted canine and bicuspid teeth to the lower margin of the mandible.

(Fig. 85.4). However, once children have a full complement of secondary dentition, adult treatment algorithms apply. Currently, absorbable plating systems are not FDA approved for mandible fracture treatment (30). Fractures of the body and angle commonly are of the greenstick variety, typically with normal jaw movement and occlusion. In these cases, soft diet and observation is appropriate. Conservative plate placement again should be observed if internal fixation is deemed necessary.

DENTOALVEOLAR FRACTURES

Dentoalveolar fractures are relatively common in pediatrics involving the incisors and canine teeth most often (38). Treatment of these fractures should occur on an emergent basis to stabilize the traumatized bone and teeth. Avulsion of primary teeth without bone is not serious, but it is often difficult to determine if a tooth is primary or secondary, so reimplantation of any avulsed teeth is a safe strategy. Acute treatment involves preserving and cleaning of the tooth with replacement in the socket in cooperative patients while arranging prompt dental consultation. If the child is uncooperative, the tooth can be placed in a saline solution, moist gauze, or submersed in milk until dental implantation. Every effort to implant within 1 hour of injury should be made to give the best chance for recovery. Treatment of the loss of multiple teeth or alveolar bone is challenging and may require MMF or miniplate fixation, generally with poor tooth survival rates (38).

FRACTURES OF THE MIDFACE

Fractures involving the midface, orbit, and nasoethmoidal region are rare in children and often result from significant forces with associated intracranial injuries. Injuries can range from isolated orbital blow-out fractures to severely comminuted fractures involving multiple facial buttresses. Severe facial edema, orbital ecchymosis, and malocclusion are signs of an underlying fracture. CT with multiplanar views is essential in diagnosis and treatment of midface fractures. Ophthalmologic examination should be undertaken with any fractures involving the orbit. Evaluation for vision loss, enophthalmos, exophthalmos, globe rupture, vertical dystopia, or elevated intraocular pressure is necessary. Sensory nerve integrity and intercanthal distance should also be inspected. Medial canthal stability and forced duction tests are generally reserved for patients under general anesthesia.

In midface fracture treatment, a multidisciplinary approach is necessary with the goal of therapy to establish facial symmetry, 3-D proportions, occlusion, and function. Taking into account the overall medical condition of the patient after a potentially severe trauma, fracture reduction should be attempted within 10 days. Pediatric bone can reossify rapidly, making future correction difficult. If necessary, acute reduction can be attempted through existing lacerations.

Lefort fracture patterns can be used to describe complicated midface fractures. However, these classifications are rarely adequate in pediatric midface fractures due to the variety of fracture patterns associated with variable paranasal sinus development. With high-velocity midface injuries, fractures of the palate instead of Lefort I patterns can be observed due to lack of maxillary sinus development and incomplete midline palatal fusion. Oblique fractures extending through the frontal bone and fractures of the cranial vault are also observed with upper midface trauma (39). Due to the variety of fractures, classification schemes to describe treatment implications have been proposed (11). Type I fractures are minimally displaced, Type II are moderately displaced with some areas of comminution. Type II injuries can involve multiple buttresses, but the fragments are recognizable and large enough to rigidly fix. Type III fractures are severely displaced with multiple areas of comminution involving buttresses where 3-D stabilization and bone grafting may be necessary for adequate reduction.

FRACTURES OF THE ZYGOMATICOMAXILLARY COMPLEX

Zygomaticomaxillary complex fractures generally do not occur under the age of 5 owing to the lack of maxillary sinus pneumatization. After this age, fracture patterns resemble those in adults although involvement of the orbital floor and rim can be observed more frequently in children (40). Greenstick fractures of the frontozygomatic suture and zygomatic arch with medial displacement of the malar fragment are commonly seen. In these cases, single-point fixation of the zygomaticomaxillary buttress may be adequate. More often, two- or three-point fixation is required and proper reduction should be confirmed with palpation at the zygomaticomaxillary, frontozygomatic, and even zygomaticosphenoid sutures. Fixation is often undertaken at the zygomaticomaxillary buttress through a

gingivolabial incision, and at the orbital rim and/or frontozygomatic suture through a subciliary or transconjunctival incision with lateral canthotomy. If exposure of the zygoma is necessary for complex or comminuted fractures, a hemicoronal incision can be added.

Isolated zygomatic arch fractures without displacement can be observed with institution of a soft diet. Minimally displaced fractures can be reduced via the intraoral route, a Gillie approach or even directly through existing wound or transcutaneously with a bone hook. Contingent upon reduction and stability, isolated zygomatic fractures may not require further fixation.

FRACTURES OF THE ORBIT, ORBITAL ROOF, AND FRONTAL BONE

Fractures involving the orbital and orbitoethmoid area can range from simple to quite complex and result in severe functional deficit and poor aesthetic outcomes. Thirty percent of orbital fractures are associated with other facial fractures (41). As with midface fractures, ophthalmologic consultation is imperative and consideration for intracranial injuries should be maintained, especially in cases of orbital roof, frontal bone, NOE, or bilateral orbital fractures. Assessment of visual acuity should be primary as optic nerve injury can result from apex fracture or extension of orbital wall buckling. Loss of visual acuity and the presence of an afferent pupil defect are hallmarks of optic neuropathy. Fractures of the orbital apex are exceedingly rare and usually associated with other nonsurvivable injuries due to the force required to injure this area. Attention should also be given to orbit position, extraocular movements, pupillary abnormalities, cranial nerve V integrity, and intercanthal distance.

Fracture patterns in this area tend to be age specific paralleling paranasal sinus development. Maxillary sinus pneumatization generally begins after age 5, when isolated orbital floor fractures are more often seen. The ethmoid air cells continually expand throughout childhood, reaching 70% of interorbital width by age 7 and frontal sinus development generally begins around age 6 (42).

ORBITAL FLOOR AND MEDIAL WALL FRACTURES

Due to lack of sinus pneumatization, isolated orbital floor fractures are infrequent in young children. In older children, they are more commonly seen as a result of play or sporting injuries. Coronal CT offers the best depiction of these fractures and ophthalmologic evaluation should be included in the work-up, but serious ocular injury occurs in less than 5% of isolated orbital blow-out fracture (43). Diplopia, enophthalmos, periorbital edema, echymosis, and infraorbital hypesthesia can be observed. Fracture patterns have been described as "trapdoor" or "saucer" patterns.

The *trapdoor* fracture is a linear orbital floor fracture, hinged medially that can allow herniation of orbital contents into the maxillary sinus (43). These are more commonly seen in the pediatric population, probably due to a higher incidence of greenstick fractures, where self-reduction occurs. Trapdoor fractures are also known as "white-eyed" fractures due to their subtle presentation. Extraocular mobility reduction with forced duction examination is diagnostic (44). CT may reveal linear fracture along infraorbital nerve but is not necessary for diagnosis. Urgent surgical intervention is indicated in cases of entrapment with oculocardiac reflex resulting in emesis, bradycardia, and/or arrhythmia (45). True entrapped fractures should be explored within 48 hours to reduce risk of permanent diplopia or symptomatic oculocardiac reflex (46).

Saucer fractures result in a depressed orbital floor with potential for herniation or orbital contents and resultant enophthalmos. Surgical intervention in nonurgent cases is based upon need for concomitant exploration with other fractures, significant enopthalmos (greater than 2 mm), extraocular muscle restriction on forced duction, symptomatic diplopia, or CT findings indicating large fracture (greater than 50% of the orbital floor or wall) (47). Patients not indicated for surgery can be observed for a period of days to weeks for resolution of edema or diplopia. The orbital floor can easily be exposed through transconjunctival or subciliary incision with delicate reduction of bone fragments. An array of repair materials has been cited throughout the literature. The more commonly described absorbable gelatin film can be used for reconstruction of floor defects and if necessary split calvarial bone for larger defects.

Medial orbital wall fractures rarely occur in isolation and are commonly denoted by orbital emphysema on CT scan (33). Surgical repair is indicated for fixed enopthalmos or entrapment of medial muscles. Exposure can be facilitated through transcaruncular or external ethmoid incision, with a transcaruncular approach offering a more inconspicuous scar (33).

FRACTURES OF THE NASOETHMOIDAL COMPLEX

Nasoorbitoethmoid fractures involve the central core of the face including the nasofrontal suture, nasal bones, medial, and inferior orbital rim. These fractures can range from minimal displacement to complicated comminution. CT is essential in operative planning with axial images demonstrating degree of posterior displacement into the ethmoid sinuses and coronal images displaying medial wall and orbital floor displacement (Fig. 85.5). Medial canthal tendon integrity should be investigated under general anesthesia with a hemostat inserted intranasally toward the medially orbital rim. Additionally, intercanthal distance should be measured to determine hypertelorism. Although there is

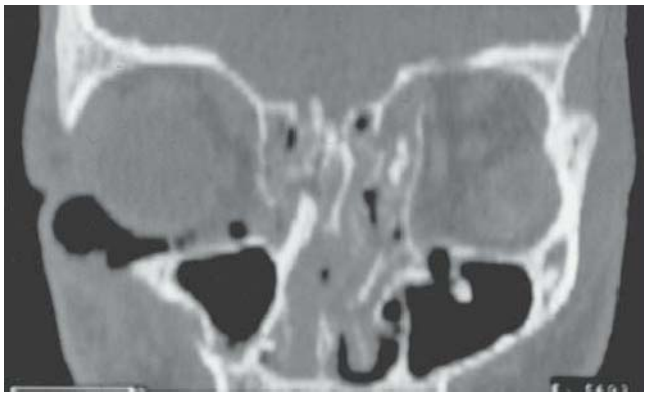

Figure 85.5 Coronal CT reconstruction of a complex nasoethmoidal fracture in a 12-year-old child. Disruptions of the nasomaxillary buttress are evident on the right, the medially orbital walls bilaterally, and the orbital floor on the left.

considerable variability in intercanthal distance between individuals, the average distance at age 3 is 25, 28 mm at age 12, and reaching 30 mm in adulthood (48). Five millimeter of widening is suggestive of a displaced fracture while 10 mm is diagnostic.

Status of the fragments can aid in treatment planning. Fractures can be categorized into three types based upon fragment status (49). In type I fractures the medial canthal tendon remains attached to a central fragment of bone, type II fractures display comminution of the central fragment without extending deep to the anterior lacrimal crest, and type III fractures are severely comminuted.

ORIF is the most reliable method of treatment with correction of the intercanthal distance paramount. Overcorrection may result in superior results versus undercorrection. Existing lacerations or bicoronal incisions can be used for intervention. Plating, wiring, and calvarial bone grafts for dorsal reconstruction may be necessary. Wiring can be accomplished by drilling bilateral holes in the anterior lacrimal crest just above and posterior to the anterior insertion of the tendon and in the posterior lacrimal crest just behind the insertion of the posterior limb of the tendon. Twenty-eight-gauge Kirschner-wire can be threaded through the holes and tightened to desired correction. Additional plate stabilization may be required and small screws can be used to anchor the wires if desired. Complications can include poor aesthetic outcome or rarely lacrimal system injury.

FRACTURES OF THE ORBITAL ROOF, SUPRAORBITAL RIM, AND FRONTAL BONE

Fracture of the orbital roof, rim, and frontal bone are more common in young children due to the large cranium to face ratio and nonpneumatized frontal sinuses. Typical history is of a blow to the brow with a late-developing hematoma. Other findings such as proptosis or dystopia can occur later and as with other orbital injuries, ophthalmologic consultation is required. While the orbit and the globe rarely suffer significant long-term damage, concurrent intracranial injuries occur in upwards of 86% of orbital roof fractures (3,50). This is especially true in older children where more significant force is required to fracture the orbital roof. Treatment of such injuries should be handled in a multidisciplinary fashion with neurologic injuries at the forefront.

A classification scheme based upon orientation of the fractured segments has been proposed (50). Type I fractures have comminution of the orbital roof without displacement, type II have displacement of the fragments toward the anterior cranial fossa whereas type III fractures have displacement inferiorly into the orbit. Most fractures of the orbital rim do not require operative intervention. Type III fractures have been associated with permanent exophthalmos, vertical dystopia and encephalocele and therefore repair via combined intracranial and extracranial approach with calvarial bone graft can be considered. A period of observation for 7 to 10 days for any resolution of dystopia or exophthalmos may be prudent in less severe injuries. However, long-term follow-up with imaging is recommended due to the appearance of late encephalocele. Hallmarks of orbital encephalocele are vertical dystopia, axial proptosis, and globe pulsation.

FRACTURES OF THE FRONTAL SINUS

Development of the frontal sinus occurs late in childhood; therefore, fractures are not common until adolescence. Isolated anterior table fractures can occur from sporting injuries, but overall, frontal sinus fractures results from high-impact trauma and in 70% of cases the posterior table is involved (51). Deformity of the anterior table must be addressed through reduction, which can be accomplished through bicoronal incisions. Careful assessment of the frontal recess should be accomplished both endoscopically and directly if possible. Posterior table reconstruction should be commenced based upon the same criteria as adults and often with neurosurgical consultation. Long-term follow-up with periodic imaging is crucial. Complications can occur both acutely and late, consisting of CSF leak, intracranial abscess, and mucopyelocele formation.

CONCLUSION

Pediatric patients suffer a somewhat different injury profile than adults with facial trauma. Basic tenets of traumatic stabilization should be observed followed by more directed evaluation and treatment. Under the age of 5 pediatric patients suffer fewer fractures and a higher proportion of greenstick fractures due in part to the elastic nature of the facial skeleton and the somewhat protected environment. As children age, fracture patterns begin to resemble those of adults with a higher proportion of mandible and midface

fractures. However, partly due to the rapid healing ability and constant growth, many fractures can be managed conservatively. When necessary, rigid fixation should consider potential facial growth abnormalities, but basic principles of proper, stable reduction should not be sacrificed. Continued evolution of absorbable plating systems may help reduce potentially deleterious effects of permanent rigid fixation. Overall, the evaluation and treatment of pediatric facial trauma should include consideration for the differential injury mechanisms and patterns as well as the potential growth implications of the developing facial skeleton.

HIGHLIGHTS

- Trauma is the leading cause of death and a major source of morbidity in children.
- Nasal fractures are the most common facial bone fractured in children. Mandible fractures are the most common facial fracture among children hospitalized for trauma.
- Facial growth and development is closely related to fracture patterns and the potential for future growth alteration.
- Midface and condylar fractures are associated with the greatest risk for growth disturbances.
- Conservative approaches to reduction are more desirable with ORIF reserved for fractures that cannot be stabilized by less invasive methods.
- If internal fixation is necessary under age 13, an understanding of tooth bud position and the role for monocortical screw placement is essential.
- In nasal injuries, septal hematoma should be ruled out and edema may require observation to assess for displaced bones.
- Nasoorbitoethmoid fractures should be suspected with high force traumas, dorsal nasal flattening, or CSF rhinorrhea.
- Associated neurocranial injuries are more common in the pediatric trauma patient and should be considered during the workup.
- If MMF is necessary, it should be limited to 2 to 3 weeks, followed by 6 to 8 weeks of elastic bands.
- Orbital fractures should consider muscular entrapment where early surgery is indicated. Observation may be appropriate in other isolated injuries.

Pediatric Otolaryngology

86

Stephen C. Maturo *Michael Cunningham*

The management of the otolaryngologic disorders of childhood traditionally has been and remains an integral part of the practice of general otolaryngology. Pediatric otolaryngology has evolved as a surgical subspecialty oriented toward the comprehensive otolaryngologic care specifically of children (1,2). The evolution of this subspecialty can be traced to developments within the fields of pediatrics and anesthesia and within otolaryngology itself (3). The establishment of freestanding children's hospitals or sections of general hospitals devoted solely to pediatric care reflected a growing appreciation on the part of the medical community that the problems of children differed from those of adults and required a different focus of diagnostic intervention and management (4). The patient population of these children's hospitals and pediatric wards changed over the years as the development of vaccines and newer generations of antibiotics led to improved control of acute infectious diseases. The focus of pediatric medicine gradually shifted to children with chronic illnesses, progressive noninfectious disorders, malignancies, and disabling or disfiguring handicaps. Patients with these much more complex conditions required the coordinated services of many subspecialty fields, including otolaryngology (5).

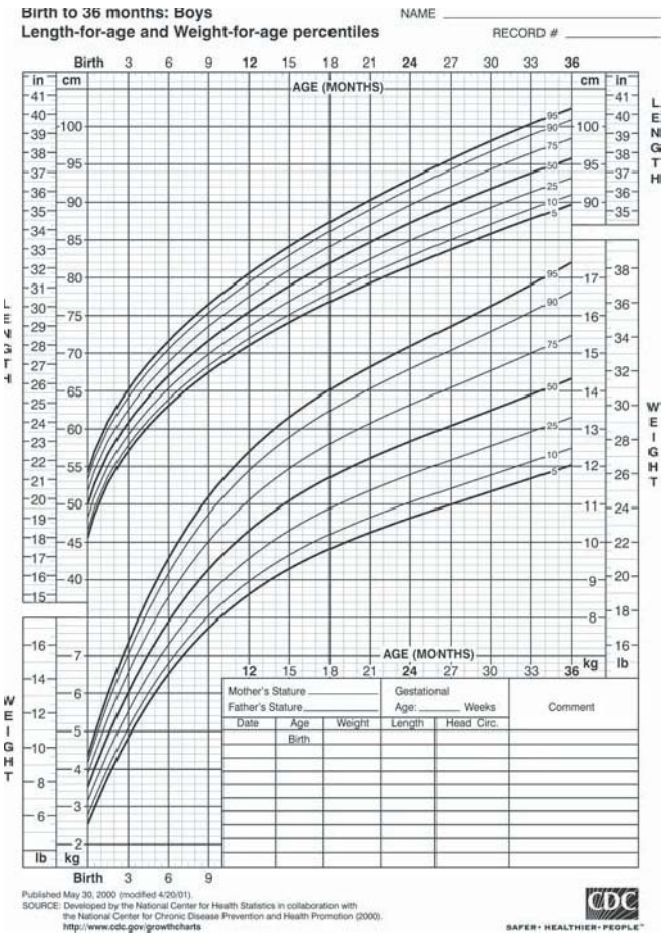
Concurrent technologic advances and a better understanding of the pathophysiologic characteristics of cardiorespiratory failure ushered in the modern era of anesthesia and intensive care unit medicine. The establishment of pediatric and neonatal intensive care units, the latter associated with advanced obstetric care hospitals, allowed the treatment and survival of younger and sicker infants and children. These children presented with a new array of medical and surgical problems of interest to the otolaryngologist, particularly regarding airway management.

Scientific advances within the field of otolaryngology–head and neck surgery further contributed to pediatric otolaryngology specialization. The development of fiber optic, illuminated, rigid endoscopes of appropriate size for use in infants and young children allowed safe operative assessment of congenital and acquired airway lesions. Small-diameter flexible endoscopes facilitated the dynamic examination of the upper airway in awake infants and children, and ultrathin versions of these scopes allowed lower airway evaluations even in intubated infants. Newer laryngoscopes and bronchoscopes were developed to allow unrestricted visualization of the pediatric airway for instrumentation and laser applications and to facilitate the delivery of inhalational anesthetic agents through standard endotracheal, Venturi jet, or spontaneous respiration techniques (6). More recently, airway-specific balloon technology and smaller microlaryngeal instruments have made minimally invasive endoscopic airway procedures a viable option.

Radiologic advances in computed tomography (CT), magnetic resonance imaging (MRI), and digital subtraction angiography added to the diagnostic acumen available for evaluating both congenital malformations and mass lesions. The management of extensive benign as well as malignant head and neck neoplasms in this age group has been greatly influenced by the application to children of angiographic embolization and microvascular surgical techniques, more precise radiotherapy protocols including proton beam and gamma knife technologies, and newer chemotherapeutic agents designed to decrease long-term maturation side effects.

Polysomnography studies enhanced the physiologic assessment of children with obstructive lymphoid hypertrophy. Immunologic antibody–antigen detection techniques facilitated the serologic diagnosis of various infections and the confirmation of inhalant atopy in young children. Novel laboratory studies have also helped aid in the diagnosis of immunodeficiency disorders commonly manifested in the upper aerodigestive tract. Electrodiagnostic techniques such as electroneurography, electromyography, brainstem auditory-evoked response testing, and otoacoustic emissions allowed more in-depth assessment of pediatric sensory

impairments. Lasers, cochlear implants, intraoperative radiologic guidance systems, and distraction osteogenesis techniques, to name a few, have all opened new avenues of therapeutic otolaryngologic intervention in children.



The application of these technical innovations to the care of children with acute and chronic otolaryngologic problems stimulated further clinical investigation and bench research activities, leading to the increasing fund of knowledge and expertise that now defines the subspecialty. Pediatric otolaryngology shares with geriatric otolaryngology a focus on a specific age group rather than on an organ system or category of disease (7). This chapter highlights otolaryngologic disorders specific to the pediatric population and relevant issues pertinent to caring for such children.

PATTERNS OF GROWTH AND DEVELOPMENT

Pediatric otolaryngology is the study of the disorders and diseases of the ears, nose, and throat as they relate to the growth and development of the head and neck structures (8). The clinical presentation and sequelae of any disease process are greatly influenced by the age and maturation of the afflicted person. Children differ anatomically and physiologically from adults, and they also change in these respects along a continuum from the neonatal/infancy period through the toddler, preschool, later childhood, and eventually adolescent years. Pediatric otolaryngology requires a working knowledge of the standard patterns of growth and development through this continuum so that deviations from normal can be recognized and age-appropriate diagnostic techniques and methods of management can be applied.

Measurement of the vital characteristics of somatic growth can provide information about a child's general state of health or illness regardless of the specific organ system of interest. Height and weight measurements of all children, supplemented by head circumference measurements during the first year of life, provide an early warning system for pathologic processes. Charts documenting serial measurements over months to years construct an accurate record of the child's general pattern of growth (Figs. 86.1 and 86.2), with deviations from normal being indicative of an intrinsic or extrinsic insult.

Different organ systems mature at different rates and at different times throughout infancy, childhood, and adolescence (Fig. 86.3). The rapid rate of neural tissue growth during fetal life explains the relatively large size of the neurocranium in relation to the face in the newborn. The face of

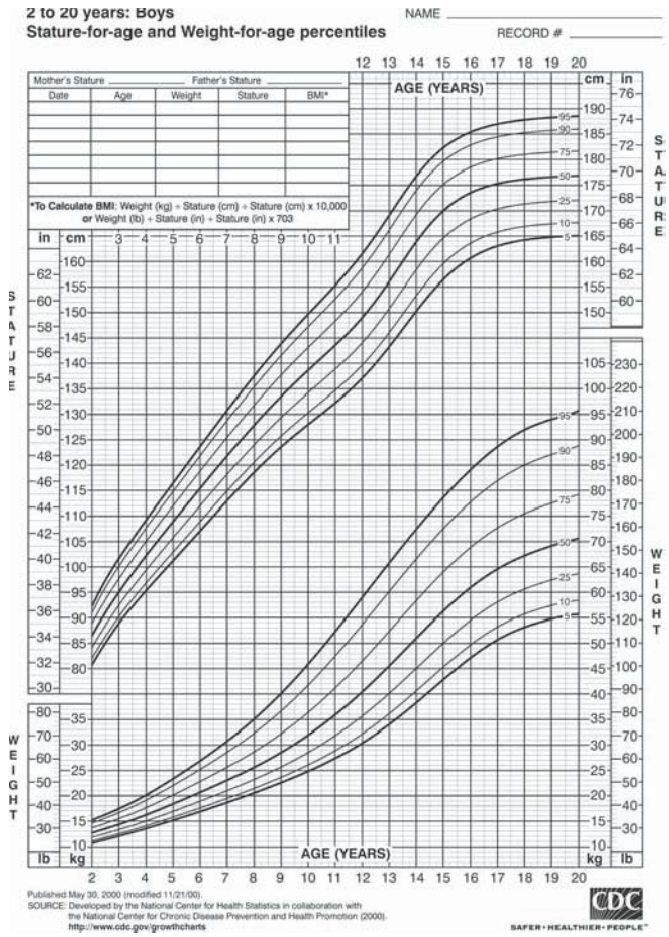


Figure 86.1 Physical growth in boys (Centers for Disease Control and Prevention).

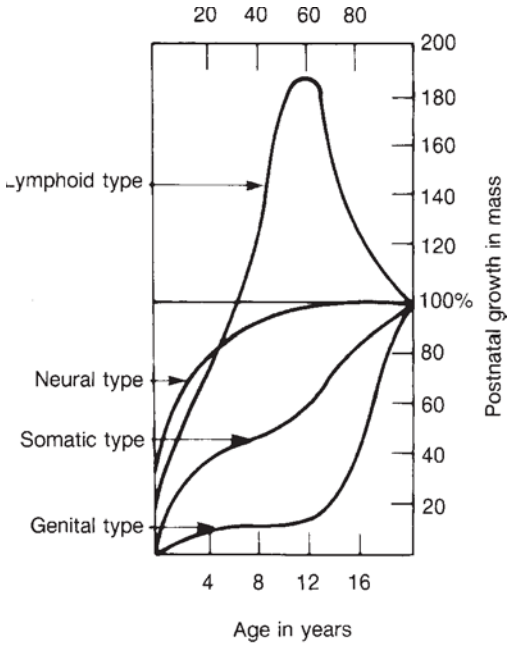

Figure 86.3 Postnatal growth of different anatomic systems with age.

the infant or young child is not a small image of the eventual adult (Fig. 86.4). The infant's forehead is prominent and the face comparatively round and diminutive. Elongation of the face occurs secondary to mandibular and maxillary growth in association with the eruption first of the primary and later of the permanent teeth. As this vertical growth continues throughout childhood, the relative proportion of facial to cranial mass gradually changes, and the narrower adolescent/adult facies eventually is achieved (Fig. 86.5). Associated with this progressive increase in facial height is a gradual change in the child's profile. The child's cheeks and chin are flat, the nose is diminutive, and the eyes appear comparatively large. With mandibular and maxillary growth, the chin and cheek bones become more prominent, and the growth of the nose and supraorbital rims decreases the relative orbital size.

The nares are small at birth and retain their roughly circular shape until puberty. The oval or oblong nares associated with the adult facies develop in association with the marked increased vertical growth of the nose during adolescence. Major forces in the vertical height and projection of the nose are the osseous and cartilaginous growth centers of the nasal septum and nasomaxillary pyramid.

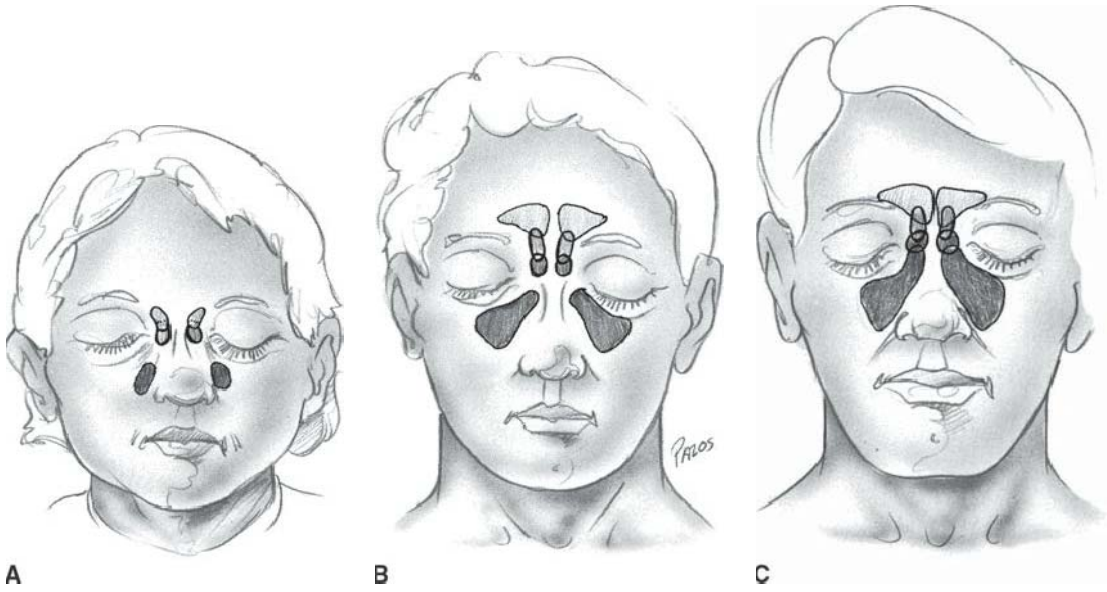

Figure 86.6 Paranasal sinus development. **A:** At birth. **B:** At 10 years. **C:** At 15 years.

Elective surgery on the nose usually is deferred until the adolescent years when full facial growth has been achieved. Exceptions to this rule include severe traumatic injuries or nasal deformities associated with congenital anomalies such as cleft lip and palate. Growth may further exaggerate the facial deformity in such cases.

Despite small anatomic nasal dimensions and increased airway resistance, infants are predominantly nasal breathers (the anatomic and physiologic explanations for this preferential nasal breathing pattern are discussed later in this section). Although the degree and duration of this reliance on the nasal airway for respiration vary with each child, complete nasal airway obstruction at birth is usually an airway emergency. Even unilateral obstruction can cause the newborn significant respiratory distress and secondary feeding difficulties. In older children, chronic nasal and nasopharyngeal obstruction, most frequently caused by lymphoid hypertrophy, may be associated with constant mouth breathing, abnormal tongue positioning, dental malocclusion, and suspected craniofacial growth changes. This so-called adenoid facies syndrome remains controversial from a cause and effect standpoint; its description, however, serves to highlight the potential sequelae of a single disease entity on an actively growing child.

The development of the paranasal sinuses is connected intimately with nasomaxillary and facial growth (Fig. 86.6). The maxillary and sphenoethmoid sinuses are present at birth, although their small size typically precludes their radiologic appearance (Table 86.1). Conspicuous growth in the maxillary sinuses begins by approximately age 3 years, but inferiorly directed expansion does not occur until eruption of the permanent dentition, when the child is 7 to 8 years of age. The floor of the maxillary sinus approximates the inferior meatus at age 8 years and reaches the level of the floor of the nose by 12 years of age. Adult size is reached by midadolescence. The ethmoid sinuses arise as evaginations of the nasal mucosa from the middle, superior, and supreme nasal meatuses. Although present at birth, significant pneumatization does not occur until the child is between 3 and 7 years of age. Final adult form typically is achieved by age 12 to 14 years. The sphenoid sinuses originate within the nasal cupola; they do not begin to pneumatize the sphenoid

TABLE 86.1 PARANASAL SINUS DEVELOPMENT

			Size (mL)			
	First Appearance	Birth	3 y	10 y	14 y	Age of Importance
Maxillary	3 wk fetal life	0.13	2.5	10.4	11.6	Birth
Ethmoid	6 mo fetal life	0.06	0.16	2.4	4.8	Birth
Sphenoid	3 mo fetal life	0.02	0.68	1.8	2.1	5 y
Frontal	1 y life		0.08	1.0	3.6	10–12 y

Modified from Schaeffer JP. *The embryology, development and anatomy of the nose, paranasal sinus, nasolacrimal passageways and olfactory organ in man.* Philadelphia, PA: Blakiston, 1920, with permission.

bone and become clinically significant until 4 to 5 years of age. Sphenoid development, although complete by midadolescence, is highly variable in terms of the final extent of sphenoid bone pneumatization. The frontal sinuses originate as outgrowths of the middle meatuses in the frontal recess regions. The frontal sinuses are typically not present at birth; growth begins during the third year of life and continues well into adolescence. Pneumatization is highly variable and is of limited clinical significance until the early adolescent years. The thin posterior table and floor of the frontal sinuses have important anatomic relationships to the anterior cranial fossa and orbital structures, respectively.

Discussion of paranasal sinus development is incomplete without mention of the ostiomeatal complex region, which represents the joint location of the maxillary sinus ostium, anterior ethmoid sinus ostia, and frontal recess in the region of the middle meatus. The channels into which these ostia open are bound by the ethmoidal bulla, the uncinate process, and the middle turbinate. Anatomic enlargement or mucosal hypertrophy of these three structures can significantly narrow these channels and obstruct maxillary–ethmoid–frontal sinus drainage. The relatively small size of the child's nose has traditionally made intranasal sinus surgery comparatively risky because of limited surgical exposure. Although still challenging, this situation has improved with the development of instruments and telescopes of appropriate size for the application of functional endoscopic sinus surgery directed at the ostiomeatal region in the pediatric population.

At birth, the pinna has an adult configuration and location, although the ears appear to rise in position as a result of the vertical growth of the lower third of the face. The pinna reaches near adult size at 4 to 5 years of age and obtains full adult size by age 9 years. The soft and pliable nature of the young child's ear cartilage also matures during this same period, which influences the timing of auricular reconstruction, specifically those procedures requiring cartilage manipulation.

The tympanic membrane is adult sized at birth, but due in part to incomplete ossification of the external auditory canal, lies in a nearly horizontal position, impairing its visualization on neonatal ear examination. The final vertical orientation of the eardrum is achieved with completion of canal ossification by approximately 2 years of age. Middle ear ossicular formation is complete at birth. Middle ear pneumatization is likewise near complete. The mastoid antrum, in contrast, enlarges significantly over the first years of life with generalized mastoid pneumatization and development continuing well into early childhood. Most postnatal mastoid growth occurs in a lateral and posterior direction, with a fully developed mastoid and styloid process not appearing until the child is about age 3 (Fig. 86.7).

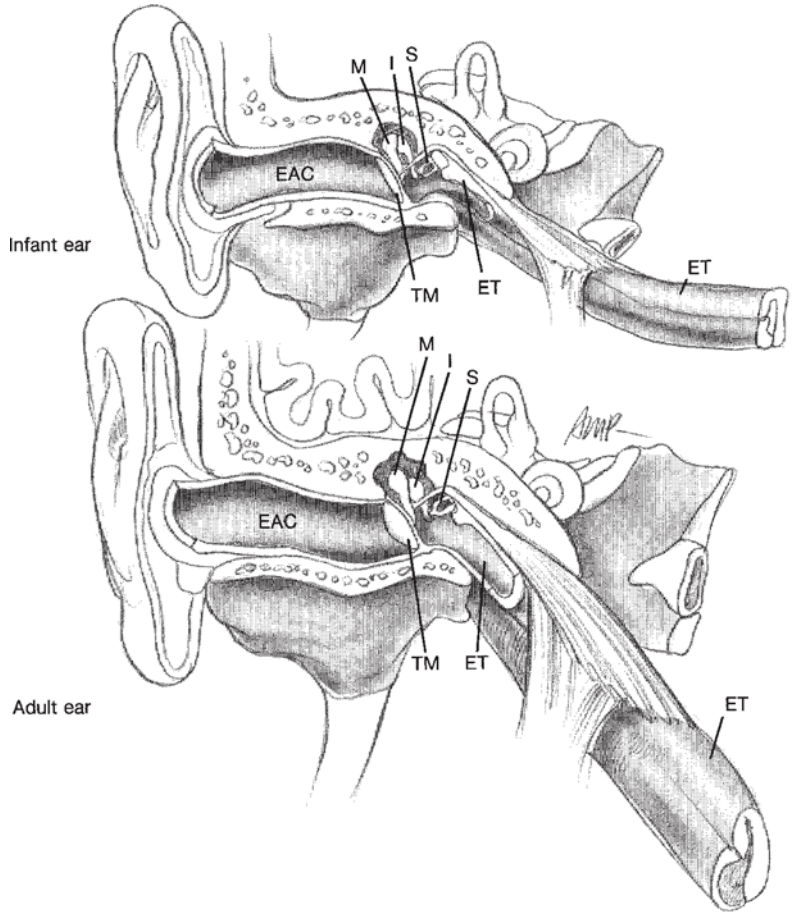

Figure 86.7 Comparison of infant and adult middle ear and eustachian tube development. M, malleus; I, incus; S, stapes; ET, eustachian tube; TM, tympanic membrane; EAC, external auditory canal.

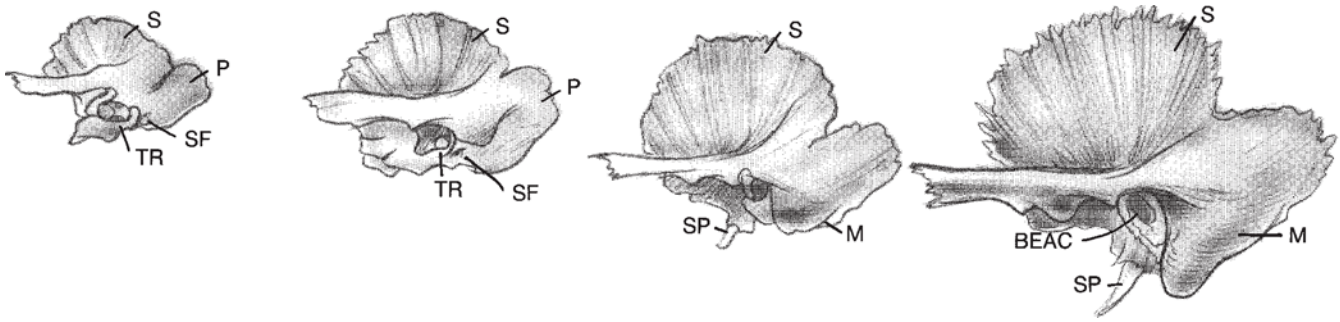

Figure 86.8 Postnatal temporal bone development. Note mastoid bony external ear canal and styloid process growth. BEAC, bony external auditory canal; M, mastoid; P, petrosa; S, squamosa; SF, stylomastoid foramen; SP, styloid process; TR, tympanic ring. (Adapted from Kenna M, Hirose K. Embryology and developmental anatomy of the ear. In: Bluestone CD, et al., eds. *Pediatric otolaryngology*, 4th ed. Philadelphia, PA: WB Saunders, 2003:136.)

The extratemporal portion of the facial nerve is relatively unprotected during this period of development, predisposing it to obstetric injury and potential iatrogenic injury during tympanomastoid and parotid surgery. The thin mastoid cortex at this young age also accounts for the potential subperiosteal postauricular spread of mastoid infection.

Eustachian tube development plays a prominent role in the predisposition of infants and young children to middle ear infection (Fig. 86.8). At birth, the eustachian tube is about 50% of its adult length and lies in a fairly horizontal position, entering the nasopharynx at the level of the hard palate. With growth, the eustachian tube lengthens, widens, and angles inferiorly, achieving its final nasopharyngeal position by the time the child is 5 to 7 years old. The petrous portion of the temporal bone, including the bony and membranous labyrinths, is formed completely at birth. The neonate should be fully functional from both a hearing and a vestibular standpoint.

The neonate's oral cavity is small and the comparatively large tongue fills it entirely, contributing significantly to the infant's status as a preferential nasal breather. The fully formed palatal structures provide the infant with velopharyngeal competence and the more superior cervical position of the larynx allows potential overlap of the epiglottis and the velum, establishing a nasopharyngeal airway during suckle feeding. The flow of milk or formula is channeled around the dorsum of the tongue and laterally around the epiglottis, protecting the airway. With mandibular growth, the oral cavity enlarges and the base of the tongue descends to its final hypopharyngeal position. The infant's suckle gradually changes to a more mature swallow pattern, which is functionally quite complex, consisting of an extremely well-synchronized series of oral, pharyngeal, and esophageal neuromuscular movements.

The larynx serves the infant immediately as a conduit for breathing. No other head and neck structure is initially so essential to life. The larynx additionally protects the lower airway by means of two mechanisms: glottic and supraglottic closure during swallowing and the cough reflex. The phonatory function of the larynx provides the infant with a means of expressing basic needs; this communicative function obviously increases in complexity and importance later in childhood.

The pediatric larynx has considerable anatomic differences from that of the adult. These differences involve the specific breathing and airway protection demands of suckle feeding in the newborn infant. The newborn neck is relatively short, and the infant larynx is positioned high, approximating the third or fourth cervical vertebra at rest and rising to the height of the first or second cervical vertebra with swallowing (Fig. 86.9). As discussed previously, this high position allows overlap of the epiglottis with the soft palate. With growth of the neck, the larynx gradually descends to its adult position opposite the fifth cervical vertebra. The still relatively high childhood position of the larynx is highlighted by the ease with which the epiglottis can be visualized on oropharyngeal examination in many children.

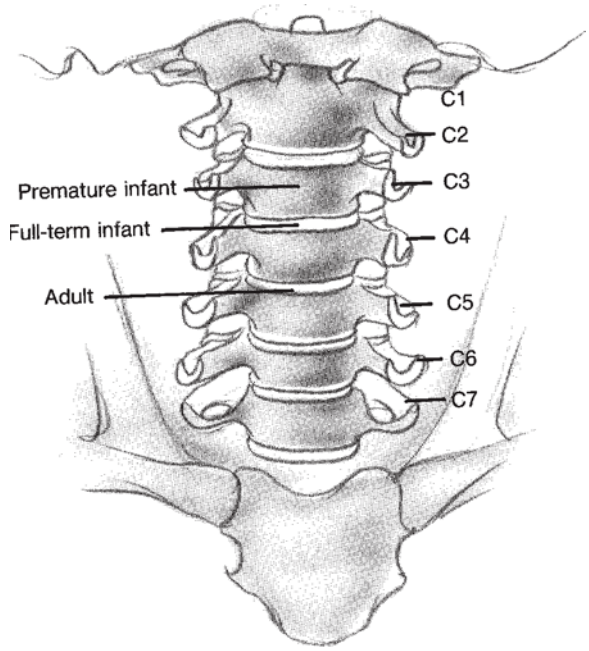

Figure 86.9 Comparative neck positions of the infant and adult larynx (glottic level).

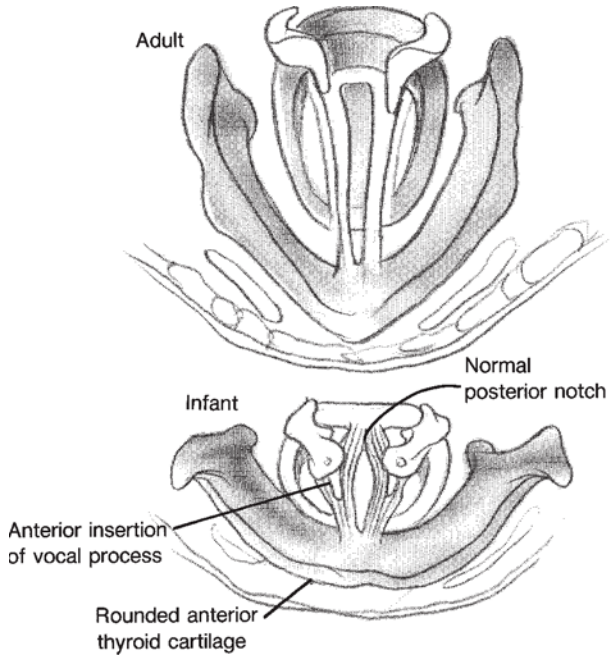

Figure 86.10 Endoscopic view of infant and adult demonstrating the comparatively large arytenoids and rounded thyroid cartilage configuration in the infant compared with those of the adult larynx.

The predisposition of the infant airway to obstruction is related to its absolute small size, the pliability of its constituent connective tissues, and some intrinsic anatomic features. The infantile epiglottis is furled or omega-shaped and the arytenoids are relatively large, covering a significant percentage of the posterior glottis (Fig. 86.10). This anatomic configuration contributes to the entity of laryngomalacia. In the infant, the cricoid cartilage is smaller in diameter than the length of the true vocal cords, making the subglottic region the narrowest portion of the pediatric airway. The resultant funnel-shaped internal dimension (Fig. 86.11) has important consequences for the young child in terms of both the sequelae of inflammatory airway edema and the effects of endotracheal intubation.

The infant larynx grows rapidly in terms of both width and length in the first 3 years of life, which may obviate the need for airway intervention in certain congenital anomalies. Laryngeal growth then slows until adolescence, when there is a rapid increase in all airway dimensions. The adolescent growth spurt of the cricoid and thyroid cartilages also changes the angulation of the true vocal cords as they insert into the anterior commissure region. This contributes, in part, to the voice changes associated with puberty.

Of additional anatomic importance is the comparative underdevelopment of the thyroid cartilage in the infant. The thyroid cartilage is relatively flat without a vertical midline prominence (Fig. 86.12) and tends to be overlapped by the hyoid bone because of the high laryngeal position. The cricoid cartilage is also small, and the cricothyroid membrane is more of a slit than a true palpable space. The standard landmarks for tracheotomy and cricothyroidotomy are not very demonstrable, making the emergent performance of either of these procedures difficult in the newborn infant. Endotracheal intubation is a far preferable choice of airway maintenance in acute emergencies in young children.

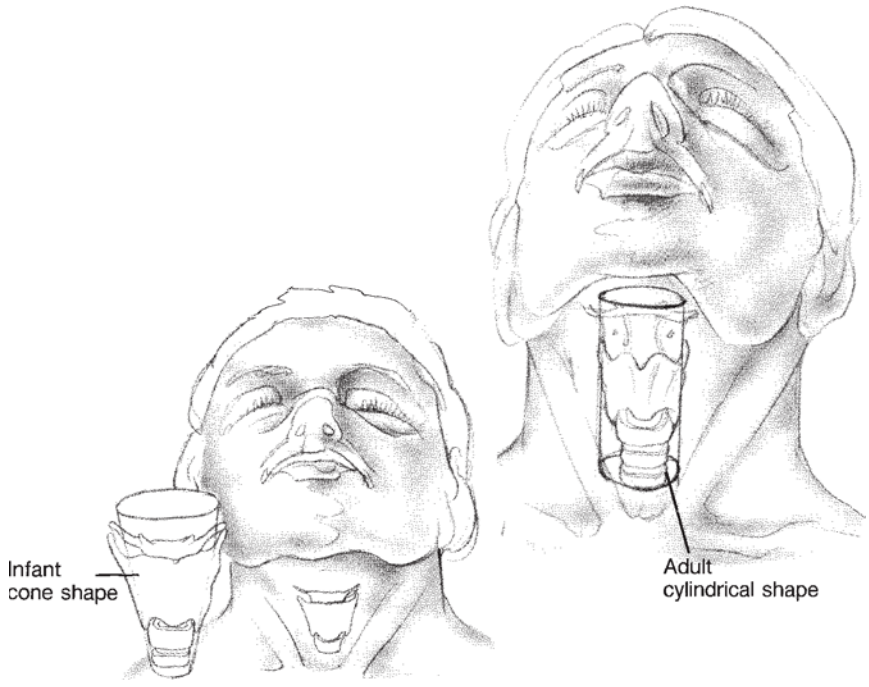

Figure 86.11 Narrowing cone-shaped internal dimension of the infant larynx is due to the smaller diameter of the cricoid cartilage compared with that of the glottis. These glottic–subglottic dimensions approximate one another in the adult larynx.

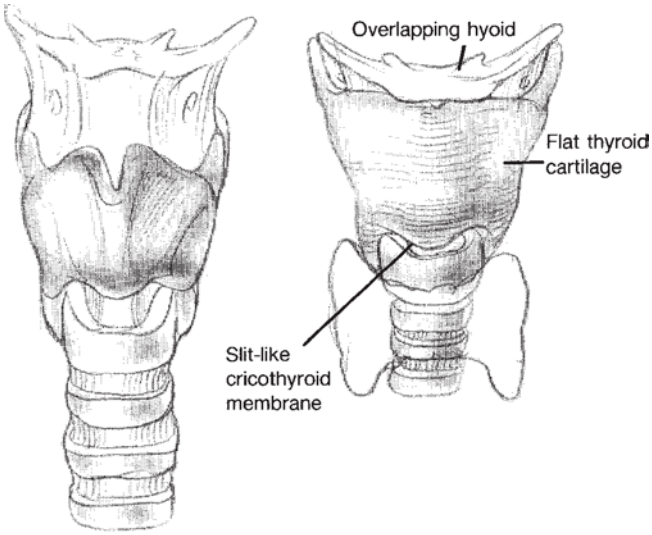

Figure 86.12 Anterior view demonstration of the flat infantile thyroid cartilage and overlap by the hyoid cartilage above and over the cricoid cartilage below. These cartilage elements separate with increasing age.

The neck of the infant and young child also differs from that of the adult in the prominence of the cervical lymphoid tissue. The cervical lymph nodes increase in size proportionally to the growth curve for the body's lymphoid tissue in general (Fig. 86.3). The variability of cervical lymphadenopathy palpable on routine pediatric neck examination can make the decision regarding when to perform a nodal biopsy a diagnostic challenge. Children at risk for significant pathology include those with supraclavicular adenopathy, worrisome clinical symptoms such as persistent fever or weight loss, and local fixation of the node(s) to the overlying skin or underlying deep tissues. The retropharyngeal and parapharyngeal lymph nodes are of additional importance in young children. Suppurative lymphadenitis in these regions can rapidly progress to abscess formation with aerodigestive tract compromise and sepsis risk.

CONGENITAL MALFORMATIONS

Diagnosis and management of congenital malformations of the head and neck structures are an integral part of the practice of pediatric otolaryngology. Children with these conditions require a thorough otolaryngologic and general pediatric assessment to ensure that their head and neck anomaly is not a manifestation of an underlying craniofacial or systemic syndrome. The discovery of additional syndromic manifestations can be of prognostic importance, altering surgical or long-term care plans, and also be of potential use from a genetics and family planning standpoint. A comprehensive list of all congenital malformations of the head and neck is beyond the scope of this chapter. A brief review of several of the more common lesions highlights the diversity of a pediatric otolaryngology practice.

Auricular Malformations

The complex origin of the middle and external ear from the first two branchial arches lends itself to varying degrees of sporadic malformation. Minor malformations include preauricular pits and tags. Although typically an isolated finding in normal-hearing children, preauricular tags may be associated with ossicular malformations and secondary conductive hearing loss. Preauricular pits can occur in the presence of renal disease and mixed conductive/sensorineural hearing loss in children with branchial-oto-renal syndrome. Not all children with preauricular pits or tags require formal audiologic or renal ultrasound examinations; such evaluations, however, should definitely be performed in those with additional congenital anomalies and in those with a family history of hearing loss or renal disease (9,10).

Major auricular malformations are microtia and atresia. These may be isolated entities, or they may occur in the setting of a generalized craniofacial disorder, such as Goldenhar syndrome. Intervention in these children is typically dictated by the unilaterality or bilaterality of the condition, the child's hearing status, and the feasibility or desirability of cosmetic or hearing restoration. Such children may develop acute otitis media (AOM) in the rudimentary ear space of the microtic ear, and they have an increased risk of developing cholesteatoma in the atretic ear canal. The normal ear in unilateral cases must be monitored closely for otitis media with effusion (OME) and secondary hearing compromise. Comprehensive care of children with these conditions includes parental counseling, detailed audiologic assessment with amplification if needed, and surgical intervention including auricular reconstruction, atresia repair, or bone-anchored hearing aides.

Nares Malformations

Choanal atresia is representative of a major malformation in nares development that, when bilateral, usually causes immediate respiratory compromise in the newborn. Modified oral airways or endotracheal intubation provide acute airway relief until definitive surgical management is possible. High-resolution CT scanning is a requisite part of the preoperative evaluation of these patients. Their operative management has been enhanced greatly by the application of endoscopic surgical techniques. Osseous as well as membranous atresias may be approached in transnasal or combined transoral–transnasal fashion, rendering the classic transpalatal approach near obsolete. Choanal atresia needs to be additionally recognized as one potential manifestation of the CHARGE syndrome. Such children have a propensity for additional airway and systemic anomalies that may dictate neonatal tracheotomy to be the most appropriate initial treatment measure, delaying choanal atresia repair until the child is older. CHARGE syndrome also highlights the importance of a thorough

cardiology evaluation in most children with syndromic abnormalities prior to committing to a surgical procedure. The long-term effect of successful choanal atresia repair on midfacial growth and future velopharyngeal function is still unknown. Debate also continues on the necessity of nasal stents and the application of mitomycin-C for improved surgical outcomes (11).

Less severe malformations of nares development include pyriform aperture stenosis and choanal stenosis. These cause varying degrees of nasal obstruction. Most affected neonates can be treated conservatively with artificial airways or topical steroid drop preparations to decrease nasal mucosal hypertrophy. Such measures often must be continued through the infant's preferential nasal breathing period. Surgical intervention to enlarge the nasal passages is required in a small percentage of pyriform aperture stenosis patients typically via a sublabial approach. Children with pyriform aperture stenosis are also at risk for associated holoprosencephaly (central mega-incisor syndrome) and their overall evaluation should include central nervous system imaging (12).

Midline Malformations

Encephaloceles, gliomas, and dermoids are congenital midline nasal masses whose typical manifestations are signs and symptoms of nasal obstruction. Their greatest risk is that of potential central nervous system infection, either spontaneously or from inappropriate surgical intervention. The complementary use of both CT and MRI is recommended as the preoperative evaluation of such lesions. Surgical resection via a transnasal endoscopic approach, an external lateral rhinotomy or open rhinoplasty, or an anterior craniofacial resection using the combined skills of both the otolaryngologist and the neurosurgeon provides definitive treatment.

Malformations of the Oral Cavity

Oral cavity malformations frequently occur in association with mandibular or maxillary hypoplasia. Such malformations can be isolated entities, may be one component of a specific craniofacial disorder as in Treacher Collins syndrome, or may be one of multiple manifestations of a systemic process as in Stickler syndrome. One of the more common presentations is the association of retrognathia, glossoptosis, and soft palate cleft in Robin sequence. Many children with mandibular and maxillary malformations have airway and feeding problems. Interventions vary from positioning strategies and special feeding techniques to surgical procedures such as tongue–lip adhesion, tracheostomy and gastrostomy in severe cases. Such treatments historically would be continued until facial growth and neuromuscular maturation were adequate to prevent further airway obstruction. This expectant approach has been supplanted in recent years by the application of distraction osteogenesis and craniofacial reconstruction techniques early in life to many of these children (13). The long term beneficial and deleterious effects of these advanced techniques on occlusion, dental formation, and facial nerve integrity are just beginning to be elucidated (14).

The oral cavity is also one of the more frequent sites of presentation of congenital lymphatic and venous vascular malformations (15). Such vascular malformations of the tongue and floor of mouth often cause airway obstruction, swallowing dysfunction, and speech impediment. Spontaneous drainage (weeping), mucosal bleeding, secondary infection, and intralesional hemorrhage are also common. Facial deformity and malocclusion may result from soft tissue and bony dysmorphisms. Treatments vary, depending upon whether the goal is to stabilize superficial manifestations or to physically reduce tongue size for functional and cosmetic purposes (16–18).

Cleft lip and palate are the most common malformations of the head and neck region. In some medical centers, the pediatric otolaryngologist has the primary responsibility for the surgical repair of these anomalies; in other centers, the otolaryngologist functions in a consultant role as a member of a multidisciplinary team. Children with cleft palate have a higher incidence of middle ear disease and are at increased risk for speech and articulation issues, particularly due to velopharyngeal insufficiency.

Airway Abnormalities

Congenital anomalies of the airway pose a particular diagnostic and therapeutic challenge. The most common laryngeal anomaly is laryngomalacia, which in some respects is a variant of normal neonatal supraglottic development (8). Historically attributed to flaccid supraglottic cartilage formation or redundant supraglottic soft tissues, more recent research suggests that immature sensorimotor integration and tone may be the more significant underlying etiology (19). The characteristic clinical manifestation of laryngomalacia is inspiratory stridor, which usually resolves spontaneously by 18 months of age. Infrequently, laryngomalacia can cause dyspnea, feeding difficulties, and failure to thrive. In such instances a supraglottoplasty is performed, in which the obstructive aryepiglottic folds are divided and the redundant supraglottic soft tissues are removed. This procedure provides immediate relief of respiratory distress in the majority of such infants, with limited risks relative to aspiration and supraglottic scarring. In severe cases of laryngomalacia recalcitrant to supraglottoplasty, a tracheotomy may be required; such children often have additional airway or associated systemic anomalies.

Congenital subglottic stenosis also may represent a severe variant of normal tracheal airway development. The time-honored standard of care for infants with this malformation was tracheotomy pending further airway diameter growth. Anterior laryngotracheal decompression with cartilage augmentation, or cricotracheal resection in severe

cases, offers a more immediate and potentially efficacious form of therapy in these children.

Hemangiomas and vascular malformations can also compromise the airway of neonates and infants. The management of subglottic and laryngotracheal hemangioma has historically involved a combination of systemic or intralesional steroid therapy, bypass tracheostomy, laser excision, or open resection. More recently, the use of oral propranolol is changing this treatment paradigm (20,21). Intrinsic laryngotracheal vascular malformations are best managed via microscopic suspension laryngoscopy and tracheoscopy with laser debulking; aerodigestive tract compromise secondary to extrinsic vascular malformation compression is alternatively often approached transcervically (22,23).

Laryngeal cleft is an uncommon and potentially devastating congenital aerodigestive tract anomaly because of the risk of repeated aspiration. A high index of suspicion with careful endoscopic examination of the posterior commissure region is required for the diagnosis of laryngeal cleft. The surgical treatment of laryngeal cleft isolated to the supraglottis or glottis can be by either a microendoscopic or anterior laryngofissure approach; more extensive laryngotracheoesophageal clefts often require a lateral cervical and thoracotomy approach performed by a joint otolaryngology, pediatric surgery, or cardiothoracic surgical team.

Congenital tracheal anomalies include tracheal stenosis and tracheomalacia. Congenital tracheal stenosis can be focal or segmental and is usually due to complete tracheal rings. Focal segmental stenosis is amenable to resection and reanastomosis. Long segment tracheal stenosis is best treated with a slide tracheoplasty procedure. Tracheomalacia can be caused by inherent tracheal cartilage weakness or due to external compressive forces such as vascular compression or mediastinal masses. The tracheal segments affected can be focal or diffuse regardless of the underlying etiology. Intrinsic tracheomalacia causing failure to thrive, apparent life threatening events, or cyanotic spells presents a difficult challenge; therapeutic options include tracheotomy with continuous positive airway pressure support, tracheal stents, and tracheal resection or augmentation in severe cases. Tracheomalacia due to external compression is best treated by identifying and relieving the external force. Aberrant vascular structures that can cause tracheal compression include double aortic arch, right aortic arch with aberrant left subclavian artery, aberrant left or right subclavian artery, innominate artery compression, pulmonary artery sling, and absence of pulmonary valves (24,25). The workup of such children may include airway fluoroscopy, barium swallow, operative endoscopic evaluation, and a dynamic airway assessment in the form of pulmonary function testing with flow volume loops if age appropriate. The latter studies have expanded the clinical indications for surgical treatment of such children to include moderate to severe exercise intolerance. Magnetic resonance angiography has replaced arteriography as the radiologic study of choice in assessing both the anatomic degree of airway compression and the vascular structures involved. Postoperative pulmonary function studies remain indispensable for children in whom residual tracheobronchomalacia is clinically suspected.

Malformations of the Neck

Congenital malformations of the neck are a comparatively rare but interesting group of childhood neck masses that typically present in the first two decades of life. Such congenital lesions may present as an asymptomatic cervical mass or may become acutely apparent when secondary infection occurs. Most of these lesions arise from developmental arrest of the fetal branchial or thyroid descent systems. Branchial anomalies include an array of cysts, sinuses, and fistulae. Thyroid anomalies include both thyroglossal duct cyst and ectopic thyroid. Anatomic location on physical examination often suggests the underlying system of origin. Definitive treatment necessitates complete excision of the lesion, including any identifiable external tracts to the skin or internal tracts to the aerodigestive system.

Over 50% of lymphatic vascular malformations occur in the head and neck region (26). The cervical site of presentation is important. The majority of infrahyoid lymphatic vascular malformations are macrocystic and extrinsic to the laryngotracheal airway, whereas suprahyoid lymphatic vascular malformations are more likely to be microcystic and intrinsically involve the upper aerodigestive tract. Treatment approaches are based on the anatomic structures involved, the severity of the symptomatic presentation, and whether or not the lymphatic vascular malformation is macrocystic, microcystic, or a combination of both. A conservative approach is advised because one must keep in mind that vascular malformations are benign lesions. Complete removal may not be feasible; rather a fine balance between lesion excision and maintenance of form and function is often the ultimate goal (27).

SENSORY IMPAIRMENTS

Of the sensory impairments relevant to the pediatric otolaryngologist, hearing loss is of the greatest importance. Inadequate speech and language development is typically the clue to an underlying hearing impairment in an otherwise healthy child. The otolaryngologist and the primary care physician must be well versed in the expected developmental milestones of receptive and expressive language to recognize such delays (Table 86.2). In the face of a normal otologic and audiologic assessment, alternative etiologies for inadequate language development such as mental deficiency, dyslexia, dysarthria, or one of the disorders of the autistic spectrum need to be sought.

Most hearing loss in children is mild, transient, and conductive in nature, occurring secondary to AOM or OME. More severe permanent conductive hearing losses are

TABLE 86.2 LANGUAGE MILESTONES FOR INFANTS AND CHILDREN FROM BIRTH THROUGH 2 YEARS OF AGE

Age (mo) at Which Behavior Should Be Established	Receptive Language Behavior	Expressive Language Behavior
1	Random activity arrested by sound	Random vocalization; primarily vowel sounds
2	Appears to listen to speaker; may smile at speaker	Vocal signs of pleasure; social smile
3	Looks in direction of speaker	Cooing and gurgling; smile in response to speech
4	Responds differentially to angry vs. pleasant voice	Responds vocally to social stimuli
5	Responds to own name	Begins to mimic sounds
6	Recognizes words like "bye-bye," "Mama," and "Daddy"	Protests vocally; squeals with delight
7	Responds with gestures to words such as "up," "come, and bye-bye"	Begins to use word like sounds and some jargon
8	Stops activity when own name is called	Imitates sound sequences
9	Stops activity in response to "no"	Imitates intonation pattern of speech
10	Accurately imitates pitch variations	First words appear
11	Responds to simple questions ("where is the dog?") by looking or pointing	Jargon well established
12	Responds with gestures to a variety of verbal requests	Announces awareness of familiar objects by name
15	Recognizes names of various parts of body	True words heard embedded in jargon, often with gestures
18	Identifies pictures of familiar objects when they are named	Uses words more than gestures to express desires
21	Follows two consecutive related directions ("pick up your hat and put it on the chair")	Begins combining words ("Daddy car," "Mama up")"
24	Understands more complex sentences ("after we get in the car we'll go to the store")	Refers to self by name

attributable to congenital anomalies of the external and middle ear. Almost all conductive hearing losses are potentially amenable to surgical correction.

Approximately 1 in 1,000 children is born with a severe to profound sensorineural loss. An equal number of children will develop profound sensorineural hearing loss by late adolescence. This incidence of sensorineural deafness is increased markedly in specific populations.

Most children with congenital or neonatal-acquired hearing losses should now be identified due to the establishment of universal newborn hearing screening as the standard of care. Such early identification screening programs are feasible because of technologic refinements in brainstem auditory-evoked response and otoacoustic emissions testing. The earlier institution of amplification, ideally between 6 weeks and 3 months of age, is the goal of such screening programs. The more frequent recognition of deafness and hearing impairment in children also places a greater responsibility on the pediatric otolaryngologist to understand the relevant genetics of hearing loss and the diagnostic potential of genetic testing. This is particularly true of nonsyndromic sensorineural hearing loss and the utility of screening for connexin mutations.

Multichannel cochlear implantation has proved beneficial for children with profound bilateral sensorineural hearing loss who are unresponsive to conventional amplification. Such benefits include improved auditory and speech production abilities and enhanced psychological and social integration. Strategies for assessing auditory function and aided benefit in such children must be balanced against the time-sensitive nature of cochlear implantation. This is particularly true in young children before age 1 year, and in the postmeningitic bilaterally deafened population in whom the potential development of labyrinthitis ossificans heightens concern about the need for earlier rather than later implantation. In addition to implant placement at younger age, a current trend in cochlear implantation is bilateral implantation, the results of which suggest an improvement in auditory abilities when compared to a single implant. Although initially thought to be a contraindication to implant placement, current data demonstrate that children with a history of AOM, OME, and those with tympanostomy tubes in place do not have a higher incidence of postoperative complications (28,29). Recent guidelines also stress the importance of appropriate immunizations to decrease the risk of otitis media and meningitis; all cochlear implant candidates should receive age-appropriate doses of pneumococcal and *Haemophilus influenzae* type B (HiB) conjugate vaccines and appropriate annual immunization against influenza (30).

Vertiginous disorders in the pediatric and adolescent age group are unusual. Both audiologic screening and radiologic imaging of such children are extremely important to rule out potential central nervous system lesions or predisposing temporal bone anomalies. Benign paroxysmal vertigo of childhood and other pediatric migraine equivalents are variants of a spectrum of vertebrobasilar circulatory dysfunction. The vestibular testing of children, particularly postural and vestibulo-ocular responses, is in its infancy. The role of peripheral vestibular and central sensory organizational deficits in the overall motor development of children remains undetermined.

Facial paralysis in children, in contrast to that in adults, is less often idiopathic and more typically represents any of a diverse number of identifiable etiologies. A careful physical and laboratory evaluation is necessary to rule out potential infectious, inflammatory, traumatic, neoplastic, or syndromic causes. Electrodiagnostic testing using electroneurography can be performed accurately in children. Advances in microsurgical techniques have made cross facial nerve grafting and free muscle transfer procedures available to children; case series with long follow-up periods reveal very adequate aesthetic and functional results with no apparent adverse effects on the developing facial skeleton (31–33).

Vocal fold paralysis is a common cause of stridor and hoarseness in infants and children. Unilateral pediatric paralysis most often occurs secondary to iatrogenic injury or cardiac abnormalities; bilateral paralysis is usually of neurogenic or idiopathic etiology. Any infant or young child with bilateral vocal fold paralysis requires a detailed neuroradiologic workup, specifically MRI, to rule out posterior fossa abnormalities. Bilateral and unilateral vocal fold paralyses present different problems in diagnosis and management. Bilateral vocal fold involvement typically results in life-threatening airway compromise, whereas hoarseness and weakness of voice are the characteristic features of unilateral paralysis. Although historically tracheotomy has been the treatment of choice for neonates and infants with bilateral vocal fold paralysis, in select patients tracheotomy can be avoided if adequate observational monitoring can be assured. Surgical techniques to permit decannulation in children with bilateral vocal fold paralysis include arytenoidectomy or cordotomy by endoscopic or external approach, lateralization arytenoidopexy, and expansion laryngotracheoplasty either via an open or endoscopic approach. When performed conservatively, such procedures can improve the airway with limited voice compromise. Reinnervation techniques using nerve or muscle pedicle graft implantation into one or both posterior cricoarytenoid muscles continue to be investigated as voice-preservation methods. Aspiration or severe dysphonia secondary to unilateral true vocal fold paralysis that remains refractory to speech and swallow therapy also has surgical options. These include laryngoplasty with various bioinjectables, medialization thyroplasty techniques, and unilateral reinnervation procedures. Such procedures (other than reinnervation) are most safely performed in older children and adolescents where the risks of subsequent airway compromise are lessened. An overall conservative approach to the treatment of true vocal fold paralysis is recommended in children in light of the increased likelihood of spontaneous recovery or excellent compensation, especially in idiopathic and neurogenic cases. Definitive voice procedures in children may obtain more optimal results if delayed until postpuberty or young adulthood.

Pediatric otolaryngologists also evaluate children who demonstrate severe sialorrhea secondary to poor oromotor control and impaired swallowing. Most of these children have underlying neurodevelopmental issues, particularly cerebral palsy. When behavioral and medical management techniques fail, several options exist. Submandibular and parotid gland botulinum toxin injections have become increasingly popular as a successful minimally invasive method, although repeated injections are usually necessary. More invasive surgical procedures include rerouting of salivary flow by submandibular or parotid duct relocation, cessation of salivary flow by submandibular and parotid duct ligations, and bilateral submandibular gland excisions. These procedures are offered individually or in combination as definitive means of removing the major sources of saliva production both at rest (the submandibular glands) and during meal stimulation (the parotid glands). In those children with sialorrhea causing life threatening aspiration, laryngeal separation may be an option.

INFECTIOUS DISEASES

Otitis Media

Otitis media is one of the most common childhood illnesses. Evidence-based, multispecialty, clinical practice guidelines exist providing recommendations to primary care physicians regarding the management of children with uncomplicated AOM (34). The focus of such guidelines is appropriate diagnosis and initial therapy, including a period of watchful waiting with appropriate pain control in children of a certain age with less severe symptoms, applicable antibiotic choices in those who warrant treatment, and preventive measures. Pediatric otolaryngology intervention is sought when AOM remains refractory to medical management, responds to treatment but is frequently recurrent, becomes complicated by additional otologic or intracranial manifestations, or is superimposed on persistent OME.

Similar clinical practice guidelines provide evidence-based recommendations on the diagnosis and management of OME (35). Underlying conditions that predispose children to OME are of particular importance to the pediatric otolaryngologist, as are the suspected long-term ill effects of bilateral and even unilateral middle ear effusion on eventual speech-language development and cognitive

function. The relative therapeutic roles of tympanostomy tube placement and adenoidectomy in the management of both AOM and OME are fairly well established, with studies indicative of improved quality of life in children so treated (36).

Streptococcus Pneumoniae Vaccination

The addition of the *Streptococcus pneumoniae* conjugated vaccine to childhood immunization schedules over the past decade has resulted in significant success. Studies indicate that infant immunization with this heptavalent pneumococcal conjugate vaccine has decreased the incidence of invasive pneumococcal infections like meningitis by more than 90% and noninvasive infections like AOM by approximately 10% (37). The former has had the secondary beneficial effect of a decreased incidence of meningitis-related sensorineural hearing loss similar to that observed following HiB vaccination.

Rhinosinusitis

The diagnosis and treatment of rhinosinusitis in the pediatric population underwent revolutionary change with recognition of the ostiomeatal complex as the primary site of involvement of most inflammatory sinus disease. Obstruction of this area leads to blockage of drainage from the frontal, maxillary, and ethmoid sinuses. Systematic nasal endoscopy and high-resolution CT have markedly increased the ability to diagnose disease in this region. Functional endoscopic sinus surgery is performed in children who fail maximal medical and appropriate surgical therapy like adenoidectomy, or who suffer from complications from severe sinus infections such as a subperiosteal abscess. The beneficial role of endoscopic sinus surgery is particularly well established in selected populations of children such as those with primary immunodeficiency disorders, ciliary dyskinesia syndromes, and severe atopic disorders such as allergic fungal sinusitis. Although concern remains, there have been no documented adverse long-term effects of functional endoscopic sinus surgery on human facial growth, yet minimalist surgery removing only the least amount of obstructive tissue is recommended to avoid possible long-term facial aesthetic changes. Within the past two decades the frequency of sinus surgery in children has decreased; this reflects the realization that pediatric sinus disease should be viewed as primarily a medical condition where allergy, immunodeficiency, and reflux mechanisms need to be considered and maximally treated prior to proceeding with operative intervention. Image guidance technology is also being selectively used in children with abnormal anatomy or whose disease process involves the skull base, orbit, and frontal or sphenoid sinuses (38). Intraoperative image guidance has been demonstrated to decrease the risks associated with the surgical removal of both congenital nasal anomalies and benign and malignant skull base lesions, as well as to enhance the safe management of complications from sinusitis such as subperiosteal abscess (39). Newer developments such as balloon sinuplasty appear to be applicable to children but long-term efficacy remains to be determined (40,41).

CYSTIC FIBROSIS

Children and young adults with cystic fibrosis are another special group of patients. Chronic pansinusitis is an almost universal problem in this population, with a variable incidence of obstructive nasal polyposis. Medical therapy offers limited benefit in the treatment of cystic fibrosis polyps. Wide antrotomy of the maxillary, sphenoid, and frontal sinuses, if age appropriate, combined with ethmoidectomy using an endoscopic microdebrider technique has proved efficacious. Initial treatment success as characterized by relief of nasal airway obstruction must be judged relative to the likelihood of postoperative polyp recurrence.

ADENOTONSILLAR SURGERY

The pediatric otolaryngologist shares with his or her general otolaryngology colleagues many of the common ear, nose, and throat procedures performed on children, particularly adenoidectomy, tonsillectomy, and the combination thereof. As a subspecialty field, pediatric otolaryngology has attempted to better define the clinical indications for these common operations, and to investigate alternative ways of performing these procedures in order to decrease risk and improve patient outcome (42).

Chronic or recurrent streptococcal pharyngotonsillitis remains one of the predominant indications for adenotonsillectomy, particularly in older children and adolescents. Adenotonsillectomy has historically been shown to be effective in treating severely affected individuals with repeated bacterial throat infections (43,44). Additional infectious indications for adenotonsillectomy include those children with pediatric autoimmune neuropsychiatric disorders associated with streptococcal infections, characterized by obsessive compulsive and tic disorders exacerbations in the presence of documented streptococcal infection, and those with PFAPA syndrome, defined by a combination of periodic fever, aphthous stomatitis, pharyngitis, and adenitis presumably of viral or autoimmune etiology (45).

Obstructive sleep disorders secondary to adenotonsillar hypertrophy account for the majority of pediatric adenotonsillectomy cases. The etiology of sleep disordered breathing is multifactorial, with craniofacial airway dimensions, oromotor muscle tone, and the rapid increase in pharyngeal and palatine lymphoid tissue size over the first several years of life playing major contributory roles. In the United States a childhood obesity epidemic is also contributing to increased rates of sleep disordered breathing. Clinical practice guidelines exist regarding the diagnosis and management of childhood obstructive sleep

apnea syndrome (46). The efficacy of tonsillectomy, with or without adenoidectomy, in the relief of obstructive sleep apnea is well established by studies incorporating preoperative and postoperative polysomnography monitoring (47,48). Significant improvements in quality of life have been documented following adenotonsillectomy in children even with less severe degrees of obstructive sleep disorder (49,50). The establishment of sleep laboratories and sleep disorders centers in coordination with pediatric pulmonary and neurology colleagues has aided greatly the understanding of the pathophysiology of this disorder and enhanced the perioperative care of severely afflicted patients. Children with craniofacial disorders such as Down syndrome and achondroplasia, or those with severe hypotonia as a result of cerebral palsy and other neuromuscular disorders, may have obstruction that cannot be reversed by adenotonsillectomy alone. Pharyngoplasty, tongue base reduction, lingual tonsillectomy, and even tracheotomy may be required in such children.

The predominant performance of adenotonsillectomy as an ambulatory procedure has focused attention on surgical techniques, methods of hemostasis, and perioperative management. Conventional extracapsular tonsillectomy with electrocautery dissection or cold dissection and snare techniques has been compared with intracapsular tonsillotomy or partial tonsil excision utilizing microdebridement or radiofrequency ablation. Postoperative pain and hemorrhage have been the principal outcome factors assessed. The perioperative use of antibiotics or steroids, the local and systemic administration of narcotics and other analgesics, the postoperative use of nonsteroidal anti-inflammatory medications, and the alteration of anesthesia and hydration practices in an attempt to decrease the incidence of adverse postoperative sequelae and reduce the risk of postoperative sedation all continue to be subjects of investigation (51,52).

SPEECH AND VOICE

The development of speech and voice in children has a significant impact on social and educational development. The inability to communicate clearly affects the psychological and emotional well-being of the growing child. The societal impact is evident into adulthood where adults with speech problems were found to be in a lower income group at a rate 1.5 times greater than controls (53).

The prevalence of voice disorders in the pediatric population ranges between 3% and 10% (54,55). Etiology varies depending on age of presentation. One of the more common causes of dysphonia in an infant is vocal fold immobility as previously discussed. Vocal fold nodules are the most common cause of hoarseness in preschool and school age children, yet one cannot overlook more serious potential pathologies such as juvenile onset recurrent respiratory papilloma. Another group of children with abnormal voice and speech patterns are those with velopharyngeal insufficiency, particularly common following cleft palate repair and occasionally manifest status post adenoidectomy (56–58). Functional voice disorders, rather than organic pathology, are more prevalent in the adolescent population (59). Functional or muscle tension dysphonia is characterized by an altered voice or, in some cases, aphonia in an individual with a normal laryngeal and neurologic evaluation. An alternative diagnosis, paradoxic vocal fold motion disorder (PVFMD), is commonly defined as the adduction of the vocal cords during inspiration resulting in dyspnea and shortness of breath. It should be noted that some practitioners also include inappropriate adduction during expiration as a reasonable exam finding in PVFMD.

The majority of children with speech and voice disorders can be helped with a multidisciplinary team approach that involves pediatricians, otolaryngologists, pulmonologists, gastroenterologists, speech–language pathologists, teachers, and psychologists. Treatment options depend on the specific diagnosis but include an array of behavioral, medical, and surgical therapies.

SPECIAL ISSUES

Children are not cared for in isolation. All pediatric otolaryngology encounters are modified to some degree by the close identification of the parent(s) and other family members with the child. The family is the major source of the clinical history of the young child and complements the history obtained from older children. A family member is often needed to hold the infant or toddler during the head and neck examination. The vigor with which this is pursued must balance the need to examine the child adequately with the need to maintain the confidence and trust of the family. Although much of the physician's encounter is spent in discussion with the child's caregiver, one should not lose focus on the child as the patient.

Treatment recommendations must consider family dynamics and the role of secondary caretakers in daycare or school settings. This may influence medication dosage schedules or modes of administration. Deferring to the child's preferences for one flavored medication over another or for an available liquid or chewable form may greatly improve compliance. Acquiring surgical consent for children from parents or other primary caretakers typically requires a great amount of time and counseling. Special problems in this regard include legally separated families, in which case instructions must be provided individually to both parents, and foster care families, in which case the social service or judicial system is the child's guardian.

The ill child who requires frequent office visits, hospitalization, or surgery places numerous stresses on the family unit. Extended families with grandparents or other relatives within the home are rare today. In families with two working parents, economic and social sacrifices are necessary so that at least one parent is present with the child throughout

the course of treatment. This poses an even greater burden on single parent families. In cases of prolonged hospitalization, the intervention of social services is often of great help. Strong consideration also should be given, when appropriate, to home nursing care; the discharge to home of a newly tracheotomized child is one prime example.

One of the facets of pediatric otolaryngology is the care of children with multiple medical problems. These children have complicated disease processes requiring the subspecialty expertise of many caregivers. Pediatric medical and surgical subspecialists often join to establish multidisciplinary groups to coordinate the care of these patients. Some of the more common of these groups include craniofacial syndrome, cleft lip and palate, and vascular anomalies clinics, cochlear implant teams, aerodigestive, speech, and swallowing centers, and head and neck tumor boards. Maintaining the economic viability of such multidisciplinary teams in the current health care environment will require outcomes data demonstrating that such improved patient access and enhanced physician to physician communication optimizes care.

Technologic advancements have resulted in a significant increase in the frequency of performance of imaging studies in children, especially CT scans. CT scans account for 70% of medically related radiation doses to the general population, and given data that one-third of pediatric CT scans are performed in the first decade of life, there is significant concern regarding the theoretical increased risk of cancer in children undergoing such imaging (60,61). The FDA has recommended that CT settings be optimized for pediatric patients using the ALARA (as low as reasonably possible) principle, that multiple phases in contrast studies be avoided, and that inappropriate CT referrals be minimized (62). Special attention particularly needs to be given to those children who require frequent imaging, with greater consideration of alternate modalities such as MRI. Although the issue of CT radiation risk is complicated and nuanced, as with any diagnostic or therapeutic study, discussing the necessity, risks, and benefits with the child's caregiver is of utmost importance (63).

The administration of anesthesia, especially in the child undergoing a first-time procedure, is often of equal or greater concern to the family than the operation itself. These fears can be decreased significantly by the use of preoperative anesthesia consultations and educational programs coordinated by a hospital-based child life therapist. Such programs require the family to attend a preoperative hospital session during which the parent(s) and child are prepared for what will occur on the day of surgery. Most institutions also allow one parent to enter the operating room and remain at the child's side during the induction of anesthesia in age-appropriate elective cases.

The long-term physiologic effects of anesthetic medications themselves on the developing pediatric neural system have garnered significant attention over the past decade in academic journals and the lay press. There is considerable debate among pediatric anesthesiologists and neuroscientists about the effects of anesthetics on children. Animal studies have demonstrated anesthetic induced neuronal cell death, and there is anecdotal evidence from infant studies that early anesthesia exposure may be associated with altered neural development (64–67). Long-term randomized studies to determine if early anesthetic exposure increases risk of developmental impairment are now underway and should provide more specific and higher quality data (68,69). At present the unknown long-term effects of anesthesia should simply be considered as another variable when deciding about the risks and benefits of possible surgical intervention.

Preoperative guidelines also have changed in recent years relative to the need for prolonged fasting. Increased knowledge concerning fluid and electrolyte maintenance in infants and young children has suggested that only a few hours of absolute fasting is necessary and that clear fluids offered up to 2 hours before planned induction do not increase the child's risk of pulmonary aspiration. Over a decade's worth of data have also reinforced the safety guidelines that allow shortened fasting periods for breast milk (3 hours), formula (4 hours), and light meals (6 hours). This change in practice both avoids the anesthetic risks of induction in a hypovolemic child and creates a much more humane preoperative period for the child and family.
